A fourth reason excess condemnation is not appreciated is a lack of knowledge of the advantages of city planning and the evils of unregulated growth. In the United States excess condemnation is not needed as it is abroad for the recoupment of expense to be obtained by it; in this country these advantages can be obtained by imposing local assessments on those especially benefited. In some States constitutional provisions forbid betterment assessment entirely or to a considerable extent. These constitutions can be changed, and in other States there are precedents for such amendments that have been tried and found to be sound. In some States the present statutes do not provide, adequately at least, for local assessment. Adequate legislation can be passed, with comparative ease, along lines adopted with success elsewhere. In many States the machinery exists and is constantly in use. Excess condemnation is needed for the harmonious planning and subsequent development of the land within and just outside, the lines of the main improvement; and for this there is no substitute for excess condemnation. In this country the law is often the impediment to progress. In city planning, there is the decision rendered in 1920 of the case of Windsor *vs.* Whitney by the highest Court in Connecticut. It is the so-called practical man who lags behind; and in this, as in so many other matters, the engineer who is at once a theorist and a man of affairs, has the privilege and the duty to lead the way and to receive as his reward the satisfaction of knowing that he has performed a public service.

THE USE OF EXCESS CONDEMNATION IN THE OPENING, WIDENING, AND EXTENSION OF STREETS

By A. L. Vedder,* Assoc. M. Am. Soc. C. E.

Cities have always found it necessary to open, widen, and extend streets. During the last few years, since the development of city planning, there has been more of this activity than formerly.

When these openings, widenings, and extensions are made in developed parts of cities, irregular pieces are often left and the cost of the part taken may be as great as that for the whole lot, the claim being sustained that "the damage to the part remaining equals the value of the whole property." Sometimes the parts of lots left are not sufficient to insure a proper development.

Excess condemnation has been suggested as a cure for these ills. The writer will give the law developed and instances where it has been found to be advantageous in Rochester, N. Y.

Law.—In 1913 a new paragraph was added to Section 7 of Article 1 of the Constitution of the State of New York, which provided that the Legislature might authorize cities to take "excess condemnation". In 1921 the City Charter was amended in accordance with this constitutional amendment, the Charter, as amended, reading as follows:

"*Sec. 2.—Corporate Powers.*—The city has power to receive by gift, grant, device, bequest, purchase, or condemnation proceedings, and to hold, lease, and convey such personal estate and such real estate within or without the limits of the city as the purposes of the corporation may require; to make and lay such restrictions, negative easements, or amenities, or to receive such covenants with respect to real property within or without the limits of the city as the purposes of the corporation may require; to take more land and property than is needed for actual construction in the laying out, widening, extending or relocating parks, public places, highways or streets, provided, however, that the additional land and property so taken shall be no more than sufficient to form suitable building sites abutting on such park, public place or street; to contract and be contracted with; to sue and defend, and to be sued in any Court; to make, have, use and alter at pleasure a common seal; to have and exercise all other rights and privileges conferred upon it by law or necessary to carry out its corporate functions and duties.

The following form of ordinance was then adopted:

"By Alderman.....

"Final Ordinance No.....

(Title.)

"The Common Council of the City of Rochester do ordain and determine that the following improvement is necessary and shall be made, to wit;

"Sec. 1. The Common Council hereby declares its intention to acquire the fee of the following described lands, which it deems necessary for municipal purposes, to wit:

(Description of lands actually taken for street purposes.)

"Sec. 2. The Common Council hereby declares its intention to acquire the following territory in fee absolute, and declares that it deems the same neces-

* Deputy Supt. of City Planning, Rochester, N. Y.

sary for municipal purposes, to wit: For street purposes; that it determines the same to be not needed for actual construction in laying out, widening, extending or relocating of said street, and determines that same is no more additional land and property than is sufficient to form suitable building sites abutting on said street.

(Description of land taken in excess.)

"Sec. 3. The whole expense of acquiring the land above described in Sections 1 and 2, estimated at.....(the estimate of the maximum cost per front foot to the property to be assessed therefor being.....; the estimate of the minimum cost per foot being.....) to be and become due and payable in.....annual installments and assessed upon.....

(Description of assessed territory.)

"Sec. 4. The Commissioner of Public Works is hereby directed to purchase said lands hereinbefore described at a price approved by the Board of Estimate and Apportionment, and in case that said Commissioner is unable to purchase said land at a price approved by said Board, the Corporation Counsel is hereby directed to institute condemnation proceedings for the acquirement of same.

"Sec. 5. This ordinance shall take effect immediately."

All sections of this ordinance, except the second, are similar to former ordinances for the opening, widening, and extending of streets, and conform to the requirements of the City Charter. This form was later modified to allow the separate assessment of Sections 1 and 2.

Ordinances were adopted and excess condemnation was used for the following purposes:

Example 1.—To Develop a Section in Conformity with a City Plan.—In 1919, the municipal authorities made a plan connecting four "dead-end" streets over a tract of vacant farm land in a moderately priced residential section. (See Fig. 1.) In 1920, an ordinance opening these streets was passed. The farm was owned by an elderly widow who asked an exorbitant price for the land required for streets, and who desired to subdivide the property in a manner different from that proposed.

If the land was to be acquired by condemnation, it was probable that a high price would be awarded by the Commissioners. The former ordinance was repealed and, in 1921, the first "excess" ordinance was passed, the land being acquired by negotiation at a rather high price.

A subdivision was surveyed and staked, and all but one lot advertised and sold at public auction, according to the provision of the City Charter. The price of the property was $17 224; the receipts from sales amounted to $16 750; the lot retained by the city is valued at $2 000; thus making a profit of about $1 500, besides opening the streets as planned without cost.

This is the only case which is near consummation and about which a financial statement can be made.

Example 2.—Reducing Cost of Opening.—A street, 80 ft. wide, connecting two existing streets in the commercial section of the city, was opened. This is part of a plan for a main thoroughfare extending from the extreme eastern to the extreme western limits of the city. This extension crossed lots diagonally and left the parts of lots not taken in an unsalable condition. (See Fig. 2.) Sufficient land was taken in excess to make good business sites on the

adjoining streets. A new pavement is being laid, after which these business sites will be sold. The surrounding property having doubled in value since the property was purchased, the financial outcome of this transaction does not seem to be in doubt.

Example 3.—The Re-Arrangement of Excess Lands to Insure a Better Development.—A secondary thoroughfare was planned through old subdivisions, the lots of which were all separately owned but had not been developed from lack of sewer facilities. (See Fig. 3.) This street cut the lots diagonally and intersected "dead-end" streets, which made the use of excess condemnation necessary.

A large part of these lands was acquired by condemnation. All the land required has been obtained and a re-subdivision is being planned. As there are several survey adjustments involved, this subdivision will not be completed until later.

Example 4.—To Reduce Cost of Widening by the Use of Rear Lots in Place of Lots Fronting on the Street Widened.—A section of a street, part of a circumferential boulevard system, was widened from 49½ to 100 ft., all the land being taken off one side. (See Fig. 4.) This reduced the depth of the lots fronting on this street sufficiently to make them unfit for later development. These lots were also higher priced than those fronting on side streets extending off the boulevard in this subdivision. Recourse was again had to excess condemnation and not only the remainder of the lots fronting on the main thoroughfare, but also sufficient of those fronting on the side streets, were taken to give lots of proper depth. This area has been re-subdivided and staked.

Other Cases.—In numerous other widenings and extensions, the entire lot has been taken where only a part was necessary for the improvement under consideration. In every case the cost of the necessary part would have been as much as the entire lot. The intention is to dispose of the unrequired part to the abutting property owner. Any money received from such sales will reduce the cost of the improvement.

Observation.—A city, by placing restrictions regulating the setback and character of buildings on the land taken, can make "excess condemnation" of great value in the re-arrangement of abutting property when widening, extending, or opening streets in the development of the city plan. The increase in price of property caused by the publicity necessary to obtain ordinances make the cost of land taken by the city higher than if purchased privately. This applies to either negotiations or condemnations. Nevertheless, if used judiciously, "excess condemnation" is of advantage to the orderly development and re-arrangement of a city.

THE NEED AND THE SCOPE OF EXCESS CONDEMNATION

By Charles Wellford Leavitt,* M. Am. Soc. C. E.

Excess condemnation! It sounds harsh and gives the feeling that it conveys no promise of benevolence. By definition it is "The lawful power, by the exercise of the right of Eminent Domain, to obtain land in a greater area than that physically necessary for a purposed public improvement, although incidental to it." The writer will discuss several reasons why excess condemnation is most necessary in present-day building of cities, and also the extent to which it should be carried, and the results of its proper use.

In opening up a new street, it is necessary:

1—To prevent waste of property.
2—To conserve to the City the greatest possible return on ratable frontage.
3—To conserve to the City its share of the increment due to the improvement.
4—To plan so that adjacent land may be replotted into lots of reasonable and useful size.
5—To protect adjoining owners from assessments unwarranted by the probable use of their lands.

Figs. 5 and 6 are views which illustrate the many small triangular areas left in private ownership by the extension of Seventh Avenue to Varick Street, New York, N. Y. About 1918, this extension was cut diagonally across a number of streets to Varick Street to form a much-needed traffic artery. Unless combined with other property, these small parcels are capable of very limited usefulness to the owner, and yet, in order to conserve to the City its needed return on frontage and the necessary increment due to the improvement created, they must be made to yield tax return. As shown, the parcels are occupied by gasoline stations and small one-story buildings. Another popular use for such land adjoining much used thoroughfares is the advertising billboard, of greater commercial value than artistic, decorative, or educational merit.

It undoubtedly will be many years before private negotiation will succeed in re-arranging property lines so that a reasonable and useful depth and frontage can be obtained on this fine new street. Instances have been cited where nearly sixty years elapsed from the time the streets were widened until the small odd-shaped lots caused by the improvements were incorporated with adjoining properties, the small parcels remaining, in the meantime, of little use and of small return. The effect on the neighborhood containing them was stultifying, if not directly degrading, and the City as well as the individual

* Civ. and Landscape Engr. (Charles Wellford Leavitt & Son), New York, N. Y.

owners suffered rather than gained by the improvement which should have meant increased instead of depreciated values.

Figs. 7, 8, and 9 illustrate the viciousness of widening a street without contingent or excess condemnation. The narrow strips of privately owned land between the new street line and the abutting ownership, in some cases only 3 or 4 ft. wide, are too narrow to be improved by buildings—not even the odorous gasoline station can use them, and the only, but excessively apparent, use to which they can be put is that marvellous blighter of artistic hopes—the sign-board.

Public interest is affected not only indirectly, but very directly, in proportion as the expense of the improved street does not bring to the City the return in ratables that it should. Both the property owner and the City are sufferers, because the property owner is assessed for benefits which he can not use, and the City cannot reasonably assess for taxes on frontage incapable of development. Many instances might be cited similar to those illustrated, not only in New York, but elsewhere as well.

Through the kindness of Charles B. Ball, M. Am. Soc. C. E., Figs. 10 and 11 are presented to illustrate the necessity for excess or remnant condemnation where diagonal streets are opened through plotted and built-up districts. The view, Fig. 12, of the unfortunate condition of a narrow lot left after widening Michigan Avenue, Chicago, Ill., is a forcible illustration of the necessity of exercising excess condemnation in such cases. Fig. 13 shows Michigan Avenue during the progress of widening and extension.

To illustrate the use of excess condemnation as exercised at Portland, Ore., the City and School District No. 1 joined forces in acquiring a site for the U. S. Grant High School and also land for adjoining playground space and for park purposes. A total of 30 acres was purchased at a price of $99 124.70, or an average of $3 304 per acre for the raw land.

The profit obtained from this transaction is, as follows:

Gross receipts, 44 lots at $1 000, average		$44 000
Expenses:		
Bonded improvements	$24 800	
Brokerage, 12½% of $44 000	5 500	
Title insurance at $15 per lot	660	
Miscellaneous	440	$31 400
Profit, or refund to general fund		$12 600

The writer is not prepared to recommend this illustration of excess condemnation as he feels that it is carrying the idea beyond the limits of justification and is a trespass on the proper field of private enterprise.

An extension of Sixth Avenue, New York (Fig. 14), has been approved. The result of this plan, if carried out as shown, will be a repetition of what happened in Lafayette Street, New York, which was widened in 1903 and made a main traffic artery. Fig. 15 shows this street in 1915, still undeveloped in a manner warranted by the expense of the improvement of widening; build-

ings suitable for the location could not be constructed on lots 20 ft. wide and 23 ft. deep; or on a sliver of land approximately 70 ft. long, with a depth of 3 ft. on one end and 23 ft. on the other! The expedient of excess condemnation should have been resorted to, and the whole block acquired for the City, in order that it could have been re-subdivided into useful lots and sold under suitable restrictions.

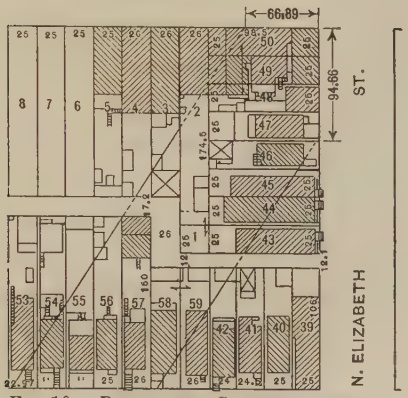

FIG. 10.—PERMANENT CONDEMNATIONS ON EXTENSION OF OGDEN AVENUE, CHICAGO, ILL.

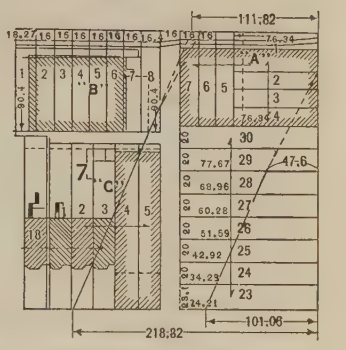

FIG. 11.—PERMANENT CONDEMNATIONS ON EXTENSION OF OGDEN AVENUE, CHICAGO, ILL.

It does not seem too strong a statement to label as a moral and economic crime, such loss to the City and to property owners. It is apparent how utterly useless small, isolated parcels of land become when left in private ownership. There is so much that can be done with the adjacent property if they are taken over by the City, and re-planned for proper development.

Fig. 16 shows the type of buildings which should be capable of construction anywhere along the Seventh Avenue Extension or on Varick Street, New York. The Grand Concourse in The Bronx is also an illustration of a fine avenue developed with suitable buildings made possible because of a land subdivision that provided lots of sufficient depth and frontage on the Parkway.

The cities of the United States are hesitating and backward about using excess condemnation. In Canada it is different; excess condemnation is exercised whenever it is deemed necessary for the public good. To illustrate, reference is made to Montreal, Que. The following figures are of interest in connection with the development of the George Etienne Cartier Square in Montreal:

Land purchased	164 504 sq. ft.
Land used as street, lots, and square	82 426 " "
Land sold	82 078 " "
Total purchase price	$82 252
Net proceeds of sales	99 032
Profit	$16 780

In other words the City acquired a park which, together with the abutting street area, was about 2 acres in extent; and the profit to the City was $16 000.

The City of Montreal has also opened one street and one boulevard with the following results:

St. Lawrence Boulevard Opening:

Land taken	102 002 sq. ft.
Land used for street purposes	49 910 " "
Land sold	53 092 sq. ft.
Total purchase price	$690 570
Net returns from sales	716 194
Profit	$25 624

Cartier Street Opening:

Land purchased	130 817 sq. ft.
Land used as street	55 637 " "
Land sold	75 180 sq. ft.
Total purchase price	$99 626
Net proceeds of sale	112 443
Profit	$12 817

This method has been so successful that the Bonaparte Boulevard has been carried forward in the same manner, namely, by condemning more property than was needed, and re-selling the remainder.

In London, England, the cost of opening the following streets was reduced by the re-sale of surplus property to the extent noted:

Carrick Street	72%
Southward Street	67%
Queen Victoria Street	53%
Northumberland Avenue	$600 000 profit
Kingsway	87%

These figures were taken from the Thirty-first and Thirty-second Annual Reports of the City Park Association of Philadelphia, Pa., furnished through the courtesy of Mr. Andrew Wright Crawford.

The following is quoted from these reports:

"A recalcitrant owner might refuse to sell, except at an exhorbitant price, or even refuse to sell altogether.

"The power of excess condemnation, in addition to the power of excess purchase, which the City already has, is thus necessary to prevent the citizens from failing to get adequate results from such an improvement and to prevent the City from being mulcted. The City usually has to pay as much as an entire property is worth, where it takes half of it or more; that being so, it ought in justice to be able to condemn the entire property. In addition to this reason for excess condemnation there is the consideration, that, when this power is exercised, the owner gets absolutely all that he is entitled to. He gets the full fair value of his property at the time it is taken; and, indeed, he often gets a high value for it. When the public takes property and a

FIG. 12.—WIDENING AND EXTENSION, MICHIGAN AVENUE, CHICAGO, ILL.

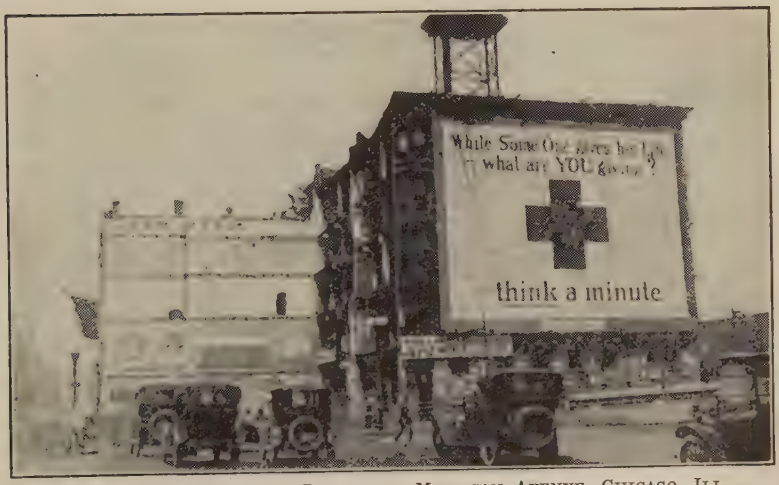

FIG. 13.—WIDENING AND EXTENSION, MICHIGAN AVENUE, CHICAGO, ILL.

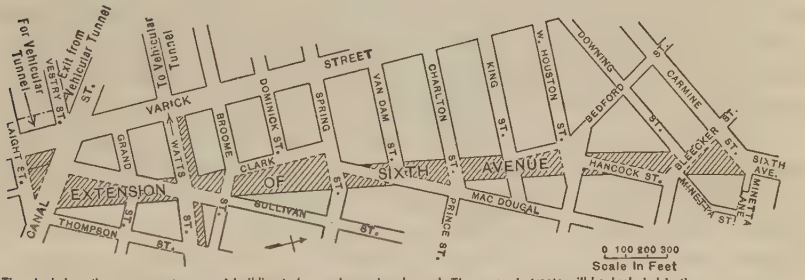
jury passes upon it, the property owner is not the one who suffers; he is usually fully compensated. Even at that, most property owners want to keep as much as possible of their property, where the City only needs a portion; they realize, that if they do keep it, they will reap a harvest; because, if the City takes a third of the property for such an improvement as the Parkway, it is safe to say the City will pay at least half the value of the entire lot, and the remaining two-thirds will be worth more than the original whole lot was worth; and in the course of a few years it may double in value, owing to the improvement."

The reasons for requiring excess condemnation for street have been stated fully and illustrated. The scope of excess condemnation at the time of construction or improvement should include not only land contiguous to new and improved streets, but also land bordering on and in the immediate vicinity of highways, parks, parkways, public and semi-public building sites, sewerage systems, trunk lines, and aqueducts.



The shaded portions represent areas of building to be condemned and razed. The present streets will be included in the new avenue, which will be not less than 100 feet wide at any point. At Spring and Canal streets the avenue's width will exceed 200 feet.

FIG. 14.—SIXTH AVENUE EXTENSION, NEW YORK, N. Y.

For highways, parks, and parkways, the taking over, by the City, or other political body interested, of more property than is necessary for the actual construction contemplated would eliminate as far as possible contingent damage collectable from the City or other political units. It removes from any private owner the damages of unfair benefits assessments. It also gives to the authorities a control, not securable in other ways, over the use of land which, if deemed advisable, can be held as open spaces for the use of future generations.

Esthetics has been called the science of the suitable embellishment of practical things, of which practical things, public buildings and their sites are by no means the least. The use of the land surrounding public buildings is, in general, a subject on which in America evidently little real creative thought has been put. The establishment and the preservation of fitting environments for governmental buildings are possible only by securing not merely the immediate grounds but a goodly portion of the land contiguous, the replotting of all not needed for immediate surroundings, and the selling of lots with suitable restrictions as to size and development. Excess condemnation must be resorted to, if private purchase at a reasonable figure cannot be made.

At Camden, N. J., it was recently proposed to select a site for a future civic center. After much deliberation a location was found which, although of somewhat greater area than might be required strictly for the public buildings in the group, was procurable in a single parcel. The City bought this land in total at private sale for an economical price, and now is in the position of being able to use as much of it for public purposes as may be required. The remainder can be sold under such restrictions as to preserve the environment of the civic center in a fitting manner. Also, as soon as the civic center is realized, the property adjoining will increase in value and ratables to an amount calculable only on consideration of the probable growth of the city in size and importance. What Camden has done for her future through private purchase, other cities, not so fortunate, must do by excess condemnation.

In the case of sewerage trunk lines and aqueducts near a built-up community, excess condemnation eliminates the expense of contingent damages—a cost for which the municipality has nothing material to show—and in its stead furnishes land possible for future parks; or if parks are not deemed necessary at these points, land capable of sale at a price approximate to the cost of the improvement. In open country, the cost of constructing private crossings may equal or exceed the value of the contiguous land.

Fig. 17 illustrates a case in which an aqueduct passed through a farm. Owing to the fact that the farm was cut in two, contingent damage would probably amount to the full worth of the farm. Fig. 18 shows what could have resulted if the farm had been condemned, for probably an equal sum of money, taken over by the municipality, and then subdivided. The re-sale figures for the lots would have been greater than the purchase price, the municipality and the land owners near-by would have been benefited, and the aqueduct, instead of being a detriment, for which the city had to pay damages, would be regarded as a benefit. Most communities constantly are face to face with their ever-present bogey, the debt limit, and find themselves unable, in the event of other needed expenditures, to avail themselves of the benefit of excess condemnation because of the nearly approached debt limit. Land is one of the most tangible of assets, and it seems logical that a community should be enabled to bond lands acquired under the exercise of excess condemnation, which are in excess of the true physical requirements of the purposed improvement, and that such a debt should be considered as outside the community on which limitations are placed.

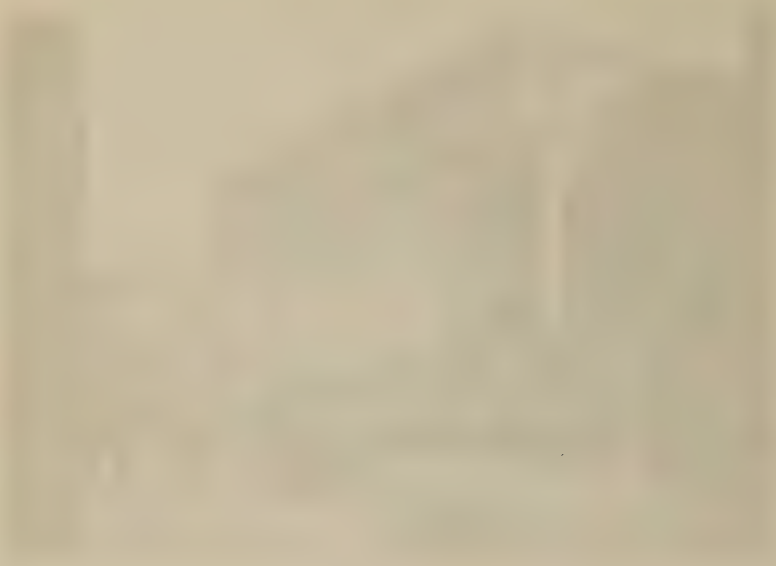
This was proposed to the people of Michigan in a constitutional amendment, as follows:

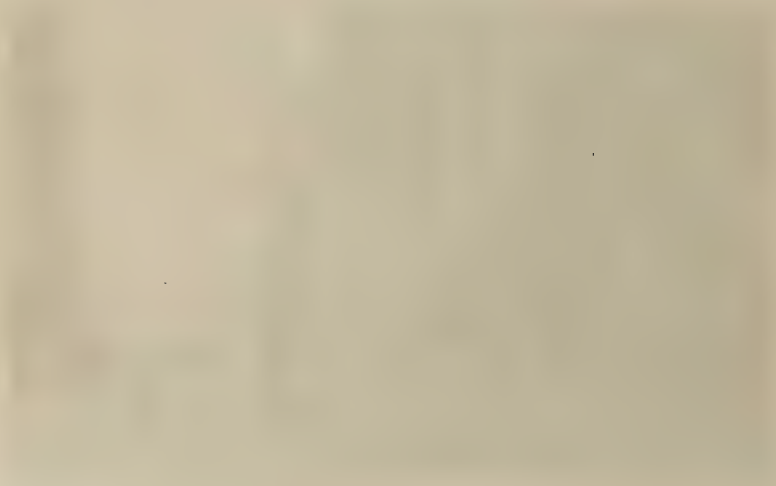
"Bonds may be issued to supply the funds to pay in whole or in part for the excess property so appropriated, but such bonds shall be a lien only on the property so acquired and they shall not be included in any limitation of the bonded indebtedness of such municipality."

It is hoped that this idea will be realized in many places and that such indebtedness will be regarded as perfectly justifiable.

FIG. 15.—WEST SIDE OF LAFAYETTE STREET, NEW YORK, N. Y., TWELVE YEARS AFTER BEING WIDENED.

FIG. 16.—VIEW ILLUSTRATING SUITABLE BUILDINGS MADE POSSIBLE BY PROPER LAND DEVELOPMENT.





Remnant condemnation impresses one as an expression which conveys the thought of possession by the municipality of under-sized parcels of property. This would be highly proper procedure, from the viewpoint of the land owner, who would be left with possession of the small useless piece. What real use, however, would such a piece be to a city, unless the City could combine it with other property and make a good lot? Ownership by the municipality of these remnants prevents the holding up of these narrow frontages for exorbitant prices, but one should go further than that, and be sure that the

FIG. 17.

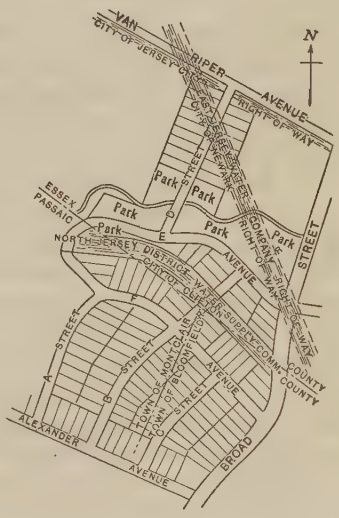


FIG. 18.

City gets its share of the profit for making the costly improvement which caused the small lots. To be safe in securing this share, the City could not take the poor end of the bargain. Remnant condemnation, with the meaning stated, is a poor half-way measure. It remains for all those interested in city planning and allied matters to educate the public authorities and the public in general, to realize the meaning and benefits of excess condemnation. How it works to the benefit of the average citizen, and enthusiastically to those in the real estate business, is self-evident because public economics mean lower taxes; the man who pays the taxes prefers to live where taxes are low, and the real estate man finds his best market there.

EXCESS CONDEMNATION IN MASSACHUSETTS

By Frederic H. Fay,* M. Am. Soc. C. E.

Synopsis

The story of excess condemnation in Massachusetts, as in most States, is a story of small accomplishment so far as the actual exercise of this power is concerned. In certain directions, however, Massachusetts has been a pioneer in formulating principles and establishing the right to use excess condemnation.

The Massachusetts Remnant Act of 1904 was the first legislation passed by any State applying the principles of excess condemnation to the taking of remnants of lots of which only portions are actually required for purposes of street improvements. This was followed shortly afterward by similar legislation in several other States.

The Massachusetts Constitutional Amendment of 1911, which is broader in scope than the Remnant Act of 1904, and permits the taking in fee of land sufficient to provide suitable building lots on both sides of a projected street or highway improvement, was the first recognition of the principle of excess condemnation for street improvement purposes in the Constitution of any State. This, too, was soon followed by constitutional amendments of like character in other States.

By the "Homestead Amendment" to the Constitution, adopted in 1915, Massachusetts has assumed the right to go into the business of providing homes for her citizens through State action.

In Massachusetts the principle has been established and upheld of applying excess condemnation to the taking of restrictive easements in private property for the public good.

These and other incidents in the story of excess condemnation in Massachusetts are given in some detail in this paper.

Excess Condemnation Applied to Land Reclamation

About seventy-five years ago, the State of Massachusetts undertook extensive work of land reclamation by a method which, although perhaps not excess condemnation in the strict interpretation of that term, is at least on the border line. This project was the reclamation of tidal flats along the Charles River, which now constitute the well-known Back Bay District of Boston. Although in most tide-water States, ownership of tidal flats rests in the State up to the high-water line, in the State of Massachusetts as well as in the State of Maine, owners of water-front property own the tidal flats to low-water mark provided the low-water mark is not more than 100 rods from the shore. Title to all flats beyond the 100-rod limit rests in the Commonwealth. This private ownership of tidal flats results from an ordinance passed

* (Fay, Spofford & Thorndike), Boston, Mass.

in 1641 under authority of the Colonial Charter of the Massachusetts Bay Colony.

The extensive tidal flats which have since been developed as the Back Bay Section of Boston were separated from the main "tidal-estuary" portion of the Charles River about a century ago by the building of a tide-mill dam on what is now the line of Beacon Street. Prior to 1850, the population of the City of Boston and of the adjoining Town of Roxbury had grown to such extent that the drainage from these communities into this tidal-flat basin had created a nuisance. Shortly after 1850, the Commonwealth undertook the reclamation of these flats as a measure of sanitation. As the simplest method of procedure, the State acquired title to the area by right of eminent domain. The flats were filled and proper drainage was provided. Suitable streets and public spaces were laid out, certain portions of the lands were granted by the Commonwealth to educational institutions, and the remaining lots were sold to private parties. The reclamation of this considerable territory was of benefit not only to the inhabitants of Boston and neighboring communities in the abolition of a nuisance, but the net result financially was a substantial profit to the State. Since that time other tidal flats along different sections of the water-front of Boston Harbor have been and are being similarly reclaimed by State agency.

Viewed from the standpoint of the abolition of a nuisance the reclamation of the Back Bay flats was not excess condemnation for the reason that the State took by eminent domain only such land as was necessary to fill in order to get rid of the nuisance. Considered as a land-reclamation project it is to be noted that the State took by eminent domain the fee in private property, filled the land, laid out streets, etc., and then in the case of a considerable portion of this land sold the fee to private parties other than the original owners. Possibly this project might have been carried out by condemning merely easements in the privately owned flats. The taking of the fee was certainly a more direct and satisfactory method, as it permitted the replotting of the land according to a well-considered plan. Probably this materially enhanced the value of the properties which were sold.

Excess Condemnation of Lot Remnants

Early Special Legislation.—The State of Massachusetts long ago passed certain special legislation dealing with the problem of remnants of land resulting from the laying out of street improvements. In 1865, an Act relating to the widening of Oliver Street, Boston (Chapter 159) was passed, which provided that any person owning an estate, part of which is taken for street uses may, "at any time before the estimation of damages * * * elect to surrender all of said estate to the city of Boston." Any remaining portion of an estate not used may be sold and "the net proceeds thereof shall be applied toward the expense of said widening and grading." This was not excess condemnation, as the City had no discretionary power; the choice rested with the owner of the land whether or not the whole of his estate should be taken.

In 1866, another Act was passed by the Massachusetts Legislature (Chapter 174) entitled "an act concerning the laying out, altering, widening and im-

proving the streets of Boston." Although the former Act of 1865 applied only to one particular street, this Act of 1866 was of broader scope and was intended to be general in its application as far as street improvements in Boston were concerned. Like the Special Act of 1865, this Act gave the owner of an estate the choice of surrendering the whole estate instead of the part to be taken for street improvements, provided his decision were made prior to the award of damages. Should he elect to surrender his entire estate, however, the City was not compelled to take it but could do so "if said Board of Aldermen shall then adjudge that public convenience and necessity require the taking of such estate." This may be considered excess taking by mutual consent, and it is not excess condemnation.

Massachusetts Commission on Excess Condemnation.—About twenty-five years ago the subject of excess condemnation became of much interest in Massachusetts. In 1903, the Legislature passed a Resolve (Resolves, Chapter 86) "to provide for the appointment of a committee to consider the matter of making public improvements under a more extensive exercise of the right of eminent domain than is now authorized by the constitution and statutes." The Special Commission created under this Resolve went abroad and made extended investigations of the workings of excess condemnation in Europe. It reported* the results of its investigation with its recommendations to the Legislature of 1904. The Commission submitted with its report a draft of a proposed statute embodying its recommendations in part and providing for the condemnation and replotting of remnants. Dr. Cushman, in his admirable book,† which is the first work on this subject to be published in the English language, states:

"There are five features of this proposed law which are worthy of note. First, it gave cities the power to condemn unusable remnants of land. In the second place, it authorized the city to offer such a remnant to the owner of the adjoining parcel with which the public authorities deemed it wise to unite the remnant at a price fixed by an elaborate system of appraisal. Third, if this offer was not accepted the city might condemn the whole or any portion of the property of such adjoining owner. Fourth, all the surplus land taken under the provisions of the Act should be sold at public auction. Fifth, the owner of a remnant the area of which was not more than one thousand square feet might compel the city to purchase it."

A sixth point, not mentioned by Dr. Cushman, is also of interest, namely, the draft provided that after the filing in Court of the plan and petition of a proposed improvement no damages should be awarded for any building thereafter erected upon the land in question; this feature had been used in connection with street improvements in London, England, to prevent buildings being erected or improvements to buildings being made for the sole purpose of enhancing the damage award collected from the City, but its constitutionality in America may be seriously questioned.

Dr. Cushman states further of the statute proposed by the Special Commission:

* For Report, see House Document 288, and for Supplemental Report, House Document 1096.

† "Excess Condemnation", by Robert Eugene Cushman (National Municipal League Series), 1917, p. 62.

"Such a law would allow a municipality to condemn not merely remnants of land but enough additional land to make possible an adequate replotting of such remnants into suitable building lots. The Legislature was unwilling to go to this extent, however, and contented itself with passing, in 1904, an act allowing cities to condemn merely the remnants of land left by the construction of an improvement."

The Massachusetts Remnant Act of 1904.—The Remnant Act of 1904 (Chapter 443) is an elaborate Act of thirty sections and defines procedure in minute detail. Section 2 of the Act is most significant and reads as follows:

"The Commonwealth, or any city in the Commonwealth so far as the territory within its limits is concerned, may in the manner hereinafter set forth, take in fee by right of eminent domain the whole of any estate, part of which is actually required for the laying out, alteration or location by it of any public work, if the remnant left after taking such part would from its size or shape be unsuited for the erection of suitable and appropriate buildings, and if public convenience and necessity require such taking."

The term "public work" in the Act is defined as meaning any public highway, square, open space, public playground, or park. As Dr. Cushman states:*

"It is important to note that this law does not confer upon the city or State unlimited discretion in the taking of remnants. The land which may be condemned in excess of actual need is only that which is not suitable for independent development. In other words, no broad power seems to be given to condemn all estates, any part of which, however small, may be needed for actual public use."

The Massachusetts Remnant Act of 1904 was the first important Act in the United States providing for the excess condemnation of remnants of land. It was followed by similar Acts in Ohio, Virginia, Connecticut, Pennsylvania, Maryland, Wisconsin, and New York. Thus, in this field of excess condemnation, Massachusetts was a pioneer. The constitutionality of the Massachusetts Remnant Act of 1904 was upheld by an opinion of the Supreme Court of the State, rendered March 4, 1910 (Opinions of Justices, 204 Mass., 616 *et seq.*). In passing on the constitutionality of certain other legislation then pending in the Legislature, the Massachusetts Supreme Court had occasion to refer to the Remnant Act of 1904, as follows:

"We are asked whether it would make any difference if the proposed statute contained provisions like those of the statute of 1904, chapter 443, section 6. In our opinion, given to the House of Representatives, we intimated that this statute is constitutional. In our judgment it goes to the very verge of constitutionality. The grounds on which we are inclined to sustain it have little relevancy to the stated purpose of the unusual provisions of the proposed statute. They are: First, that there can be no taking outside the location of the public work except of a remnant of an estate a part of which is actually required for the laying out, alteration, or location of the public work, and then only if the remnant left after taking such part would, from its size or shape, be 'unsuited for the erection of suitable and appropriate buildings'—in other words, only when there is a remnant that is too small or too ill shaped to be of any practical value for the use to which valuable land is commonly put; and, secondly, that such a remnant can be taken only upon an adjudication that public convenience and necessity require the taking. Unless it can be said that public convenience and necessity never can require the taking of

* "Excess Condemnation", p. 63.

such a remnant the statute cannot be declared unconstitutional. While it is plain that a city or town cannot take land outside a public work for speculative purposes, we can conceive of a remnant of an estate, a part of which is necessarily taken, which remnant is so small, or of such shape and of so little value, that the taking of it in the interest of economy or utility, or in some other public interest, may be fairly incidental and reasonably necessary in connection with the taking of land for the public work."

The authority conferred by the Massachusetts Remnant Act of 1904 was seldom used. The only instance known to the writer was in the City of Springfield, where it was utilized on five occasions both for new street layouts and for the widening of existing streets and is understood to have been found of advantage to the city and protective to property interests.

The 1904 Remnant Act was repealed by the Legislature in 1918 (Chapter 257, Section 203 of Acts of 1918), partly because it has been little used and more particularly because under the Constitutional Amendment of 1911 all the powers of the 1904 Act and much broader powers of excess condemnation could be conferred at any time by special legislation.

Constitutional Amendment of 1911 Applying Excess Condemnation to Street Improvements

Proceedings Leading to Proposal of Constitutional Amendment.—The limited power incurred by the Remnant Act of 1904 was brought out as the result of a report of the Joint Board on Metropolitan Improvements made to the Legislature in 1910. This Joint Board, consisting of four State Commissions, created by legislative resolve (Chapter 113, Resolves of 1909) to consider the question of needed improvements in Metropolitan Boston, advocated the building of an important new thoroughfare through the down-town portion of the city. This thoroughfare would not only provide an important artery for surface traffic, but would also be utilized as a route for a railroad tunnel, connecting the North Station and the South Station, the two passenger terminals of Boston. The building of this thoroughfare which would cut through closely built-up territory, would necessitate the taking of the whole or portions of more than 150 parcels of property. If the City were to proceed under the Remnant Act of 1904 and condemn in addition to the land actually required for street purposes only such lot remnants as were not suitable for the erection of proper buildings, it was felt that the results would by no means insure suitable development along the new street. The Joint Board was of the opinion that this was a case in which it seemed desirable to exercise broader powers of excess condemnation and to take, in addition to the remnants which might be condemned under the 1904 Act, other parcels which could be combined with the remnants and the whole replotted into suitable building lots.

The Joint Board reported:

"A thoroughfare such as suggested will fall far short of its full usefulness if it furnishes simply a convenient route for traffic. It cannot entirely fulfill commercial requirements unless individuals and corporations desiring to erect important business and office buildings or warehouses and manufacturing plants can secure suitable lots thereon."

Commenting on the unsuitability of remnants remaining after takings under the Remnant Act of 1904, the Board reports further:

"If, however, takings in addition to these remnants can be made wherever needed to provide areas sufficient for the construction of buildings of large size, then the street will more quickly and surely become an important business thoroughfare, and the commercial and industrial growth and prosperity of the city will be promoted in a larger and more adequate way."

In accordance with the recommendation of the Joint Board, legislation was proposed in 1910 to broaden the powers of excess condemnation conferred by the Remnant Act of 1904 so as to make possible more extensive property takings for the new thoroughfare. In accordance with Massachusetts practice the Legislature sought and secured from the Supreme Court an advance opinion as to the constitutionality of the proposed measure, if it became a law. The Court held that the measure proposed would be unconstitutional, although by indirection it upheld the Remnant Act of 1904, which the Court believed went to the very limits of constitutionality. This decision has been reported* as follows:

"39. Opinion of the Justices, 204 Mass., 607, 91 N. E. 405, 27 L. R. A. (N. S.)—483. The House of Representatives passed an order requiring the opinion of the Justices of the Supreme Judicial Court upon the following question (in substance): If the commercial interests and general prosperity of the inhabitants of the Commonwealth and particularly the city of Boston are dependent upon the existence in that city of facilities for the transaction of foreign and domestic trade and commerce, and chief among such facilities is a broad thoroughfare with adequate sites upon it for warehouses and other buildings, and no such street exists, and if such a street should be laid out in the ordinary way the adjoining land would be left divided into parcels of such unsuitable size and shape, that the proper facilities could not be furnished by the mere laying out of a street, but could only be secured by the concentration through the exercise of eminent domain of estates abutting thereon into parcels of suitable size and shape, is it within the constitutional power of the Legislature to authorize the taking by the city of land for such a thoroughfare and of so much land on both sides thereof as may be reasonably necessary to furnish the proper facilities and with a view to subsequent use of such land by private individuals in such manner as to secure the public interests referred to?

"The answer of the Court was in part as follows:

" 'The question seems to relate particularly to the power of the Legislature to take and use land outside of the proposed thoroughfare, for purposes which have no direct relation to the construction or use of the street for travel. It is presented upon the hypothesis that the desired facilities for the profitable use of the land can be secured only by the obliteration in whole or in part of the present lines of individual ownership along the street, the concentration, through the exercise of the power of eminent domain, of these abutting estates, in parcels of suitable size and shape, and the development or use of such parcels for warehouses, mercantile establishments and other buildings suited to the demands of trade and commerce. The question is whether such land can be taken with a view to the subsequent use of it by private individuals, under conveyances, leases or agreements which shall embody suitable contracts for the construction on the land of buildings adapted to use in domestic and foreign trade and commerce, and for the use, management, and control of the lands and buildings in such manner as to secure and promote such trade and

* "The Law of Eminent Domain", by Philip Nichols, 1917, p. 179.

commerce. The proposed legislation to which the inquiry relates, necessarily would contemplate action by the city in the procurement, management and control of land along a street within the city, for no other purpose than to induce and promote a use of it by merchants or traders. It would contemplate a taking of private property in the exercise of the right of eminent domain, and an expenditure of money to pay for it and fit it for occupation. It is a rule of law universally recognized in this country that neither of these things can be done unless the taking or expenditure is for a public use. This has been stated so often, and the principles on which it is founded have been considered so fully that it is unnecessary to discuss it or to cite authorities. The only question about which there is a possibility of doubt is whether the proposed use of the land outside of the thoroughfare is a public use. It is plain that a use of the property to obtain the possible income or profit that might enure to the city from the ownership and control of it would not be a public use. The city cannot be authorized to take the property of a private owner for such a purpose, nor can the city tax its inhabitants to obtain money for such a use. It could as well tax them to raise money to carry on any other private business with a hope of gain. Such proceedings are entirely outside the functions of a state or of any subdivision of a state. It is equally true and indubitable that a management and use of such property to promote the interests of merchants and traders who might occupy it, and to furnish better facilities for doing business and making profits, would not be a public but a private use of the real estate. An affirmative answer to this question would make it possible for the city to take the home of a resident near the line of the thoroughfare, or the shop of a humble tradesman, and compel him to give up his property and go elsewhere, for no other reason than that, in the opinion of the authorities of the city, some other use of the land would be more profitable and therefore would better promote the prosperity of the citizens generally. We know of no case in which the exercise of the right of eminent domain or the expenditure of public money has been justified on such grounds. * * * We answer the question in the negative.' "

Constitutional Amendment of 1911.—Finding in the case of the proposed law for the construction of a new thoroughfare between the North and South Stations, that the exercise of broad powers of excess condemnation was not possible under the Constitution of Massachusetts as it then existed, the Legislature of 1910 proposed a constitutional amendment as follows:

"Article ten of part one of the constitution is hereby amended by adding to it the following words: The Legislature may by special acts for the purpose of laying out, widening or relocating highways or streets, authorize the taking in fee by the Commonwealth, or by a county, city or town, of more land and property than are needed for the actual construction of such highway or street: *provided, however,* that the land and property authorized to be taken are specified in the act and are no more in extent than would be sufficient for suitable building lots on both sides of such highway or street, and after so much of the land or property has been appropriated for such highway or street as is needed therefor, may authorize the sale of the remainder for value with or without suitable restrictions."*

In Massachusetts a constitutional amendment must be passed by two successive Legislatures and then ratified by the people. Accordingly, the amendment quoted, passed by the Legislature of 1910, was again passed by the Legislature of 1911 and was ratified by the people at the election on November 7, 1911.

* Now Article XXXIX of the Constitution of Massachusetts.

It is to be noted that the Constitutional Amendment of 1911 relates solely to the laying out, widening, or relocating of highways or streets. Also, that the powers of excess condemnation made possible by this amendment may only be exercised through special acts of the Legislature.

Massachusetts was the first State to adopt a constitutional amendment of this character. It was followed by amendments in Ohio and Wisconsin in 1912, in New York in 1913, and in Rhode Island in 1916.

Special Legislation Under Provisions of 1911 Constitutional Amendment.— Several Special Legislative Acts have been passed under this constitutional amendment although the project for the proposed thoroughfare between the North and South Stations in Boston was not carried out. Among the Special Acts may be noted the following:

Acts of 1912, Chapter 186, authorizing the City of Worcester to take land for the widening of Belmont Street.
Acts of 1913, Chapter 169, relating to highway improvements in the City of Brockton.
Acts of 1913, Chapter 201, authorizing land takings by the City of Worcester in connection with the extension of Madison Street.
Acts of 1913, Chapter 326, authorizing the City of Worcester to take certain lands near Washington Square and to sell part of the same.
Acts of 1913, Chapter 703, providing for the widening of Bridge Street in Salem.

As far as the writer is aware, the authority to use excess condemnation, conferred by these several Special Acts, has in no instance been exercised.

It is to be noted that the constitutional amendment permits special legislation to be passed authorizing the sale of remaining land with or without restrictions. The permission to sell remaining land with restrictions was granted in some but not all of the Acts enumerated. There seems to be some doubt whether a city could impose restrictions unless expressly authorized so to do by legislation or by the State Constitution.

The only Special Act permitting the application of excess condemnation, which has been passed with relation to street improvements in the City of Boston, is that relating to the Stuart Street Improvement (Special Acts of 1917, Chapter 329, as amended by Special Acts of 1918, Chapter 118; Acts of 1920, Chapter 312; Acts of 1920, Chapter 465; Acts of 1921, Chapter 407). The Stuart Street Extension was the first stage in a comprehensive plan for a "western artery" proposed by the City Planning Board in 1917 to provide an adequate street outlet for the down-town business section of the city. Under the original Act the excess condemnation plan was to be used and the Act specified the parcels of land to be taken. The City was authorized to issue bonds outside the debt limit to the amount of $4 000 000, but was directed to enter into agreements with, or take guaranties from, property owners so that the total expense to the City would not exceed $250 000. This requirement was due to the fact that the Park Square Real Estate Trust, which had extensive property holdings in the vicinity, gave assurance at the time the legislation was passed that it would take over the excess land on terms such that the net expense to the City would not exceed the amount stipulated in

the Act. The original Act was approved May 14, 1917, shortly after the United States entered the World War. Under war conditions it was deemed inexpedient to proceed with the Stuart Street Improvement and the Special Act of 1918 extended the earlier legislation by providing that the 1917 Act "shall take effect upon its acceptance by the Mayor and City Council of the City of Boston at any time before the expiration of one year after the termination of the present war, as defined by Federal authority." The Park Square Real Estate Trust made an offer to the City to take over the properties in excess of the actual requirements for the street on terms such that the estimated net cost to the City would not exceed the limit of $250 000 prescribed by law. This offer held until February 1, 1920. Meantime, the City Council had not accepted the 1917 Act and doubt was expressed as to the constitutionality of its excess condemnation provision which had never been tried in so large and important a project. The City Council being apparently hostile to the undertaking, no agreement was reached with the Park Square Real Estate Trust, and the excess condemnation proposal fell through. In 1920, further legislation was passed authorizing the Stuart Street Improvement without the excess condemnation feature, and the street has since been constructed without the exercise of excess condemnation.

One other proposal for the extensive application, under the 1911 Constitutional Amendment, of the principle of excess condemnation in Boston is worthy of notice. This was the Bill (Senate No. 268) introduced in the Legislature of 1920 for the North End Improvement. The section of Boston known as the North End is one of the oldest parts of the city and two centuries ago was the leading residential section. Originally, its house lots were large and the street system which was gradually developed resulted in irregular city blocks of large size. During the latter part of the Nineteenth Century the North End became a tenement house district, all available land was built upon, and many tenements were constructed in the interiors of these blocks without suitable street access and without adequate provision for light, air, and recreation. Thus, a population of great density, in certain blocks exceeding 500 persons per acre, came to be housed under unwholesome conditions. The remedy proposed was the cutting of new streets through the larger and more congested blocks and the widening and improvement of existing streets and alleys. To carry out the improvement properly, and secure suitable replotting of the land, the proposed legislation provided for a liberal amount of excess condemnation. The measure was strongly endorsed by public and semi-public organizations, was passed to be engrossed by the Senate, but was finally defeated in the House of Representatives. Thus was lost another opportunity to apply the excess condemnation principle in Boston on a large scale and to a major improvement which could not be carried out adequately by other means.

Although Massachusetts by its Constitutional Amendment of 1911 has made possible the application of excess condemnation to street improvements, this authority has not yet been exercised.

Excess Condemnation for Park Purposes Declared Unconstitutional

One instance has occurred in Massachusetts where the attempt to apply the principles of excess condemnation to land takings for park purposes has been declared unconstitutional. In 1912 the Legislature passed an Act (Chapter 715) "to make Salisbury Beach a public reservation and to establish the Salisbury Beach Reservation Commission." This Act authorized the Commission which it created to take by eminent domain any or all of certain shore lands in the Town of Salisbury within certain wide limits which were defined in the Act. The Act provided (Section 10) that the Commission "may sell or lease any lands or rights in land taken or acquired by it, which are not needed as a public reservation for the use, exercise, and recreation of the inhabitants of the Commonwealth, with or without restrictions as to its use as it may deem advisable." The Act was of such broad scope that the powers of the Commission to condemn and re-sell land were practically unlimited. Its constitutionality was brought in question before the Supreme Court in 1913. In its decision (Opinions of Justices, 215 Mass. 371), the Court held the Act unconstitutional on the ground that it was "an attempt to authorize the exercise of the right of eminent domain in part for a private purpose, and because it is impossible to separate the valid from the invalid portions of the statute," and, further, that "the interest of the public that the people should be well housed although proper to be considered in the exercise of the police power, is not a proper subject for the exercise of eminent domain." Under the takings contemplated an existing seaside resort with a number of summer cottages would have been included in the reservation.

According to Chief Justice Rugg, who wrote the decision:

"The underlying objection is that the main end of legislation for this purpose is a private utility rather than the general good. While incidentally it may be an advantage to the public that private persons prosper, if the essential character of the transaction in its direct object is private benefit to individuals, the purpose is not public. * * * Legislation which is designed or which is so framed that it may be utilized to accomplish the ultimate result of placing property in the hands of one individual for private enjoyment after it has been taken from another individual avowedly for a public purpose is unconstitutional."

In the opinion of the Court the power conferred on the Commission was too broad. It is implied in the decision that if the power to take land and sell it had been restricted as to time, or by "changed conditions", or to the sale of remnants, that part of the Act might be considered as constitutional.

It is to be noted that this opinion of the Supreme Court of Massachusetts was rendered in 1913, prior to the adoption of the Homestead Amendment to the Constitution in 1915, which does permit the Commonwealth to condemn land for housing purposes, and, after improvement, to sell it for the purpose of relieving congestion of population and providing homes for citizens.

The "Homestead" Constitutional Amendment of 1915

By 1911, prior to the shortage of homes resulting from the World War, the question of proper and adequate housing of its citizens received the attention of the Massachusetts Legislature. In that year the Massachusetts

Homestead Commission was created by legislative enactment (Acts of 1911, Chapter 607). The Commission was directed to make an investigation and report and to recommend legislation "embodying a plan and the method of carrying it out whereby, with the assistance of the Commonwealth, homesteads or small houses and plots of ground may be acquired by mechanics, factory employees, laborers, and others, in the suburbs of cities and towns." In its report to the Legislature in 1912 the Commission recommended that part of the unclaimed deposits of savings banks which had been called into the State Treasury should be loaned to the Commission for the purpose of providing workingmen's homes as contemplated in the Legislative Act of 1911.

Although the Homestead Commission Bill, as it was called, was pending in the Legislature in 1912, that body requested the opinion of the Supreme Court on the constitutionality of the measure. The Court held that the legislation proposed would not be constitutional. The main questions decided by this opinion were that the purpose of the bill was to enable the State Commission to do private business, utilizing public funds, therefore, it was unconstitutional; that the Commonwealth could not raise money for such purposes by taxation; and that money from unknown owners deposited in the State Treasury by savings banks was held in trust by the Commonwealth, subject to the claims of the owners at any time (Opinions of Justices 211 Mass. 624).

After the Supreme Court declared the proposition unconstitutional the Legislature further instructed the Homestead Commission (Chapter 714, Acts of 1912) to:

"Continue its investigation of the need of providing homesteads for the people of the Commonwealth and its study of plans already in operation or contemplated elsewhere for housing wage-earners * * * and * * * recommend such legislation as in its judgment will tend to increase the supply of wholesome homes for the people."

The Commission made exhaustive studies of governmental aid to housing in twenty-seven foreign countries, including Australasia, the United Kingdom, Continental Europe, and parts of South America and of South Africa. As a result of its studies, the Commission concluded that "if there is to be created a sufficient supply of wholesome homes within the means of the ordinary wage earners, cities and towns must be built according to well considered plans." Accordingly, two bills were recommended to the Legislature of 1913, one providing for the establishment of local planning boards by the cities and towns of Massachusetts and the other for studies by the Commission of questions of town and city planning and for the Commission's aid to cities and towns in planning work. These bills were passed as Chapter 494 and Chapter 595, respectively, of the Acts of 1913.

The first of these two Acts made City Planning Boards mandatory in every city of the Commonwealth and in every town having a population of more than 10 000 and marked the beginning of organized official city planning work in Massachusetts. This was the first mandatory city planning legislation to be passed by any State.

Being unable to find a way to provide homes for working people through governmental aid under the provisions of the State Constitution as it then

existed, a constitutional amendment was passed by two successive Legislatures, in 1914 and 1915, and ratified by the people on November 2, 1915.

The Homestead Amendment, as it is called, is as follows:

"The General Court shall have power to authorize the Commonwealth to take land and to hold, improve, sub-divide, build upon and sell the same, for the purpose of relieving congestion of population and providing homes for citizens: *provided, however,* that this amendment shall not be deemed to authorize the sale of such land or buildings at less than the cost thereof."

Two Legislative Acts have been passed upon recommendation of the Homestead Commission under the provisions of the Homestead Constitutional Amendment of 1915. One Act (Chapter 185, General Acts of 1916) permits cities to maintain schools of agriculture and horticulture. This was passed as an educational measure, as the Homestead Commission thought that:

"Great waste would result, and possibly danger to the homestead movement, if many persons, inexperienced in the care and management of the soil, were put in possession of 'small houses and plots of ground', as contemplated in the Act under which the Homestead Commission was created."

The other Act (Chapter 310 of the Acts of 1917) authorized the Homestead Commission to provide homesteads for citizens, and carried a small appropriation of $50 000 for inaugurating the work. A site of about 7 acres was purchased by the Commonwealth in the City of Lowell and a number of houses were built at moderate cost. These workingmen's homes are being sold on a long-term basis at prices ranging from $2 400 to $3 100 each. This marks the entry of the State of Massachusetts into the business of housing. Although the housing experiment at Lowell is working out satisfactorily and the State will, in due time, recover its investment, there has as yet been no disposition on the part of the State to embark upon another housing development.

As in the case of the reclamation by the State of tidal flats, noted previously, it is a question whether the "Homestead Amendment" falls under excess condemnation as strictly interpreted.

Excess Condemnation Applied to the Taking of Easements in Property

In 1893, the Legislature passed an Act (Chapter 462) granting to cities and towns authority to establish building lines parallel to, and not more than 25 ft. from, a highway or street and to prohibit the erection of buildings within such restricted area. The right was given owners to recover damages in the same manner as in the taking of land for a highway.

Supplementing this legislation of 1893, an Act was passed in 1896 (Chapter 313) granting further power to cities and towns to limit the heights of buildings on parkways and boulevards, the Act reserving to owners the right to recover damages by reason of such restrictions.

Following the precedent thus set by this general legislation, the Legislature in 1898 passed a Special Act (Chapter 452) limiting the height of buildings on or near Copley Square in Boston, this Act also reserving to owners the right to recover damages by reason of the restrictions imposed. The Special Act of 1898 was contested and its constitutionality upheld by a decision of the Supreme Court in 1899 (Attorney General *vs.* Williams, 174 Mass. 476).

The Court held the Act to be constitutional because:

"The statute gives rights in the nature of an easement over lands facing Copley Square, which easement is annexed to the Square for the benefit of the public, for whose use and enjoyment Copley Square was laid out; and * * * these rights are similar in their nature to rights in highways, in great ponds, and in the navigable waters of the Commonwealth. * * * In all respects the statute is in accordance with the laws regulating the taking of property by right of eminent domain, if the Legislature properly could determine that the preservation or improvement of the park in this particular was for a public use."

In regard to limitation of buildings around Copley Square as relating to public use, the Court was of the opinion that:

"If the Legislature, for the benefit of the public, was seeking to promote the beauty and attractiveness of a public park in the capital of the Commonwealth, and to prevent unreasonable encroachments upon the light and air which it had previously received, we cannot say that the law-making power might not determine that this was a matter of such public interest as to call for an expenditure of public money, and to justify the taking of private property. * * * It hardly would be contended that the same reasons which justify the taking of land for a public park do not also justify the expenditure of money to make the park attractive and educational to those whose tastes are being formed and whose love of beauty is being cultivated."

Conclusion

Massachusetts, in 1904, was the first State to apply the principle of excess condemnation to the taking of lot remnants in connection with street improvements. Massachusetts, in 1911, was the first to provide through amendment to its Constitution, authority for the broader exercise of excess condemnation in connection with street improvements so as to secure "suitable building lots on both sides of such highway or street." In Massachusetts, the principle has been established that parkways and boulevards may be protected by the taking of easements in abutting property, restricting the construction of buildings thereon. Thus, Massachusetts has laid the foundation for the protection and the adequate development of street improvements through the reasonable, although limited, exercise of excess condemnation. Except for the taking of easements and the condemnation of fee in lot remnants, these powers have not yet been utilized, however, and no project for street improvements involving the broad application of excess condemnation has been put into execution in Massachusetts.

In two other directions, which strictly speaking may not be interpreted as excess condemnation, but which are close to the border line, Massachusetts has carried out public improvements by State agency. These are the reclamation and development of tidal flats, work which has been going on for seventy-five years; and the provision of homes for its citizens, made possible by constitutional amendment, and for which thus far one small project has been built.

DISCUSSION

HORACE H. SEARS,* M. AM. SOC. C. E.—The speaker proposes to bring to the attention of engineers certain facts which relate to matters of design and construction where excess condemnation forms a part of eminent domain proceedings discussing the several matters under various headings, as follows:

Municipal Use of Power of Excess Condemnation.
Public Utility Use of Excess Condemnation.
Excess Condemnation Compared with Zoning Laws and with Police Power.
Financial Considerations: (*a*) Special Assessment; and (*b*) Issuing Securities.

The municipal engineer should have a clear understanding of these topics as his work of preparing the preliminary plans is one of the first matters of procedure. Given a valid law under which to proceed, the engineer plans his improvement district; he describes it definitely by metes and bounds, and thus takes the initial step. The laying out of a proposed street on an official map has been held not to be a taking to divest or impair the owner of the title. (See McQuillin Mun. Corp., Em. Dom. Sec. 1471; citing N. Y. C. R. Co. *v.* State, 55 N. Y. S. 685; 37 App. D. 42; affmd. 165 N. Y. 658; and 59 N. E. 1130; also, similar holding in *re* Phila. Pkway, 250 Pa. 257; but see case of Daley *v.* St. Paul, 7 Minn. 390, as limiting the act of filing plans, etc.)

The municipal engineer in co-operation with the City Attorney, should prepare the plans and the description characterizing the construction work proposed. The "public use" which forms the basis for eminent domain proceedings must be shown by engineering description in specifications and plans as a necessary part of proposed excess condemnation proceedings. The importance of excess condemnation is an engineering factor which the lawyer and legislator need to have defined and described for their use by civil engineers.

The proper legal status or the position of the law (valid law) cannot be insisted upon too much. That must come first. As frequently the engineering fees are to be paid from funds obtained from the ultimate financing of this project, the engineer should be certain that there is a valid law and not merely a favorable opinion of counsel. If the engineer can evolve his designs with the assistance of additional land secured by excess condemnation, it may make a material saving in cost over restricting his design to the rigid lines permitted under eminent domain powers. The engineer should make sure that there is a valid law before risking his recompense or reputation. If the attorney's procedure goes wrong, he should have known better; but any mistake will rise up to plague the engineer who has been identified with invalid municipal proceedings.

MUNICIPAL USE OF POWER OF EXCESS CONDEMNATION

This filing of plans (under a valid law) with a proper description (metes and bounds) for purposes of publication, will be incorporated by the City Attorney

* Cons. Engr. and Attorney-at-Law, New York, N. Y.

in the first legal procedure as a Notice of Intention. The engineer should follow this step and check up his part of this very important preliminary as to plans and description. The plans in general will be concerned with a taking of private property under eminent domain proceedings, with which excess condemnation is an integral part. For reasons set forth in the Symposium, it is highly desirable that the engineer should have the most economical area for his design, as he most certainly will be limited to the minimum expenditure for construction purposes.

This matter of economy of design and lowest cost of construction is so related to "public use and necessity" as to give an added argument for the use of excess condemnation. Where a design for construction can show material savings by the use of excess condemnation it may well be argued before the Court that boundaries limiting the area needed for construction are to be determined by "cost" and not by the minimum limits within which skillfully designed construction may be completed; but this is a fair question for the Court to decide and more properly belongs to a discussion of the legal phases of excess condemnation.*

Excess condemnation has received special attention from legislative action as to streets and parks. It should be noted that special legislative action is limited and does not give powers outside or apart from itself. There is also the need for engineers to consider whether the State Constitution permits this legislative action of a special kind. Many legislative enactments have been held invalid when tested by Court decisions. Frequently, a so-called "friendly suit" is brought to test a particular situation where untested laws are the basis for special assessment procedure.

The need of excess condemnation in connection with city planning applies to the entire schedule of public improvements wherever the power of eminent domain is exercised. Streets and parks usually receive attention, but water, gas, sewer, and service mains also require consideration when the matter of economy in engineering design calls for additional land adjacent to the minimum area which present methods under eminent domain allow the engineer to use.

Decisions on municipal uses of the power of excess condemnation are very limited. These decisions have been summarized,† as follows:

Unfavorable Decisions.—

(*A*) The "public use" for which private property may be taken by eminent domain means "use by the public", which is invalid when the city plans to dispose of the excess property later. (Penn. Mut. L. I. Co. *vs.* Phila., 242, Penn. State, 47.)

(*B*) Without relying on the "use-by-the-public" rule, the promotion of commercial and industrial development (that is, the creation of business thoroughfares) is not a purpose which is "public use" in the sense of justifying the condemnation of land or the use of taxation. (Opin. Just., 204, Mass., 607; 209 Mass., 616.)

* See "Financial Considerations," p. 1866.

† "Excess Condemnation," Robert Eugene Cushman, 1917, pp. 305–306.

(*C*) The actual result of excess condemnation, whatever may be the motive back of its use, is the taking of the property of one man by eminent domain and transferring it to another. This is violative of the spirit if not of the letter of the Constitution, etc. (The Matter of Albany St. 11 Wend., 148; Dunn *vs.* City Council of Charleston, Harper's Law Rept. (S. C.), 189.)

Judicial Approval of Excess Condemnation.—

(*D*) A taking by excess condemnation involves the taking of private property by eminent domain proceedings for educational and esthetic purposes constituting a "public use". (Penn. Mut. L. I. Co. *vs.* Phila., 22 Penn. Dist. Repts. 195.)

(*E*) The condemnation of remnants of land is an exercise of the right of eminent domain for a use necessary and incidental to a public purpose. (Opin. Just., 204 Mass., 616.)

To the engineer engaged in the preparation of plans for municipal improvements, the foregoing may seem confusing and very unsatisfactory; but these legal distinctions must be understood as controlling in the States where they were rendered. Mr. Williams* states the most reliable rule as to the valid features by which engineers may work, as follows:

"Whatever doubt there may have been with regard to the validity of the statutes of excess condemnation, under the State Constitutions as interpreted by the State Courts, there can be no doubt with regard to the validity of the constitutional amendments, which can be challenged only on the ground that they are contrary to the Constitution of the United States as construed by the Supreme Court."

The need and scope of the municipal use of excess condemnation may therefore be as extensive as that of exercising the power of eminent domain, as will be developed under "Public Utility Use of Excess Condemnation".

Public Utility Use of Excess Condemnation

This phase of city planning is entitled to similar considerations of a valid law as a basis for procedure as already discussed.

A separate consideration is needed for those cases in which the city acts as a corporation to furnish water, gas, or electric service—and sometimes transportation—to the public as an incident of its charter rights. The bona-fide public service corporation is the other basis for special consideration in exercising the sovereign right of eminent domain and its attendant powers of excess condemnation.

Relative to special legislative enactment, take the Rochester, N. Y., case cited by Mr. Vedder (page 796):

"*Sec. 2.—Corporate Powers.*—The city has power * * * to take more land and property than is needed for actual construction in the laying out, widening, extending or relocating parks, public places, highways or streets, provided, however, that the additional land and property so taken shall be no more than sufficient to form suitable building sites abutting on such park, public place or street; * * *."

Assume that the engineer has under consideration the design for a trunk-line sewer, requiring the exercise of the power of eminent domain and the

* See, p. 794; see, also, Williams, "The Law of City Planning and Zoning," Chapter III.

use of a street which must be widened in connection with this improvement. Can this special statute amendment of the Rochester City Charter of 1921, made in accordance with revised constitutional provisions to authorize "excess condemnation", be considered as a valid law for this sewer construction? Will this statute relating to city powers be strictly construed, or can several additional matters be saddled on a proposed street improvement, the said street improvement being clearly within the statutory powers?

It is not proposed to discuss here the legality of the legislative enactment mentioned. A word of caution may be in order, as all legislative enactments, until approved by subsequent Court decisions, are of doubtful value; hence, the so-called friendly suit, which most quickly determines specific points of legality with respect to a particular construction procedure.

The point under discussion is that of saddling an otherwise perfectly valid street proceeding with additional construction work. If excess condemnation is valid for necessary street widening, it would seem to follow that the engineer may introduce at the same time other construction as water, gas, electric, and even a street railway, the total cost of all this construction to be carried by the same bond issue that is the source of funds. This shows the imperative need for excess condemnation accompanying eminent domain proceedings and for a constitutional provision in every State, which will permit (and thus leave unquestioned) the validity of engineering designs based on the properly safeguarded use of excess condemnation.

Public utilities are entitled to utilize the powers of eminent domain. The attendant use of excess condemnation is of practical importance to the engineer when designing construction within city limits as well as outside them. Once the door to the validity of excess condemnation for specific use of streets and parks is opened through constitutional amendment, the same treatment must logically follow with respect to public utilities. The use of excess condemnation can be based on the cost of construction as well as on the area. The area necessary for "public use" has been the basis for eminent domain proceedings. The cost of construction is of the essence of "public use", and is frequently a greater deciding factor than area when public improvements are considered. Excess condemnation is a logical development of the use of eminent domain. It is an agency incidental to the proper "public use" of eminent domain. Why should not the principle of "agency" as recognized by the Courts be considered here. That what one may do himself, he may do through the agency of another? Apply this principle to eminent domain and there results "what the State authorizes as permissible under eminent domain, may be exercised by excess condemnation proceedings." There is constitutional authority for eminent domain—the time has arrived to secure constitutional authority for this very necessary agency of eminent domain—the power of excess condemnation.

Excess Condemnation Compared with Zoning Laws and with Police Power

The topics of zoning and police power may be properly considered together as of interest to the engineer in his program of municipal improvements wherein excess condemnation has its part. Zoning laws should be understood

as forming a special feature of the police powers which the State delegates by implication and by express authority. The city charter derives its express authority from the State; but this express authority carries with it certain implied (unwritten) powers which are reasonably incidental to those powers specifically set forth. One of the most important of these powers is that which restricts absolute free personal action so that the liberty of all may be assured. This assurance of liberty in a shape that will result in the greatest good to the greatest number is a form of police power and is concerned with public safety as much as the matter of morals and health is incidental to public safety.

Zoning laws have recently come into use and have been upheld as a valid exercise of the police power. Claims have been made that the power of eminent domain was being exercised and that compensation was due an owner where damages resulted. An example of a police law of special legislative design affecting New York, N. Y., is the so-called "Rent Laws" which have undoubtedly, in some cases, arbitrarily impaired contracts made between landlords and tenants. Even this extreme and valid exercise of the police power is of interest to engineers. However, it is the zoning law that the engineer should study. The application of the principles of zoning by the engineer when the plans for sub-division of territory are in their formative stage, offers great possibilities, which are independent of the use of excess condemnation powers.*

The selection of zoning laws in developing new areas gives partial assurance that in the future excess condemnation will not be as necessary as formerly. The engineer should clearly understand the fundamentals which distinguish zoning from excess condemnation; and also the relation which each of the following terms bears to the other, namely, excess condemnation, eminent domain, zoning, and police power. This is of importance to the municipal engineer as his preliminary designs are intimately concerned with one or all. The legal viewpoint on these subjects is quite different from the practical application which the engineer must make of them.

The building laws are typical of special police power ordinances passed by a city, within its charter powers. The restricting of areas for special purposes so as to safeguard and promote the public health have generally been held valid, but many instances have occurred where zoning laws have been held invalid. The engineer, therefore, is interested in knowing whether the procedure under which he works is a law for zoning or for excess condemnation.†

The use of zoning laws under the police powers should be clearly understood as to their legal and practical distinction. The powers of excess condemnation are more closely related to the powers of eminent domain. Each of these last two powers is found where there is a condemnation without the owner's consent (a taking of realty and the incidents connected therewith) and a payment to the owner for his property thus taken by virtue of the sovereign right to take for "public use".

* "The Law of Zoning", by H. S. Swan, and "Zoning", by Edward M. Bassett, National Municipal League, New York.

† "Zoning and the Courts in Texas," *National Municipal Review*, June, 1924.

Financial Considerations

Remnants of realty and gore strips of unusable area form a costly part of the use of excess condemnation. Mr. Vedder gives a condensed statement of the condemnation of excess area and the sale of part. This feature has been discussed in certain cases already cited. (See 11 Wend. N. Y. 148; Harper's Law. Rep. (S. C.) 189; 204 Mass. 607; 242 Penn. St. 47.) The available decisions on excess condemnation treat this practice as unconstitutional in the absence of express constitutional amendment making such use valid.

Cases where the right of exercising the power of eminent domain requires a right of way as an easement over the land of another and the boundaries are clearly defined, illustrate the application of the principle of "minimum area for a public use" and clearly of "reasonable necessity". It came within the province of the civil engineer to determine and describe the area for a highway —its length and breadth—and to file an accepted plan. When embankments became necessary and the foot of the slope (or top of the cut) made an increased width necessary—as compared with the width of actual traveled way—this constituted in reality the first departure from the "eminent domain" area actually needed for the traveled portion of the highway. The excess spread for the slope was excess area if it be conceded that a vertical wall retaining the traveled width of the roadway could have been erected.

As a matter of practice many engineers have sanctioned the additional expense of building a retaining wall to avoid condemning a remnant or gore piece of land because the owner would secure damages for his injury out of all proportion to the proposed use. Eminent domain proceedings would have been allowed but their excessive cost justified the engineer in neglecting the minimum construction cost in favor of keeping off additional land. It is submitted that, the principle of eminent domain being admittedly the seizure without consent and payment therefor to the owner, the same principle should obtain in the taking of excess land without consent and payment therefor, the use of the excess land being based on financial considerations within the scope of the engineer to determine; and dependent for its supporting facts on the engineer submitting to the same tribunal that passes on eminent domain proceedings the cost data and valuations which form the basis for the valid eminent domain procedure.

This "financial" element of the cost data is the criterion and not the area. "What does the public pay?" is as pertinent to decide as, "What does the public acquire in land area?" The public is burdened for years with a bonded debt, long after a suitable use is made of the excess area. Let the engineer approach this need of excess condemnation as he would the plans for an earth fill for a highway; let him file his preliminary plans for eminent domain based on the "cost" of the proposed project, and make the condemned area include all that is reasonably incidental to a "public use" and to the lowest total cost to the taxpayer. The engineer's estimate will include, of necessity, future transactions in land, but it also includes costs of future construction and the purchase of materials. Land is merely an additional element to the customary items of labor and materials. The cost of land, labor, and materials should be

recognized by the Court as equally applicable in determining the reasonably necessary cost to the public. This is submitted to engineers, because they constitute the proper source of initiating proceedings. They will have to work in harmony with the City Counsel.

Changed conditions demand changed methods. A change in the law has been refused, therefore it is necessary to change the method of applying valid laws. This matter of applying new methods will not meet with favorable reception in the older cities, especially where decisions have been handed down which have rejected the method of reducing costs by selling "remnants" of land resulting from excess condemnation proceedings. There is a possibility of using "cost to the public" in those jurisdictions where constitutional amendments have allowed excess condemnation proceedings.

Given a constitutional amendment allowing the use of excess condemnation proceedings, the next step is to limit its application. By showing on the procedure plans filed for publication the total area affected by eminent domain plus an excess area which is "reasonably necessary", a rational claim would be placed before the tribunal which will consider the objections of owners and citizens.

Financial considerations also enter into the use of excess condemnation by way of paying the cost, initial and final, of any given municipal improvement. The engineer is interested in this feature of the "source of funds", be it the general city fund, the special fund created by ordinance, or the special assessment tax on the property benefited. This opens a field for discussion which is here arbitrarily confined to (*a*) special assessment financing and (*b*) issuing securities.

Engineers who are not acquainted with methods of financing the projects on which they somewhat blindly follow political activities may well be careful. The reputation of an engineer is in part related to the success or failure of the projects on which he works. Failure of a splendid engineering project may frequently be laid to the fact that it was not financed properly or to invalid proceedings—that is, invalid from the start and not detected until some months after the project is in full swing. Special assessment proceedings are not difficult—merely routine—but frequently mistakes are made by ignorant public officials. The engineer should verify these proceedings as his initial fees and his ultimate recompense are often dependent on their validity. Given a valid law under which to use the power of excess condemnation, the construction work will frequently follow procedure known as "special assessment".

Special Assessment.—The details of special assessment procedure do not come within the scope of this discussion, except as it is based on excess condemnation, which calls for financing by a district specially benefited. The Southern and Western States are more inclined to handle special assessment district procedure than the Eastern cities. Whenever possible, the engineer should have the general credit of the city as an underlying promise on all special assessment financing. When securities are issued which are merely a lien on the abutting property of a special assessment district, a greater price must be paid for the use of money, as these securities are considered of inferior

quality compared with those that have the general credit of a city supporting them. (See Fla. Laws, 1923, Chapter 9298 (Special Assessment Bonds as General Obligations of the Municipalities).)

Issuing Securities.—The engineer should have a good understanding of the auditing and financing of the projects which he initiates. Given the organized engineer office of to-day, with subordinates capable of handling routine engineering matters, the chief engineer should study the related legal and financial questions which may make or break his project.

The securities that must be issued to pay for the excess condemnation procedure give one cause for thought. Shall the entire cost of the project—direct costs, eminent domain cost, and excess condemnation costs—be treated separately? If the entire budget can be handled as one item it will certainly simplify matters. Then comes the very usual and vital question—does an invalid excess condemnation item, which has been grouped with valid items, invalidate the entire procedure? This is a point worth considering. The answer depends on the project and all the surrounding circumstances.

The total amount involved is some indication of the cost of handling excess condemnation. Anticipated profits from realty transactions are not always realized; no more than where a private operator in real estate is concerned. If the municipal operations in the sale of remnants from excess condemnation proceedings fare no better than the average results from municipal operation of public utilities, there will be little for the profit side of the ledger. Municipal activities had best be restricted to acting as an agency of the State. At the same time, the new, rapidly growing communities of the South and West have a legitimate use for municipal ownership of public utilities, because no one else will help activities that have still to demonstrate their value. Thus excess condemnation proceedings are most likely to be favorably received in those States where the Courts have not taken a decided stand against their validity. The full faith and obligation of the city should be pledged to support the securities issued to finance excess condemnation. The engineer should see that this is done in every case. The type of security, whether notes or bonds, will depend on so many factors that only the character of the lien supporting the loan can be mentioned. The very highest kind of financial obligation should be given by the city to support excess condemnation financing.

To the engineer is given an opportunity to study excess condemnation procedure as affecting his designs and as the proper auxiliary of eminent domain proceedings. The consideration of the legal, engineering, and financial elements only serves to emphasize the importance of this subject and to indicate the large amount of educational work which must be done before all the States will grant proper constitutional amendments placing excess condemnation on a par with eminent domain proceedings. The economic use of remnant land for the furtherance of the public welfare provides an opportunity for the engineer to assist in the education of the public concerning the powers of excess condemnation as a saving in cost to them on numerous improvements.

FRANK O. WHITNEY,* M. AM. SOC. C. E.—The subject of excess condemnation has been very carefully studied by the Street Laying Out Department of the City of Boston. Before it was enacted, the Massachusetts law was expected to open a way to secure much benefit esthetically, and, in some cases, to become a source of much profit. Since the enactment of the law making it possible to take excess quantities, its application on a large scale has been considered in numerous cases of proposed thoroughfares.

Generally, it has been deemed to be impracticable on account of the great value of the properties concerned, of their present complete development, and of the necessity of placing high values on the property to be sold after the condemnation. In only one instance has the Legislature been asked to give its approval to the use of the law, namely, the laying out of Stuart Street in the Back Bay. Although the Legislature complied, the street was laid out and constructed under the general statutes, as the City Council failed to accept the Special Act.

This is one instance where excess condemnation might have proved beneficial, as the street (about a mile in length) was laid out over run-down or stagnant property the value of which before the improvement had been assessed at from $3 to $12 per sq. ft., and was either vacant land or occupied by ancient and cheap buildings. The improvement has resulted in a greatly increased value to abutting property, as evidenced by recent sales averaging from $20 to $25 per sq. ft. As the City of Boston is allowed to assess betterments wherever sustained up to the cost of the improvement, the seeming loss of opportunity in this case was not as great as it would at first seem, the cost ($3 100 000) being offset by a betterment assessment of $2 700 000.

Several propositions for an adequate thoroughfare connecting the North and South Stations have been suggested and estimated; as yet these propositions have not materialized. Excess condemnation has been considered in these estimates, but in each case on account of the high value of the properties involved, it has not been used, as the remaining land would have had to be sold for three times its present value to provide a profit equal to the cost.

In the case of a large improvement a considerable amount of property would be temporarily untaxable. The carrying of this real estate would require large capital with heavy interest, and also involve the city in an immense real estate business.

The Massachusetts law necessitating a special act of the Legislature in each case of the application is very inconvenient, as comparatively few cases arise when the Legislature is in session. The general assessment laws provide ample means for such compensation as is necessary in most instances.

Excess condemnation may be of great benefit in special cases, but should not be expected to provide a universal remedy for all the ills involved in laying out streets. If the City of Boston could have a law that would allow the taking of small remainders at will, much good would ensue, as abutters could then be protected from the avarice of small owners, and unsightly indentations would be avoided.

* Cons. Engr., Boston, Mass.

ANDREW WRIGHT CRAWFORD,* ESQ.—The principle of remnant condemnation, which is restricted excess condemnation, was applied in the case of Fairmount Park in Philadelphia, Pa., about 1870 and proved very valuable.

In the case of the King's Highway, in London, where a street 100 ft. wide was extended through a closely built-up area, the cost of the entire outlay for the right of way and for the abutting property was about $30 000 000. None of the abutting property was resold; it was leased on 100-year improvement leases. Capitalized on the basis of 4%, the entire cost has been recouped, according to the latest information.

It is necessary to "think through" in such matters, in the case of this London example to the end of 100 years, when the municipal corporation will own the enormously valuable property on both sides.

One of the greatest advantages of excess condemnation is that in the re-sale of the excess property, or in the leases of such excess property, on a 100-year improvement lease, it may be provided that whatever buildings are erected must be approved as to design by the Municipal Art Commission. In the long run that will be a very powerful factor in beautifying the city, especially on the wider and longer streets.

Excess condemnation ought frequently to be used in the case of remnants fronting on streets. Mr. Leavitt instanced a small strip, 3 to 20 ft. in width, running along the street for some distance. The trouble there was in the lack of education of the engineer. There is no reason why any street intended to be about 100 ft. wide, should be exactly 99 ft. 12 in. wide all the way through. For a block, it might be 97 ft., or 103 ft., or even 110 ft. It is well enough to have straight streets, but as to their boundaries, that is absurd. In the case of small remnants that are parallel or slanting at a slight angle to the street, the real trouble is with the inflexibility of the particular engineer who was not sensible enough to vary his street somewhat from block to block, or within the block.

HAROLD M. LEWIS,† M. AM. SOC. C. E. (by letter).—The advantages of excess condemnation have been very well summarized by Mr. Leavitt. It may seem strange that a policy which has so many arguments in its favor and is generally admitted by students of city planning to be equitable and advantageous should meet with so much local opposition when attempts are made to utilize it. A brief summary and analysis of the reasons for such opposition may be of interest. The principal ones can be stated as follows:

1.—The term, "excess condemnation", which is an unfortunate one tending to arouse immediate opposition.
2.—Objection to any change in old and well-tried methods.
3.—An increased first cost of improvements.
4.—Reluctance of local property owners to relinquish the opportunity of making large speculative profits from holdings immediately adjacent to the improvement.

There are probably no two words the use of which is more apt to have the effect of waving a red flag in the face of public opinion than "excess" and "con-

* Philadelphia, Pa.
† Executive Engr., Regional Plan of New York and Its Environs, New York, N. Y.

demnation". The former implies that more property is to be taken than is necessary and the latter implies a confiscation of private rights. The term, "Remnant Act", used in Massachusetts, was much less inclined to arouse opposition, but the acquiring of remnants did not go far enough to bring about the best results. The writer does not attempt to suggest a better term, but if one could be found which would refer only to the taking of remnants and a re-subdivision of abutting property, it would certainly be advantageous. Provisions for purchase or condemnation of adjacent parcels necessary to make an effective re-subdivision of land fronting on the new street or park improvement properly belong in the text rather than in the title of the legislation.

Any change in customary methods will always meet with opposition but this can be overcome through courageous perseverance by progressive citizens, if they are properly enlightened by the professional men studying the problems.

A method of decreasing the first cost of bonding the excess lands acquired and exempting such bonds from the debt limit has been suggested by Mr. Leavitt. There is no doubt that such bonds would prove safe investments, as in many cases the re-sale of the land outside the limits of the improvement should provide a substantial profit. By this means a fund might be created which could be utilized to assist in financing other similar improvements needed in the city.

Some street-widening improvements result mostly in local benefit but any large scale improvement is greatly to the advantage of the whole city and raises land values several blocks distant from the actual improvement. If the project is the cutting through of a new and important traffic or transportation thoroughfare its influence may be felt to still greater distances. It is obvious, therefore, that many property owners and the city at large could profit by improvements which may be held up by the selfish ambitions of those few whose property might be taken, although they would receive a fair value in return. The majority should rule.

M. W. Weir,* M. Am. Soc. C. E. (by letter).—In excess condemnation the element of speculation looms large with the profit going to the deserving, that is, to the community in which an improvement requiring condemnation takes place. No doubt some will think that such a proceeding comes dangerously near to the acceptance of some of the political theories of several decades ago when the single tax was being discussed.

Others will look upon excess condemnation as a public usurpation of individual rights and the public ownership question will again be brought up for discussion, because public ownership of utilities will be confused with the temporary public ownership of property corollary to a public utility, such as a street. There is no ground tenable for questioning the policy of subjugating the rights of the individual, no matter what they are, to the public necessity, benefit, and welfare.

Whether or not a discarded political theory is revived is less a question than whether there is value in the project. Applying excess condemnation has a double object, namely, to eliminate an improbable individual speculation

* Cons. Engr., New York, N. Y.

and to conserve to the community that accretion of values which the community as a whole creates when a public improvement is completed.

There never has been displayed an organization of individuals as parcel property owners in a community, with sufficient public spirit or sufficient trust in the worthiness of each other to carry on property improvements involving the re-plotting of a number of small holdings to fit the new lines created by the necessary public improvement affecting those properties abutting and adjacent. Few individuals have the financial resources necessary to carry out such a program nor the courage to attempt it. Yet such a public improvement will have only partly succeeded if it leaves ragged outlines and uneconomical building units in its wake, as in the cases of Lafayette Street and the Seventh Avenue Extension, New York City, cited by Mr. Leavitt and the Flatbush Avenue Extension in Brooklyn.

In these three cases, certain communities or districts of the city have been the sufferers to the advantage of other districts lying to the north and to the south; all are glaring examples of the economic loss to the city at large in its failure to clean up the path and save to itself the increment of valuations of its own creation, now lying waste and impossible of individual development through many years.

It would even seem reasonable that adjoining owners had good grounds on which to sue for contingent damages because they could not share in the accretion of value which should be theirs and for which they had paid a share in the taxes and assessments.

Sins of commission are seized upon with avidity by political parties for campaign material; the misappropriation of petty hundreds of dollars receives glaring double headers in the newspapers and the story continues with gloating and glee, but the obscure sin of omission involving lost millions in assessed valuations, in such instances as Lafayette Street and the Seventh Avenue Extension, pass by unnoticed by political parties and unheralded by the press.

Some may say that with political corruption a constant evil, how much greater the opportunity for corruption in applying excess condemnation in public improvements. This may be true, but no one stops raising wheat and more wheat because rats in the granaries cause losses. Not long ago there appeared an article written by a manufacturer on the subject of city planning. Among other things it was stated that engineers, as a rule, permit themselves to become the victims of concentration and, therefore, to fall into narrowness of vision, failing to take a broad interest in public affairs.

This is not the first time such an accusation against engineers has been made, nor is it an unwarranted or undeserved statement. It is a regrettable truth that, singly, collectively, or as a professional class, engineers do not take the interest in public affairs that they should. Why is it; is it fear of criticism? Physical dangers galore have been encountered by engineers. It cannot be possible that they lack moral courage. Then let them prove that public questions, such as excess condemnation, have received their attention and let them demand that the public authorities put into practice those theories which engineers have discussed, weighed, and found worthy. In like manner, let them fearlessly condemn such sins of omission wherever they may be found.

Paper No. 1586

THE IMPROVED VENTURI FLUME*

By Ralph L. Parshall,† Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. H. B. Muckleston, E. W. Lane, E. S. Lindley, C. E. Carter, Julian Hinds, E. A. Jacob, J. C. Stevens, Carl Rohwer, and Ralph L. Parshall.

Synopsis

The device herein described is a promising structure for measuring the rate of flow of either small or large quantities of water. It has no moving parts, and is simple and inexpensive. It utilizes the principle of an hydraulic control and sacrifices little head. Tests indicate an accuracy of about 5 per cent.

Requirements to Be Met.—The measurement of flowing water in irrigation practice often requires that little loss of head be sacrificed by the measuring device. Because of the relatively large loss of head, the standard overfall weir is, in many cases, objectionable. Although when operating under standard conditions, it is one of the most accurate of measuring devices for practical field installation, it is not always possible to maintain these standard conditions, such as proper bottom contraction, velocity of approach, and aeration of nappe. The submerged orifice has not met with entire success because of the uncertainty of the coefficient of discharge, velocity of approach,

Note.—The Special Committee on Irrigation Hydraulics selected the subject of "Measuring Irrigation Deliveries" as one of ten for study and research. This paper was submitted to the Committee by its author, and the Committee recommended its publication. (See Progress Report of the Committee, *Proceedings*, Am. Soc. C. E., March, 1925, Society Affairs, p. 137).

and constancy of condition. The ordinary rating flume often becomes inaccurate within a short time.

To meet the objections found in other measuring devices now in common use, the present Improved Venturi Flume has been developed. The improvements over the old Venturi flume consist in the reduction of the convergence in the inlet section, lengthening of the throat section, change of divergence of the outlet section, and depressing the floor in the throat section.* These changes have improved the flow conditions, reduced the effect of submergence, and simplified the operation by reducing the number of gauges necessary to determine the discharge.

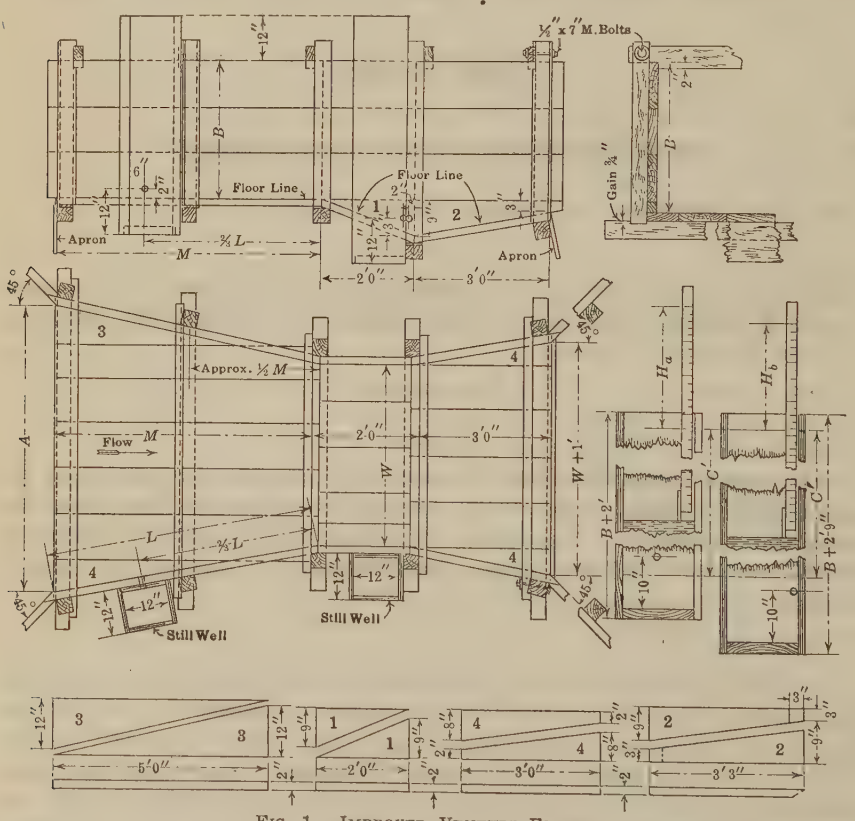

FIG. 1.—IMPROVED VENTURI FLUME.

Type of Structure.—This flume (Fig. 1) has three major parts, a converging inlet, a parallel-sided throat, and a diverging outlet. All the sidewalls are vertical. The inlet has a level floor between the sides, each side converging at a rate of 1 ft. in 5 ft. of length. The floor of the throat slopes downward with a vertical fall of 9 in. in a horizontal distance of 2 ft. The outlet floor slopes upward at the rate of 6 in. in 3 ft., and each wall diverges

* "The Venturi Flume," by V. M. Cone, *Journal of Agricultural Research*, Vol. IX, No. 4, 1917; "The Venturi Flume," by R. L. Parshall and Carl Rohwer, Associate Members, Am. Soc. C. E., *Bulletin 265*, Colorado Agricultural Experiment Station, 1921.

at the rate of 1 ft. in 6 ft. of length. The crest is the down-stream end of the level floor, and the crest length or size of flume is the distance, in feet, between the vertical walls of the throat. The lengths of the throat and the outlet of the flume are 2 and 3 ft., respectively, for flumes of all sizes from 1 ft. to 8 ft. The side of the inlet is made longer as the width of the flume increases, according to the arbitrary rule, $\frac{W}{2} + 4$, in which, W is the width of the flume, or crest length, in feet.

There are two general conditions of flow, namely, "free flow" when the elevation of the water surface at the throat gauge, or H_b, is lower than the crest, and "submerged flow", when the elevation of the water at the throat gauge is higher than the crest. The upper head, H_a, is observed at a point two-thirds the distance from the crest to the upper end of the inlet, along the side-wall, whereas H_b, the throat head, is observed at a point 3 in. vertically and 2 in. horizontally up stream from the lowest point of the depressed throat floor. Both the upper head, H_a, and the throat head, H_b, are referred to the crest level as the datum. Under certain conditions of flow the throat reading may be negative, as shown in Fig. 2.

Laboratory Tests.—Calibrations were made on flumes having crest lengths of 1, 2, 3, 4, 6, and 8 ft., with a minimum flow of 0.3 sec-ft. through the 1-ft. flume, and a maximum of 62.5 sec-ft. through the 6-ft. flume, the supply not being available to exceed this maximum through the 8-ft. flume. The discharge in second-feet through this device, under free-flow conditions, and under submerged conditions when the down-stream head does not exceed 70% of the upper head, is very closely approximated by the empirical formula:

$$Q = 4\ W\ H_a^{1.522\ W^{0.026}}$$

in which,

Q = discharge, in second-feet;
W = width of flume or crest length, in feet; and
H_a = upper head, in feet.

The accuracy of this device under these conditions is believed to be sufficient for practical field purposes. Table 1 shows the distribution of errors resulting from the comparison of the observed discharges with the results computed from the empirical formula. In determining the errors and their signs, the observed values are taken as the basis of comparison. Table 1 is based on the complete free-flow series of tests made on the six sizes of flumes studied, except one test which is believed to be in error* and the submerged flow tests for submergence up to 71% of the upper head. Submergence, as herein mentioned, means that the water surface, as indicated by the throat gauge, or H_b, is positive or above the crest level. For conditions of flow, as shown in Figs. 3 and 4, the degree of submergence, as indicated by the ratio, $H_b : H_a$, is somewhat less than the actual submergence would be if the water surface in the outlet were considered.

*Test No. 6512 on the 3-ft. flume, in which, $H_a = 0.705$ ft.; $H_b = 0.264$ ft.; percentage of submergence = 0; observed quantity = 8.33 sec-ft.; computed quantity = 6.94 sec-ft.; percentage of error = 16.7.

FIG. 4.—EXPERIMENTAL 3-FOOT IMPROVED VENTURI FLUME AT WELLINGTON, COLO.

Table 2 shows the percentage of deviation of the calculated free flow from the observed discharge, where the degree of submergence varies from 69 to 79 per cent. It will be noted in this table that the agreement of calculated and observed values increases with the head, as well as with the width of flume. The increased velocity of the water in the throat section, together with the action of the depressed floor, causes a hydraulic jump to be formed immediately below in the diverging outlet of the flume, as shown in Figs. 3 and 4. This combination of increased velocity and depressed floor has the effect of resisting the submergence to a point of about seven-tenths of the upper head, H_a. It will be observed in Table 2 that for the 1-ft. flume and small flow the velocity is not sufficient to overcome the resistance of the water held in the depressed section, or, in other words, the point of measuring the throat head, H_b, is too far down stream to be within the range of the draw-down of the water surface for these small heads.

For the most satisfactory operation of this device, it is recommended that the flume operate under conditions in which the submergence does not exceed 70 per cent. Under such conditions only one observation of depth is necessary to determine the rate of flow. For submergence greater than 70 to 75%, the discharge is then a function of both the upper head, H_a, and the throat head, H_b. Laboratory tests show that when the submergence is greater than about 98%, no great dependence can be placed on the measurement.

Field Tests.—After completing the calibrations of the various sized flumes, outside field installations were made to test the device under practical conditions. At Wellington, Colo., a small lateral was selected having a flat grade, where the stream of water carried some sand and silt. In Fig. 4 is shown an experimental 3-ft. improved Venturi flume in this lateral, where the upper head, H_a, is 0.86 ft., and the throat head, H_b, 0.63 ft., with a difference of 0.23 ft., the ratio, $H_b : H_a$, being 73 per cent. The discharge under this condition is in accordance with the free-flow law, and the rate of flow can be assumed to be a function only of the upper head, H_a, thus giving a discharge of 9.48 sec-ft. A standard weir will not operate successfully in this lateral, first, because of the deposit which would occur in the weir box; and, second, because of the small head available. This discharge of 9.48 sec-ft. over a 3-ft. rectangular weir would require a head of exactly 1 ft., and to this possibly an extra 0.10 ft. should be added to assure a complete aeration, making a total loss of head of about 1.1 ft. By careful measurements with an engineer's level, the loss of head through the improved Venturi flume, under the conditions as stated, was only 0.19 ft.*

Under conditions where sand and silt occur, it has been observed that if a difference in head of 0.05 to 0.10 ft. can be maintained for a moderate upper head, no deposit will accumulate in the flume even where excessive quantities of sediment are carried in the stream.

Velocity of approach seems to have little or no effect on the rate of discharge for free-flow conditions.

* Note approximately similar conditions of heads for the 3-ft. flume, Table 2.

Pertinent Features.—From the standpoint of measuring irrigation water, the improved Venturi flume has the following desirable features:

1.—It is sufficiently accurate for practical purposes.
2.—It operates in sand or silt-laden streams without trouble.
3.—It operates successfully with relatively small loss of head.
4.—It is able to withstand a high degree of submergence.
5.—It maintains constancy of condition.
6.—It possesses simplicity of operation.
7.—There are no moving parts.

DISCUSSION

H. B. Muckleston,* M. Am. Soc. C. E. (by letter).—The measuring device described in this paper should hardly be called a Venturi flume, at least, as long as only one head is measured and the formula on page 843 is applied. Under these conditions the device is a weir with the bottom contraction suppressed.

The ordinary form of weir can hardly be called a satisfactory instrument for measuring irrigation water. Theoretically, perhaps, a weir is a very accurate device, but the theory implies a great many things which are seldom obtainable under ordinary irrigation conditions. It is not to be expected that any one device will be applicable under all conditions. Much depends on the system of charging for the water. When the charge is for the actual quantity delivered, some kind of integrating mechanism is necessary; and such a mechanism, applicable to any device which really measures the rate of flow, is apt to be very expensive. Under such conditions, a device which actually measures the quantity and delivers it in batches is cheaper. When the charge is for the irrigable area covered, whether or not actually irrigated, time-rate devices are the cheapest and the simplest. The main object, in such conditions, is to satisfy the user that he is getting his share of the supply. Much depends on whether each user must have his individual measuring-box. When water is rotated among a group, group measurement is all that is really necessary. The quantity delivered to the unit then depends on the time of flow.

Considering only time-rate devices, a satisfactory measuring instrument must meet a number of conflicting requirements. It must be cheap, nearly "fool-proof", immune to silt troubles, easily read, and fairly accurate; it should hold its accuracy under considerable abuse, and it should require a minimum of lost head. The weir meets the first and fourth requirements very well, but its virtues stop there. The Venturi flume, as first described by Mr. Cone and afterward by the author, came more nearly to meeting all the conditions than any other with which the writer was acquainted. It is possible that the new device will do even better.

One of the main objections to the weir was the loss of head which it involved. This might be several inches or even a foot or more. One consequence was that the user developed a strong tendency to back up the water and drown the weir. The original Venturi flume was fairly accurate even when deeply submerged, and the use of a plug, as described by Mr. H. K. Smith, extended the accuracy over a wider range. The new device gives promise of sufficient accuracy, and it should be nearly proof against abuse; but it should be noted that, as long as it must work under the condition of free flow, the possibility of the user drowning the flume is present. The indications from a single head measurement will then be inaccurate, possibly greatly inaccurate. The device promises to be a cheap one.

As long as other factors are so indefinite, third decimal accuracy is not required in measuring devices. Under any conditions, 6% should be close enough; less than 3% would be splitting hairs.

The rather formidable looking formula on page 843 is easily plotted as an alignment nomograph, Fig. 5. The lines for Q and H_a are simple loga-

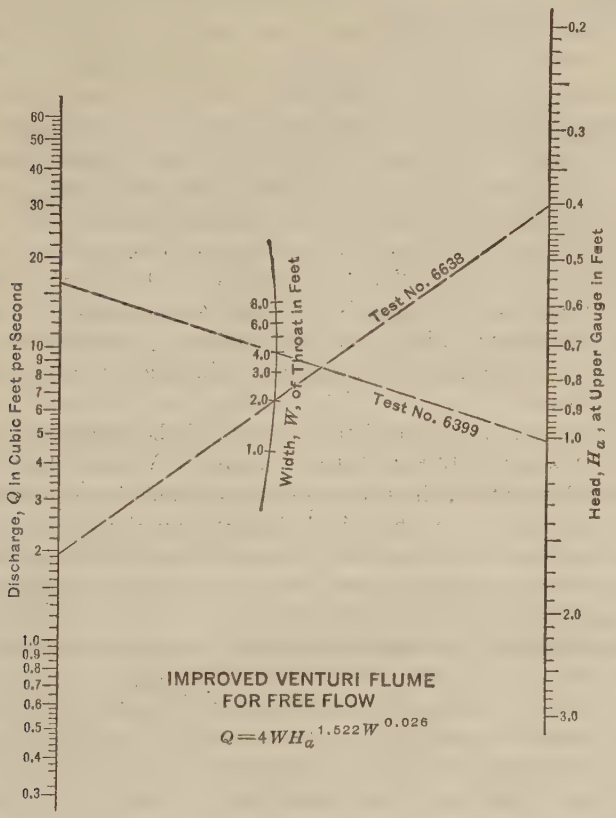

FIG. 5.

rithmic scales to any convenient pattern. The line for W can be established by cross-intersections, using the calculated discharges from Table 2. No calculations are needed.

E. W. LANE,* M. AM. SOC. C. E. (by letter).—In his paper, "Experiments on the Flow of Water Through Contractions in an Open Channel",† the writer pointed out that the experiments for developing the Venturi flume for measurement of irrigation water dealt only with conditions of discharge under which readings of both up-stream and throat gauges were necessary to determine discharges, and that for a large range of conditions the discharge could be determined from readings on the up-stream gauge only, the advantage of which had been overlooked. The flume described by the author seems to be a recognition of this advantage, as the improvement claimed over the Venturi type

* Lafayette, Ind.

† *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1201.

seems to be principally that the discharge over a larger range of conditions can be determined from readings of one gauge.

The writer knows of no experiments to show over what range of conditions the Venturi flume will discharge under what may be called "single gauge conditions", but the indications of his experiments are that for a flume with gradual expansion it is likely to be considerable. Perhaps with the loss of hydraulic efficiency which the adaptation of this device to practical irrigation conditions necessitated, the range over which it would operate under "single gauge conditions" was reduced, and, therefore, the new device is better.

Since small loss of head is one of the advantages claimed for the improved flume, it is to be regretted that the experimental results do not include the total loss of head due to the flume. A value of 0.19 ft., with a discharge of 9.48 sec-ft. through a 3-ft. flume, is the only one mentioned. Run No. 3 of the writer's experiments with a Venturi flume at practically the same discharge per foot of width and operating under "single gauge conditions" showed a loss of 0.12 ft.

To the writer the most interesting feature of the new flume is the principle on which it acts. It is called an "improved Venturi flume", but it is not a Venturi flume at all, since the principle on which it acts over the greater part of its range and from which it derives its superiority over the original type is not the same as in the true Venturi flume or Venturi meter. The new flume is really a trough with a free drop at the end and a device for converting the resulting velocity of the water back into head. This conversion is accomplished by causing the water to flow up an inclined plane, the velocity being expended in actually lifting the mass of water to a higher elevation. There is nothing new about this in principle, but the practical application is rare. The trough part of the flume is not essentially different from a type of measuring device developed just before the Venturi flume in which the water flowed through a trough with a free, or nearly free, fall at the lower end and had a discharge varying practically as the three-halves power of the head. The effect of the converging sides of the trough section seems to be to increase the velocity through the narrow section, thus insuring, over a greater range, velocities higher than the critical value, and, therefore, a flow through the opening independent of back-water conditions. Although the author does not seem to have appreciated that a new principle is involved there is no reason why this flume may not be named for the originator and the name Venturi dropped.

The term, "free flow", as used by the author is confusing if not incorrect. Any condition in which water at the crest of the weir is flowing at a higher than critical velocity is a condition of free flow, since the flow is independent of the tail-water level. This may occur with the water levels indicated by the throat gauge either higher or lower than the crest of the weir. The author seems to recognize this in his title to Fig. 3, "Free-Flow Discharge, 6-Foot Venturi Flume, with Approximately 75 Per Cent. Submergence", which is obviously contradictory according to his definitions of "free flow" and "submerged flow".

E. S. LINDLEY,* M. AM. SOC. C. E. (by letter).—The first mention of this device quoted by the author, and the first in America of which the writer is aware, is the paper by Mr. V. M. Cone, published in 1917.† In the Panjab, use of the device was initiated by the late Messrs. Stoddard and Harvey of the Irrigation Department some time before 1914.

The object with which the device was primarily developed in the Panjab, was control; that is, to secure a constant relation between discharge and water level above the device, with only a small drop of level through it. Calibration and precise knowledge of the discharge passing were of course also important.

The writer wished to extend the use of the device and use it as a Venturi flume, that is, to measure discharge by means of gauge readings at the throat as well as up stream. In correspondence, Clemens Herschel, Past-President, Am. Soc. C. E., recorded the opinion that this was not really practicable; the writer soon came to agree with him. The attempt to develop the Venturi flume was still proceeding in America. To avoid the confusion that arose over applying that name to the "control section" use of the device, the name, "Standing Wave Flume", was originated instead. It would appear that part of the improvement described by Mr. Parshall is to omit the use of the throat gauge except to show when there is a drop of water surface sufficient to avoid damping the maximum discharge.

It is to be remarked that the principles involved are the same whether the "control section" be produced by constricting the width of the channel, or by raising a hump or broad-crested weir on the bed, or by both in combination.

The workers at this form of device are divided into two schools. One school starts with a design of weir or flume that is convenient to build, and that is an effective control, and then calibrates it experimentally. The other school argues that the well-known broad-crest weir formula generally ascribed to Unwin entails a definite physical condition of flow, that any departure from the rates of discharge given by that formula indicates a state of uncertainty of flow, and that the best course is to determine the limits of form that the work must satisfy in order to discharge according to that formula. The former school produces a new formula (as does this paper) for every new shape tested; the latter claims that each such formula is uncertain of correct application outside the range of the tests on which it is based, and that a structure of any size can be built which will discharge correctly.

Unfortunately, those who have done the most work on this device in India have not placed their facts and views on record. The writer has made an attempt to fill the gap in the course of a technical paper;‡ a certain amount of data are also to be found more accessibly in a discussion that he contributed to another paper that bears on the subject.§ He does not propose to repeat the whole matter here, but only to outline the main points, leaving those who are sufficiently interested to read the original.

The limits of shape have been ascertained, which a broad-crest weir must satisfy to discharge according to the broad-crest formula. Data are quoted

* Executive Engr., Indian Public Works Dept., Panjab Irrig. Branch, Care, Messrs. Thos. Cook & Son, London, England.

† *Journal of Agricultural Research*, Vol. IX, No. 4, 1917.

§ "Measurements of Discharge Over a Rock-Faced Dam", *Minutes of Proceedings*, Inst. C. E., Paper No. 4515, 1924.

from structures built for discharges up to 8 000 cu. ft. per sec. and up to 6½-ft. depth on the crest. Subject to a few limitations and conditions that will be obvious to practical hydraulicians, and in no way impair the practical utility of the works, they are probably correct within about 1 per cent. Those not built to effect any recovery of head are independent of fluctuations of down-stream levels as long as the drop does not fall short of one-third of the depth on the crest. Those built to work with less head are thus independent as long as the drop does not fall short of one-sixth of the depth on the crest for small structures, while the fraction may be shown to be even smaller for larger works.

A rational weir formula is also given (due to Mr. E. S. Crump of the Panjab Irrigation Department), which indicates the manner in which many weirs and flumes discharge more than the broad-crest formula.

Such weirs and flumes on a small scale, and orifices similarly made to discharge as if they had free falls, are now being largely used in Indian irrigation to eliminate manual control and secure automatically correct distribution of irrigation supplies. This subject is fully dealt with in another technical paper by the writer,* which also gives a full bibliography of the subject.

In Mr. Parshall's paper, an accuracy of 5% is claimed for the device described. Greater accuracy is not likely to be achieved as long as angles are allowed in the sides and floor. These relatively loose limits also probably cover a certain amount of dependence on the fluctuation of down-stream levels. In the only observation of which the necessary data are reported, the limit for independence occurred with a 0.19-ft. fall for a 0.86-ft. depth on crest, a fraction of two-ninths, or only little better than the Panjab form without attempting to recover the head. The writer considers the position for taking the throat head unsatisfactory; in fact, the essence of objections to a Venturi flume is that throat gauges are unreliable unless the fall is quite small. The reasons for this are fairly obvious even from theory.

The exponent of W in the formula, given on page 843 as 0.026, would appear to be a misprint; judged by a few checks of calculations in Table 2, it would seem that the exponent of H_a in the formula should be nearer 1.6 than 1.52, and that the exponent of W is actually 1.0.

The coefficient, 4.0, in the formula is surprising. Mr. Crump's rational formula, previously alluded to, indicates a maximum possible coefficient of 4.18. In some tests with small weirs intended to give the greatest possible coefficients, the writer was unable to find one greater than 3.9, and that seems to be the largest value given by the late Hamilton Smith, M. Am. Soc. C. E.

A paper of this kind is less convincing than it should be, when no account is given of the means and manner of testing, and only a few of the observed data are included.

C. E. CARTER,† M. AM. SOC. C. E. (by letter).—A means of measuring accurately the flow of water in irrigation canals and other open channels has long been needed and that fact is well appreciated by those who have ever had anything to do with the delivery of certain definite quantities of water to individual consumers.

Mr. Parshall's paper opens the way for making such measurements of flow within a reasonable degree of accuracy, and it is to be hoped that future experiments will extend the scope of those presented to include wider channels, greater depth of flow, and larger rates of discharge.

Believing that the author's formula for discharge,

$$Q = 4\ W\ H_a^{1.522\ W^{0.026}}$$

would be in a more workable form if the function of W could be eliminated from the exponent of H_a, the data presented have been studied with this in view and the formula,

$$Q = 3.90\ W\ H_a^{1.58}$$

has been deduced. The writer believes that this formula gives results that are fully as close to the actual discharges as that of the author for the sizes of flumes and quantities of discharge shown.

Using this formula, Table 2 has been recomputed as shown in Table 3. Only ten items show deviations greater than those by the author's formula, of which only one varies more than 5% from the actual quantity discharged. The remaining thirty-eight items show deviations less than these by the author's formula.

A comparison of the percentages of deviation shows (Table 4) that 75% of the computed quantities, using the writer's formula, are within 2% of the observed quantities and that 96% vary less than 5% from the observed quantities.

TABLE 4.—Comparison of Deviations from Observed Discharges.

Although the 1-ft., 2-ft., and 3-ft. flumes show discharges under heads as low as $H_a = 0.20$ ft., the 4-ft., 6-ft., and 8-ft. flumes do not show discharges for

heads lower than $H_a = 1.0$ ft. In order to compare the two formulas for heads lower than 1.0 ft., controlling computations have been made, giving the results shown in Table 5.

TABLE 5.—COMPARISON OF FORMULAS FOR LOW HEADS ON THE 4-FOOT, 6-FOOT, AND 8-FOOT FLUMES.

Width of flume, in feet.	H_a, in feet.	Computed Discharge, in Cubic Feet per Second.			Percentage of variation, $\left(\frac{\text{Column (5)}}{\text{Column (3)}} 100.\right)$
		Parshall formula.	Carter formula.	Difference.	
(1)	(2)	(3)	(4)	(5)	(6)
4	0.20	1.27	1.24	—0.03	—2.5
	0.60	7.15	6.96	—0.19	—2.6
	1.00	16.00	15.60	—0.40	—2.5
6	0.20	1.84	1.86	0.02	1.1
	0.60	10.63	10.44	—0.17	—1.6
	1.00	24.00	23.40	—0.60	—2.5
8	0.20	2.41	2.48	—0.07	2.9
	0.60	14.09	13.92	—0.17	—1.2
	1.00	32.00	31.20	—0.80	—2.5

A study based on the complete record of experiments for all the flumes might show that a slight change in the constant or exponent could be used to advantage, but, from the foregoing, the writer would expect that the formula,

$$Q = 3.90\ W\ H_a^{1.58}$$

would give results well within 5% of actual discharges for all sizes of flumes and heads within the scope of the experiments.

JULIAN HINDS,* M. AM. SOC. C. E. (by letter).—This paper is an important contribution to engineering knowledge on the subject of water measurement. The open Venturi flume has come to be recognized as a valuable device because of its freedom from interference by silt accumulations and because of the small head required for its operation.

As originally contemplated, the Venturi flume requires the reading of two gauges, as in the case of the closed Venturi tube. Because of the variable areas of the water prism at points of measurement, diagrams and tables for the original device are more complicated than for the closed Venturi meter. It is now proposed to eliminate one of the gauges and to simplify the utilization of the device, putting it on an equality with the sharp-crested weir so far as reading the discharge is concerned, without seriously interfering with the advantages of the original type.

The writer is in full accord with the proposal to develop a one-gauge Venturi flume, and is of the opinion that the type of structure tested by the author can be satisfactorily developed.

However, it is believed that the proposed details can be improved. The discharge formula presented by the author is entirely empirical, and is applicable only to structures of the precise form tested. By slightly altering the structural details it is believed that the device can be made to operate in accordance with a rational theory. The writer considers this desirable, al-

* Engr., U. S. Bureau of Reclamation, Denver, Colo.

though the resulting formula may be as difficult to use as the empirical formula. The proposed flume takes partial advantage of the controlling effect of a point of critical depth in open-channel flow. By taking full advantage of this effect the flow formula can be rationalized.

If a flow of water is required to pass through the flume shown in Fig. 6, the floor of the flume being level from *A* to *D* and moderately steep down stream from *E*, then, at some point between *D* and *E*, flow will take place under a minimum energy head and the depth will be critical. The critical depth will occur at the point where the slope of the bottom of the channel is just sufficient to overcome friction due to flow at critical depth, which point is called the "control point." The corresponding cross-section of the canal may be called the "control section."

The theory of the critical depth and the point of control has been thoroughly discussed in recent years before the Society and in technical publications, and need not be referred to here further than to call attention to the fact that it assumes normal hydrostatic pressure throughout the depth of the stream. At points of irregularity, such as sharp corners in the floor or sides of the channel, or at the outfall end of a flume discharging freely into the air, the hydrostatic pressure in the stream departs from normal, and the energy equation is correspondingly disturbed. Usually the critical depth is not situated exactly at such points, although it is often assumed to be.

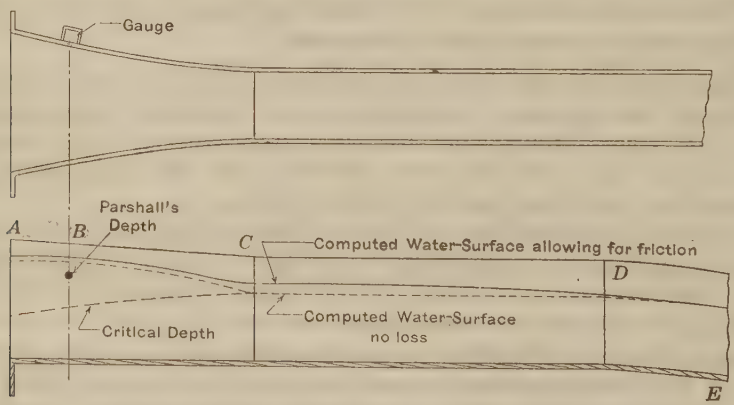

FIG. 6.—ELONGATED CONTROL-SECTION METER. CURVED INTERSECTIONS.

If irregularities of this kind are avoided, a point of control always exists where an open channel changes, within certain limits, from a comparatively flat slope to a comparatively steep slope. At the point of control many of the uncertain factors normally affecting flow, such as unknown friction coefficients, velocity of approach, etc., are eliminated, and the depth bears a definite relation to the discharge. Thus, by introducing into a canal a proper change in grade, a point of definite stage for any given flow is established. It is not necessary that the steep slope to the right of *E* in Fig. 6 continue for any great distance, provided the elevation of the back-water below,

after allowing for recovery of velocity head, is low enough to prevent submergence of the point of control.

So far as the writer knows, no attempt has been made to utilize the directly measured critical depth for determining discharge, although the relation between this depth and the flow is simple. This is probably because the exact location of the control is likely to be uncertain. The depth near the critical point is subject to rapid variation and there is a lack of confidence in measurements taken at the theoretical point of control. A flume such as that shown in Fig. 6, 2.00 ft. wide, will flow 2.00 ft. deep at the point of control with a discharge of 32.08 sec-ft. With Kutter's $n = 0.013$, the friction slope for the critical depth is approximately 0.008. The friction loss in the first 0.25 ft. above the control, therefore, will be about 0.002 ft. To build up the energy head needed to compensate for this loss requires an increase in depth of approximately 0.05 ft. Therefore, if the floor of the flume is level above the control, the water surface will rise more than 0.5 in. in the first 3 in. of channel, due to the flatness of the energy curve near the point of critical depth. For shorter distances the rate of rise is even more pronounced, and a slight error in the selection of the point of measurement will appreciably affect the measured depth. A curved bottom for a short distance above the control tends to compensate for the disadvantageous shape of the energy curve, and it may eventually be found possible, with a proper type of structure, to use the measured critical depth for the determination of discharge. Such a plan would have the distinct advantage of being free from the influence of changing approach conditions.

With the gauge located in the inlet section as advocated by the author, the theoretical relation between depth and discharge may be computed from Bernoulli's theorem, making allowance for friction and transition losses between the point of measurement and the control. If the length of the structure is great, or if the transition is imperfect, the uncertainty as to the total value of the losses is likely to be considerably greater than if the depth is measured at the point of control. However, the effect on the computed flow of an error in determining the loss is less marked with the gauge in the inlet. The gauge should be set at a point where the channel will always be swept clean by the velocity, to avoid interference by accumulations of silt.

Two water surface curves are shown in Fig. 6, one for frictionless flow and one allowing for friction due to Kutter's $n = 0.013$. Transition losses are disregarded. The divergence of the two lines indicates that with carefully rounded corners of the type shown, and with a long radius vertical curve from D to E, the head may be safely measured at the control.

The gauge height for the assumed flow, computed from the author's formula, is shown at A (Fig. 6), and is appreciably lower than that computed from the control theory. This discrepancy is explained by a study of the flume shown in Fig. 7, which is identical with that of Fig. 6, except that all curves in the side-walls and bottom are omitted. The inlet is identical with that proposed by the author for a 24-in. flume. Because of the angular change in the slope at I, the stream will leave, or tend to leave, the bottom. As a result there will be a reduction in the hydrostatic pressure, and an alteration

of flow conditions, preventing the formation of a control at *I*. Passing up stream from *I*, normal hydrostatic conditions are no doubt gradually approached, and if the flume is sufficiently long a control will exist at some point. If a control does exist, the flow may be determined from a gauge reading at *G*, the only effect of the irregularity at *I* being the introduction of further uncertainty as to the head lost in friction between the gauge and the point of control. The contractions at *H* (Fig. 7) introduce eddy losses of unknown value which probably affect the gauge reading at *G* more seriously than do the irregularities at *I*.

The throat section, or level, parallel part of the flume in Fig. 7, is purposely made long to avoid the possibility of overlapping the effects of disturbances at the two ends. If the distance, *H I*, is gradually reduced the point of control will approach the disturbed region below *H* and will eventually pass above *H*. An entirely new set of conditions will thus be set up, and if the inlet transition is blunt, weir discharge will be approached. If the taper of the inlet is gradual a control probably will be established a short distance up stream from the junction between the inlet and the throat. The control thus coming at a point where the flume is wider than in the throat, the relation of the gauge reading at *G* to the flow will be altered.

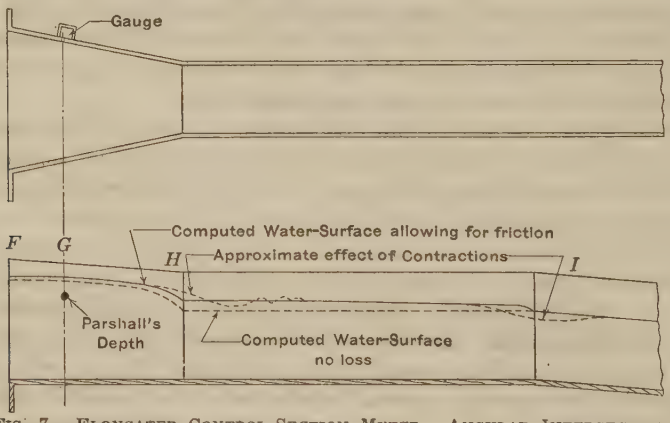

FIG. 7.—ELONGATED CONTROL-SECTION METER. ANGULAR INTERSECTIONS.

This is believed to be the situation existing in the author's device. The throat of the structure is not lengthened, as claimed, but is shortened to a zero length by the vertical expansion beginning immediately below the end of the converging inlet.

The distance from the end of the transition up stream to the point of control is probably influenced by the angle of break in the grade line. The relation between the depth at the gauge and the discharge depends on the width of the channel at the point of control, which is dependent on the location of the control and on the rate of flare of the inlet. The author's formula is, therefore, applicable only to flumes constructed in strict conformity with the structures tested.

By making the floor of the throat section of the flume level, extending the throat sufficiently to avoid overlapping the effects of angularity at the two ends, and providing sufficient fall to prevent flooding the throat, the device can be made to follow the theoretical law for flow through a point of critical depth. This alteration brings the structure back to the form of the original Venturi flume, which the writer believes to be a better structure fundamentally than the one now proposed.

The U. S. Bureau of Reclamation has developed a type of measuring device designed to operate on the control-section principle. To facilitate construction in concrete, without the use of forms, the throat and approach walls are given a 1 on 1.5 slope. A discussion* by the writer regarding this structure and its operation was published in 1920. The bearing of Venturi flume tests made at Cornell University on the control-section theory was discussed at the same time.

CONTROL SECTION
C-G CUTOFF CANAL

FIG. 8.

The first experiments by the U. S. Bureau of Reclamation on the trapezoidal control section were made at a structure on the C-G Cut-Off Canal on the Klamath Project (Fig. 8), in Oregon, and have been described in a paper† by J. L. Savage, M. Am. Soc. C. E. A number of additional measurements have been made at this structure. All the ratings made to date are shown on Fig. 9. The discharge measurements were made with a current meter. Field measurements were made by Allen L. Darr and H. K. Smith, Assistant Engineers, U. S. Bureau of Reclamation. The agreement between the current-meter discharges and the theoretical discharge of the control section is good. A single test made on a similar structure on the main canal of the King Hill Project, in Idaho, showed practically exact agreement with the theoretical discharge.

* "Venturi Flume Data Throws Light upon Control Weir," *Engineering News-Record*, December 23, 1920, p. 1223.

† "Discharge Measurements for Control-Section Weir," *Engineering News-Record*, May 15, 1924, p. 842.

In the fall of 1923, a 24-in. trapezoidal control-section structure was installed at the Hydraulic Laboratory of the Bureau of Reclamation, at Boise, Idaho, and a series of tests were run by W. G. Steward, Assistant Engineer, U. S. Bureau of Reclamation. The structure was built of wood, the inlet being warped to conform as nearly as practicable to the lines of the standard concrete device. Timber construction was adopted to facilitate remodeling during the progress of the tests. It is not contemplated that wood will be used for permanent installations of the warped type. Details of the structure as installed are shown in Fig. 10. Results of the ratings are shown in Table 6 and Fig. 11. The position of the scales and gauges and the hydraulics of a typical run are shown on Fig. 6.

Gauge readings were made with hook gauges in stilling-wells, located as shown on Fig. 12. The flat scale at the upper end of the inlet structure was countersunk flush with the surface of the wall. The structure was constructed and maintained accurate to the theoretical dimensions within 0.01 ft. The discharges were measured volumetrically in carefully calibrated concrete-lined measuring tanks.

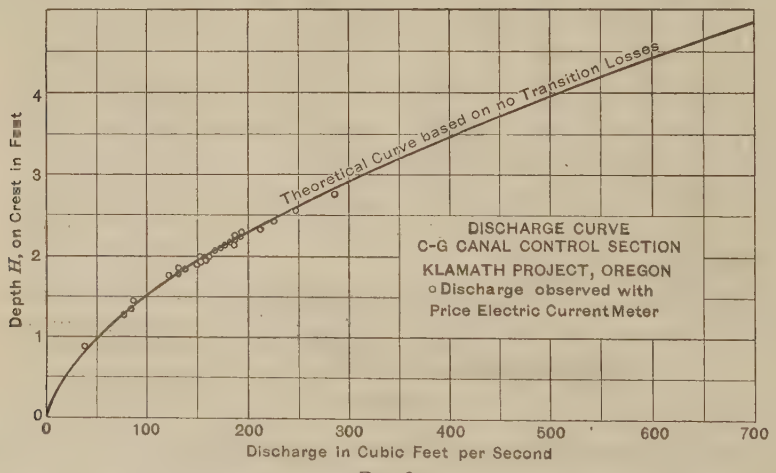

FIG. 9.

In order to determine the influence on the gauge height of the throat length and of curvature at the down-stream end of the throat, the parallel part of the structure was made removable, and removable curved "throat pads" (Fig. 10) were provided at the junction of the throat with the outlet transition. Throat lengths from zero to 3 ft. were tried, both with and without the throat pad. Eighty-seven separate observations were made. The data obtained are not sufficient to establish with precision the laws of flow for a trapezoidal control-section, but they indicate substantial conformity with theory to depths approximately equal to the throat length.

During the progress of the tests a slight erosion of the banks occurred above the up-stream head-wall, causing a disturbance opposite Gauge No. 1 and the scale. To prevent this condition the side-walls were extended as indicated

by dotted lines on the plan view, Fig. 10. These extensions were maintained in place from Series 5, Run 2, to Series 11, Run 6. For Series 12 to 15, inclusive, the extensions were removed and the banks carefully rip-rapped.

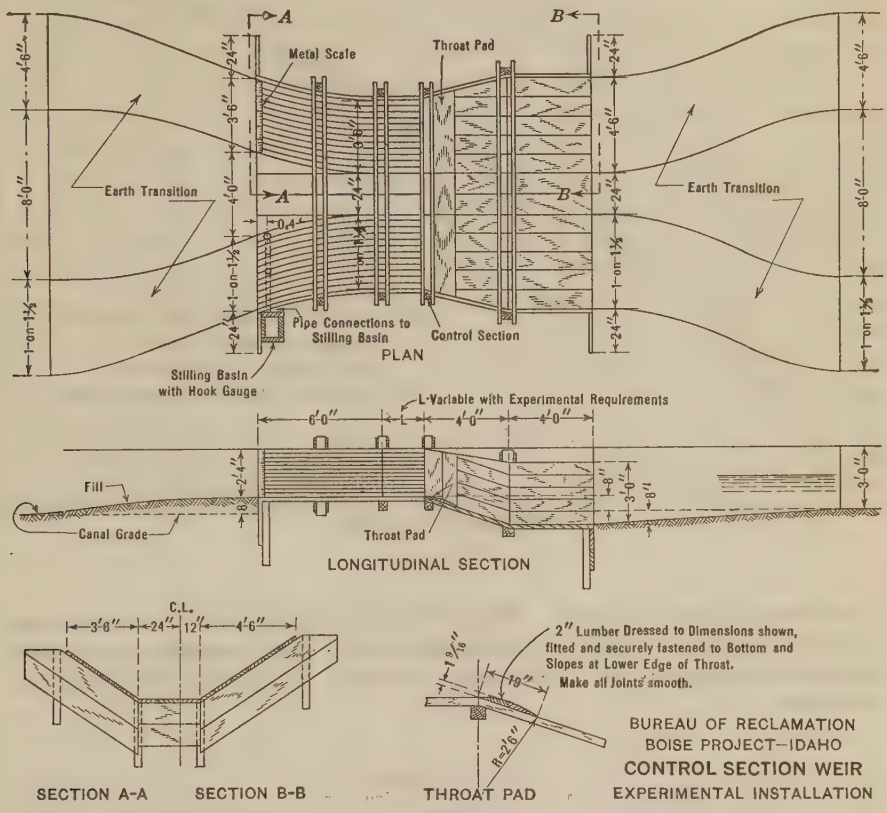

FIG. 10.

The theoretical discharge curve shown in Fig. 11 is based on the assumption of no entrance or friction loss, and is determined by making the gauge depth for a given flow such that the energy gradient at the gauge is equal to the minimum energy gradient at the control.

The general conformity between observed and computed discharges indicates that friction and inlet losses are small. Increased friction in the long throat partly explains the apparent reduction in discharge for Series 15. The computed theoretical discharges shown in Table 6 were scaled from an enlargement of the theoretical curve shown in Fig. 11. All notes shown under the heading, "Remarks", in Table 6 are copied from the original field notes.

In addition to the data tabulated, Gauges Nos. 2 and 3 were read for all runs. These readings are not shown in Table 6. Scale No. 1 was also read for the majority of the runs, and, in general, gave results reasonably close to the theoretical. The scale was originally installed as shown in plan in Fig. 10. For this position of the scale the readings were not the same on the two edges,

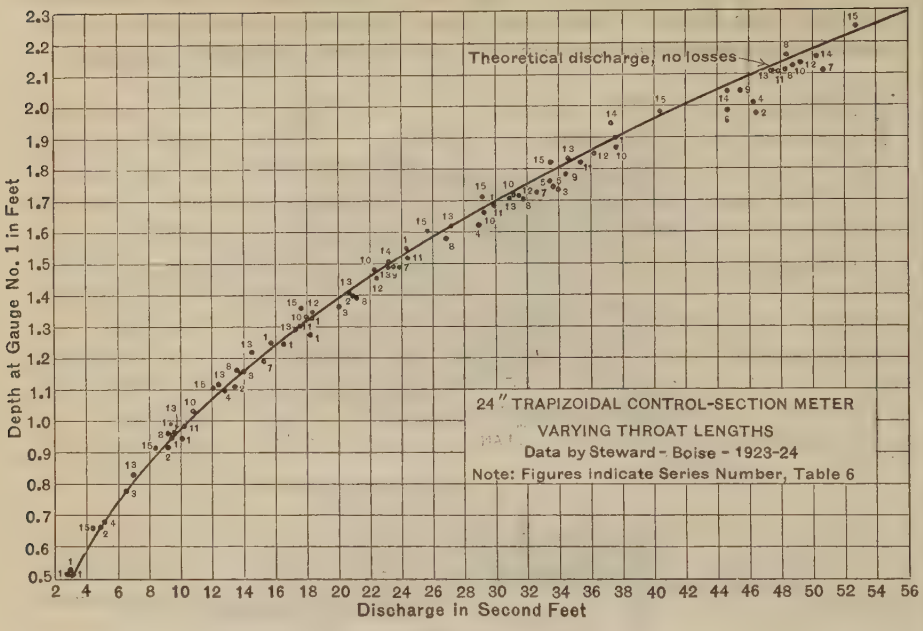

FIG. 11.

which caused some confusion. Scales located at other points were tried out later, but yielded no results of particular value. The impression was gained that a scale, properly set, is sufficiently accurate for field use for irrigation purposes.

Fig. 12 shows the hydraulic conditions existing at the time of Run 4. Series 3, with a discharge of 33.97 sec.-ft. The condition shown is typical for the structure. A standing wave was maintained below the throat for all non-submerged flows. By means of a check located down stream from Gauge No. 3, back-water could be caused to flood the control. The point of flooding was determined by slowly increasing the depth at Gauge No. 3, with constant flow, and observing the point at which the depth at Gauge No. 1 began to increase. This observation was made for 18 runs. The results are given in Table 7. The percentage of submergence at the point of flooding varied from 63 to 85, the average being 77. Only three runs indicated a reduction in flow below a submergence of 74 per cent.

While making the submergence test, the standing wave was closely watched to determine, if possible, the visual evidence of the change from free to submerged flow. Submergence appears to begin when the wave reaches approximately the location of the control. The control in Fig. 12 might be expected to come at about the point shown for the up-stream position of the jump. Run 8, Series 10, was made with a 24-in. throat without a throat pad, and, following the theory outlined in the first part of this discussion, the control might be expected to be a short distance above the down-stream end of the throat. Flooding began when the wave had moved 6 in. back into the throat. Run 1, Series 3, was made with the throat pad, but with a zero throat length. Flood-

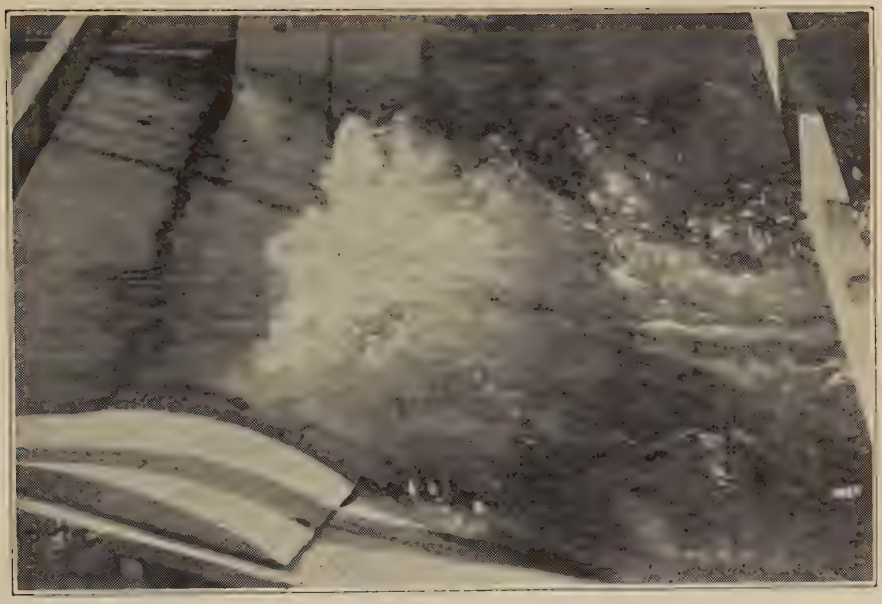

FIG. 13.—CONTROL-SECTION METER AT BOISE, IDAHO, SHOWING HYDRAULIC JUMP.

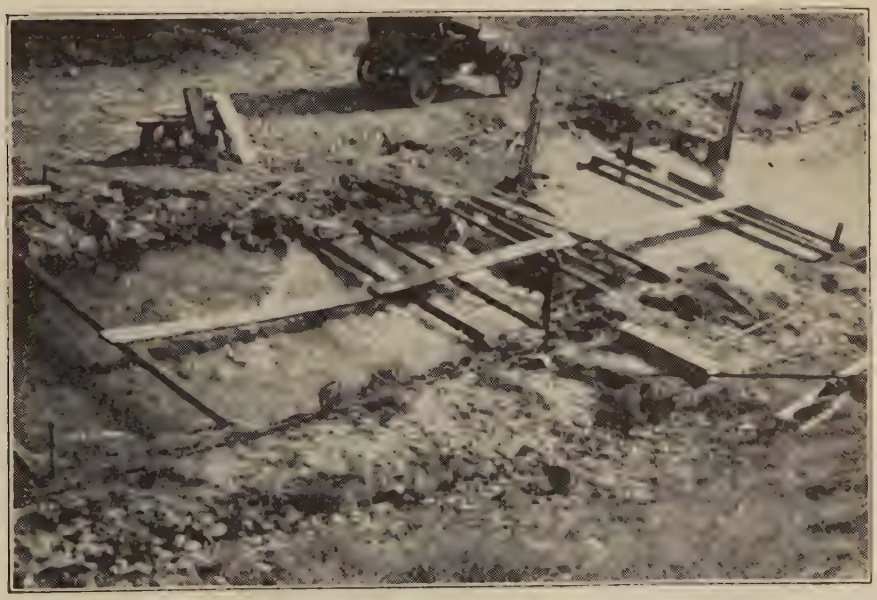

FIG. 14.—CONTROL-SECTION WEIR AT BOISE, IDAHO, RUNNING AT FULL CAPACITY.

ing began with the wave slightly farther up stream than the position shown for flooding in Fig. 12. The characteristic appearance of the wave just before submergence is shown in Fig. 13, and a view of the control-section weir running at full capacity is shown in Fig. 14. After submergence the wave usually changes to a series of ripples, which may be practically as rough as the last stage of the wave, but which have a distinctly different appearance. It is believed that with a little development the change from submerged to non-submerged flow can be made clearly visible.

*At instant of flooding.

No attempt was made to rate the structure for submerged flow, since under such conditions the device becomes a true Venturi flume, for which many ratings have been made.

Conclusions.—It is believed that the data submitted in this discussion justify the following tentative conclusions:

1.—A Venturi flume, properly set, can be made to act as a control and indicate flow from a single gauge reading in accordance with a fully rational law.

2.—For all practical purposes, especially in irrigation work, the coefficient of discharge for such a structure may be taken as unity.

3.—For practical purposes, the throat length of a structure similar to that shown in Fig. 10 should not be less than the greatest depth expected at the gauge. For best results, a throat length equal to twice the depth is desirable.

4.—The necessary throat length may be somewhat reduced by carefully rounding the corners at the junction of the throat and the outlet.

5.—For carefully rounded approaches no entrance loss need be expected.

6.—Friction losses may be ignored unless the structure is long or extreme precision is required.

7.—The Venturi principle is not utilized and the device should not be called a Venturi flume. Control-section meter is suggested as a more appropriate name.

E. A. JACOB,* M. AM. SOC. C. E. (by letter).—The improved Venturi flume is a type of measuring device that deserves to be used more generally on irrigation canals. However, there are practical limitations to its adoption.

Some time ago, the writer installed a test Venturi flume in a canal having a grade of 0.0003, and carrying about 60 cu. ft. per sec. of water. The canal was in clay which would withstand a velocity of 3 to 4 ft. per sec. The flume itself operated well, but the canal below it was inadequate for the velocity of the outlet stream, about 5 ft. per sec. The flume remained in the canal a few days, and then was taken out.

Venturi flumes may be used only in canals where the material will not erode under the force of the current flowing from the flume; otherwise, the canal must be lined with concrete or other stable material for some distance below the flume. If this outflow velocity is kept low, that is, 3 to 4 ft. per sec., the throat of the flume must have a water cross-section relatively large as compared with that of the canal. This would produce a high percentage of submergence which would make the formula proposed by the author unreliable if not entirely erroneous.

In Utah, most of the canals have moss growths which, in July and August, greatly decrease their capacities and produce back-water effects that would make it necessary to take into account both the throat head, H_b, and the upper head, H_a. It would seem that more experiments showing the effects of variable back-water conditions with a constant discharge should be made, and a formula developed for such conditions involving both heads.

J. C. STEVENS,† M. AM. SOC. C. E. (by letter).—The Special Committee on Irrigation Hydraulics feels that the importance of proper measurement of deliveries in irrigation work deserves especial emphasis. The pay-for-what-is-consumed principle, if generally adopted, will eliminate many of the perplexing problems of operators and managers. It will reduce waste, eliminate the "water hog", and conserve the available supply to such an extent that in many instances substantial increases in the irrigated acreage may be possible. The chief difficulty in the way of putting such a system into general practice has been the lack of practicable metering devices, such as the one described by Mr. Parshall.

This is an excellent start in the right direction. It offers a means of metering the flow without sacrificing much head—a most desirable feature in flat countries. The writer, however, believes it can be improved and simplified to the point where the flow through it can be calculated from hydraulic principles.

Any device that requires the recording of two heads does not meet the requirements of simplicity. The improved Venturi flume requires only one observation of head to the point of about 70% submergence and, therefore, should be considered as a practical metering device up to but not beyond that limit.

* Engr., Provo Reservoir Co., Provo, Utah.
† Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

The writer suggested to the Committee the use of a straight-sided, level-bottomed flume with a hump on the bed over which the water would have to flow at critical depth. In order to recover as much of the velocity head as possible the use of a second hump below the first was also considered, the purpose being to force the water from low stage below the critical to the high stage above without appreciable impact or eddy loss. A flume of this type was constructed and some experiments have been made on it at the Fort Collins Hydraulic Laboratory by Mr. Parshall.

Although the results of these tests have not been fully analyzed it appears that the second hump is superfluous. Its function is to raise the water to the high stage without a hydraulic jump, but this can occur for only one rate of flow. The intention in design was that this rate should be the maximum and that for all lesser rates of flow a hydraulic jump would occur. The eddy loss in a low jump is practically negligible.* Thus, for a depth after the jump 25% greater than that before, the energy loss is only 0.17% and for a 50% increase in depth the loss is only 1.2 per cent.

Plans are being made, therefore, for laboratory tests on such a flume with a single hump in the bottom somewhat along the lines shown in Fig. 15. Julian Hinds, M. Am. Soc. C. E., suggested to the Committee the desirability of measuring the head at the critical depth. If this can be effected in a practical way all question of velocity of approach, silting, weeds, etc., will be eliminated, and the formula for flow will reduce to the simple theoretical form:

$$Q = L \sqrt{g}\, d^{\frac{3}{2}} \qquad (1)$$

in which, Q is the flow, in second-feet; L is the length of crest of the hump or the width of flume at the point of critical flow; and d is the critical depth. A coefficient may have to be introduced, since theory does not take account of variable velocities in the plane of critical flow.

Theoretically, the critical depth should remain at the same point on a hump of this kind for all rates of flow. Neglecting friction, the following relation is obvious at any point in the flume:

$$y + z + h = E \qquad (2)$$

in which, z is the height of the hump above the flume bed; y is the depth of water; h, the velocity head; and E, the energy head. Differentiating,

$$dy + dz + dh = 0 \qquad (3)$$

since E is constant but, in a unit width of a rectangular channel,

$$h = \frac{V^2}{2g} = \frac{Q^2}{2gy^2}$$

hence,

$$dh = -\frac{Q^2}{gy^3}\, dy$$

* See "Determining the Energy Loss in the Hydraulic Jump," by J. C. Stevens, M. Am. Soc. C. E., *Engineering News-Record*, June 4, 1925.

but,*

$$\frac{Q^2}{g} = d^3$$

hence,

$$d\,h = -\left(\frac{d}{y}\right)^3 d\,y$$

which, substituted in Equation (3), gives,

$$d\,z + d\,y\left[1 - \left(\frac{d}{y}\right)^3\right] = 0 \quad \ldots\ldots(4)$$

At the point of critical flow, $d = y$, and Equation (4) reduces to:

$$d\,z = 0 \quad \ldots\ldots(5)$$

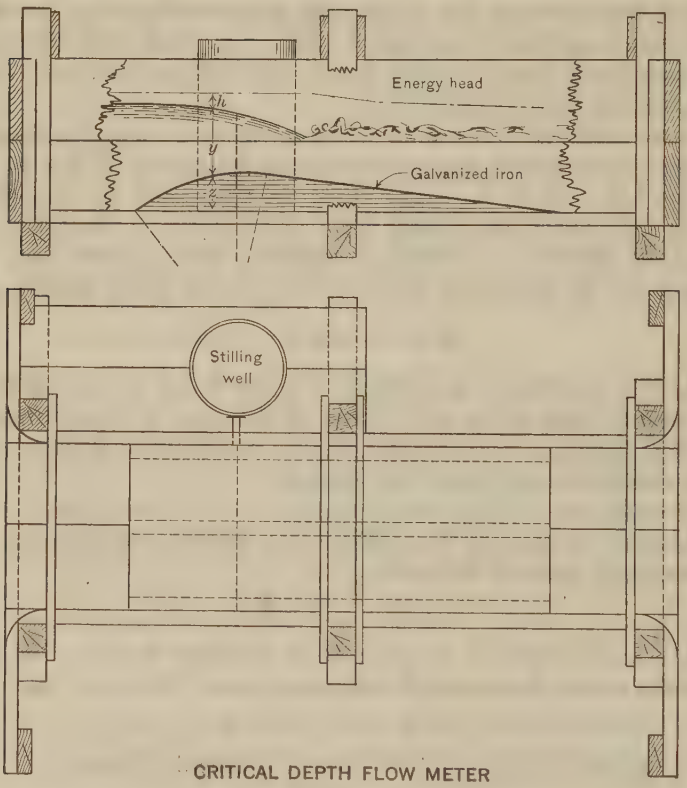

FIG. 15.

This can only occur at the crown of the hump where a tangent to the curve of the hump is parallel to the bed of the flume. It would appear from theoretical considerations, therefore, that the critical depth can be measured at one point for all flows.

* At critical flow the velocity head is one-half the depth, that is, $\frac{V^2}{2g} = \frac{1}{2}\,d$, also, $V^2 = \frac{Q^2}{d^2}$; hence, $\frac{Q^2}{g} = d^3$.

It is the writer's opinion that a metering flume of the type shown in Fig. 15 will retain control of the flow under a submergence considerably in excess of 70 per cent.

The term, "Venturi flume", is not a happy expression for the device described by the author, nor for the one suggested herein. The term, "Critical Depth Flow Meter", is more to the point and is offered as a substitute.

Carl Rohwer,* Assoc. M. Am. Soc. C. E. (by letter).—Mr. Parshall lays particular stress on the effect of submergence. According to his report, the degree of submergence is immaterial for amounts of less than 70 per cent. Compared with the weir this is unusual, as shown by Table 8,† which is a comparison between the effect of submergence on a 4-ft. rectangular weir and a 4-ft. improved Venturi flume. Table 8 gives for different percentages of submergence the ratio of the submerged flow discharge to the free flow discharge. The percentages of submergence for both the weir and the Venturi flume are based on heads referred to the crest level.

On account of the nature of the data it was not possible to obtain similar percentages of submergence for both the weir and the Venturi flume,

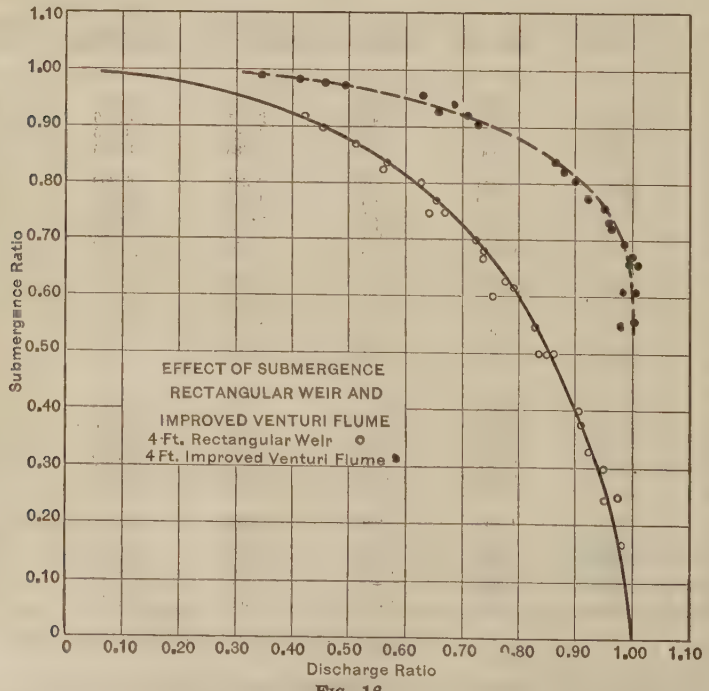

Fig. 16.

and in order to make direct comparisons possible, Fig. 16 was prepared. A study of the diagram shows that for submergences below 70%, there is little effect on the discharge of the Venturi flume, while the discharge from the weir is materially reduced. For submergences from 70 to 90%, the discharge ratios for both the weir and the Venturi flume decrease at about the same rate, but for values greater than 90% the effect is greater on the Venturi flume.

The fact that submergence does not affect the flow of the improved Venturi flume for ratios less than approximately 70% is to be expected. It has been shown* that at the control point, which in this case is at the crest, the depth cannot drop below two-thirds of the total head at the upper gauge point. In other words, submergence does not affect the discharge until the down-stream depth is sufficient to cause the depth at the control point to exceed two-thirds of the total head at the upper gauge point. For the improved Venturi flume, this apparently occurs when the down-stream head, as measured by Mr. Parshall, exceeds 70% of the depth at the upper gauge.

RALPH L. PARSHALL,† ASSOC. M. AM. SOC. C. E. (by letter).—When experiments were first made in the spring of 1915 on a type of measuring device having a converging and diverging section joined by a short throat section, with floor level throughout, this device was called the Venturi flume, because in plan it greatly resembled the converging and diverging sections as found in the Venturi meter, although in the flume the angles of convergence and divergence were equal. However, in this new device the water was not under pressure. As in the Venturi meter, two heads were observed, one in the converging and one in the throat section. Later, when experiments were conducted on the improved type of this device in which the angles of convergence and divergence were not equal and a depression in the throat section was introduced, this modified form was first called "the hydraulic jump flume"; but because of its similarity to the original type, both in design and section, it was thought advisable to designate it merely as the "improved Venturi flume."

For conditions of flow in which the discharge is a function only of the upper head and width of the throat, the law is not similar to that of the Venturi principle, but the device may be considered as a broad-crested weir without contractions. However, the additions of the depressed section at the throat introduces other conditions which modify its action. The improved Venturi flume, when under submergence of more than 70 to 75%, operates under the Venturi principle. It would seem, therefore, that it may or may not be a Venturi flume, according to the condition of flow.

From a theoretical standpoint, when the depth of water below the crest becomes positive, the flow is regarded as being submerged. As the depth below increases and approaches that of the upper depth, the percentage increases, approaching a limit when both these values are equal. Theoretically, under this condition the flow would be zero. For small differences or a high degree of

submergence, when based upon readings taken as indicated in the plan and elevation of the improved Venturi flume, it has been found that a considerable discharge results when these heads are practically identical. The real effective head, however, is not considered because the points where the observations were taken do not give the true difference causing the velocity of the stream.

As pointed out by Mr. Lane, the flow is theoretically submerged when the elevation of the water surface in the throat is higher than the crest elevation, but because the rate of discharge is not affected by this submergence until the ratio of heads approaches about 0.7 and because it follows the law of free flow, this range of conditions is called free flow and is a function only of the upper head and width of throat. When the upper head, H_a, is approximately 0.5 ft., the velocity of the water through the throat is sufficient to clear the throat section of the agitated condition, and the stream, through this section, is smooth and of relatively high velocity. When this condition is once established, the discharge may be reduced materially and yet this smooth condition of flow persists until the resistance, due to the upward inclined surface of the converging section, is sufficient to overbalance the momentum of the flowing stream. At this point the flow breaks and runs back into the throat. It is found that the law of flow is not changed where the stream passing the throat section is smooth or where the hydraulic jump is formed in the throat section, providing the ratio of the throat head to the upper head does not exceed approximately 0.7. Where the ratio of the throat head to the upper head exceeds this value of 0.7 the condition of flow is assumed to be submerged.

In his discussion, Mr. Carter has developed a formula based on the original data limited in submergence from 69 to 79 per cent. The total free-flow data were not all presented in Table 2. The data given were for the purpose of showing merely the agreement of computed and observed discharges for these limits of submergence.

In the determination of the free-flow discharge formula,

$$Q = 4\ W\ H^{1.522\ W^{0.026}}$$

observations were considered only where the degree of submergence was not greater than 69.9 per cent. These data were obtained both at the Bellvue and Fort Collins laboratories for discharges ranging from 0.3 sec-ft. to approximately 80 sec-ft., the size of the flumes being 1, 2, 3, 4, 6, and 8 ft. These data, taken by various observers, were plotted logarithmically, giving the mathematical relation as stated.

The free-flow series consisted of 162 tests, of which 2 were rejected. The remaining 160 tests formed the basis for the determination of the free-flow expression previously stated. Of this number it was found that in the comparison of the computed and observed discharges, 155 tests, or 97%, agreed within $\pm$ 3 per cent.

It is not claimed for the improved Venturi flume that its accuracy is superior to that of a standard weir, but from the writer's experience in the field with standard weirs, he would be inclined to think that the flume is as

accurate as the ordinary weir under field conditions. This would be especially true where much sand or silt is carried in the stream.

The calibration of this type of measuring device of various sizes included an extensive series under submerged flow conditions. It appears from the study of these data that although the submerged flow does not give as close agreement as the free-flow condition, it may be assumed to be within practical limits. Of a total of 229 submerged flow tests, in which the upper head did not exceed 2.52 ft. and the degree of submergence ranged from 70 to 95%, 1 test was rejected. Of the remaining 228 tests, it was found that in the comparison of the computed and observed discharges, 194 tests, or 85%, agreed within $\pm$ 5 per cent. The tests in which the submergence was greater than 95% were inconsistent and erratic and were not included in the computations.

In 1924 preliminary tests were conducted for the purpose of ascertaining the effects of introducing a parabolic curved surface as a floor in the throat section. These tests seem to indicate that an increase in the degree of submergence could be realized before it materially affected the free-flow discharge. The introduction of a warped surface, especially where structures are to be built by workmen of little mechanical experience, leads to the conclusion that the inclined plane floor surface in the throat section would be better, even if the effect of the degree of submergence would be slightly less. Tests were also made on a small-sized improved Venturi flume with a trapezoidal section.

It has been found from the practical application of the improved Venturi flume in the field, that protection is necessary below the structure when the stream is being discharged under free-flow condition. The exit velocities are relatively high, and unless the bottom and sides of the channel are protected, erosion will result. A wire net, filled with stone, anchored to the lower sill of the structure, has been found to be effective in preventing excessive erosion.

It would seem that the flume shown in Fig. 6 may be impracticable because of the high velocities that would exist at the exit end, *E;* even when the section is expanded as in the improved Venturi flume, protection is frequently necessary. The measurement of the critical depth would, perhaps, be uncertain as well as difficult to obtain because of the doubt as to its location. To base the discharge on this one reading may not be altogether satisfactory, even if the simple relation between discharge and depth exists from theory. The structure shown in Fig. 6, from a practical standpoint, would be unduly expensive because of its great length, and it might be that an undisturbed flow in this section could not be depended upon. Too much weight should not be given to the advantage of its single gauge reading because submergence is always a possibility, and in that case it is necessary to have both the up-stream and throat-gauge readings to determine the actual discharge.

The type of flume shown in Fig. 15 will, in all probability, measure successfully under certain conditions but it is doubtful whether the head could be measured accurately at the critical depth. Experiments would be necessary to verify the statement that this device is immune from silting troubles. For small flows it would be expected that there would be an accumulation of deposit

immediately up stream from the hump, and as the velocity increases this deposit may be washed out, thus changing the velocity of approach or contractions. Practical formulas of the type,

$$Q = L\, g^{\frac{1}{2}}\, D^{\frac{3}{2}}$$

will hold only when the critical depth is accurately determined. Since this point is unknown, it is not apparent how a formula of this type can apply without modification.

SIDE CHANNEL SPILLWAYS: HYDRAULIC THEORY, ECONOMIC FACTORS, AND EXPERIMENTAL DETERMINATION OF LOSSES*

By Julian Hinds,† M. Am. Soc. C. E.

With Discussion by Messrs. C. H. Howell, H. B. Muckleston, I. Gutmann, A. J. Wiley, Ivan E. Houk, J. C. Stevens, and Julian Hinds.

Synopsis

The design of a side channel spillway involves certain special hydraulic and economic factors which, it is thought, have not been previously discussed. On account of the disturbed conditions of flow, there are large internal frictional losses, the relative amounts of which are largely dependent on the magnitude and form of the individual installations. Flow can be computed by Bernoulli's theorem, using an experimentally determined coefficient of loss, similar to that of friction in ordinary flow, but such a coefficient would not be constant, and would need to be determined separately for many different sets of conditions. This situation can be avoided by utilizing the law of conservation of linear momentum for determining the flow. Formulas required for this purpose are developed.

The question of the proper location of the spillway on the ground is discussed, and a systematic method of determining the most economic design is suggested.

Although the fundamental principles utilized are well established in physics, the question arose as to the propriety of applying these principles to

Note.—The subject of this paper is one of ten selected by the Special Committee on Irrigation Hydraulics for study and research. The Committee, after studying the paper, has recommended its publication. (See Progress Report of the Committee, *Proceedings*, Am. Soc. C. E., March, 1925, Society Affairs, p. 137).

the conditions under discussion. A series of experiments was planned and carried out for the purpose of establishing the correctness of the assumption used. The results of experiments at the Arrowrock Spillway, and of laboratory experiments at Bellvue, Colo., are given in the paper.

The two most important conclusions reached are, as follows:

1.—Bernoulli's theorem is not conveniently applicable, because of lack of uniformity in the coefficient of loss.

2.—The law of the conservation of linear momentum is directly applicable without an experimental coefficient, subject only to a small correction for swell in volume due to entrained air and unequal distribution of velocities.

Introduction

The proper design of a spillway of the type shown in Fig. 1 involves a number of more or less novel problems, which, although simple if taken sepa-

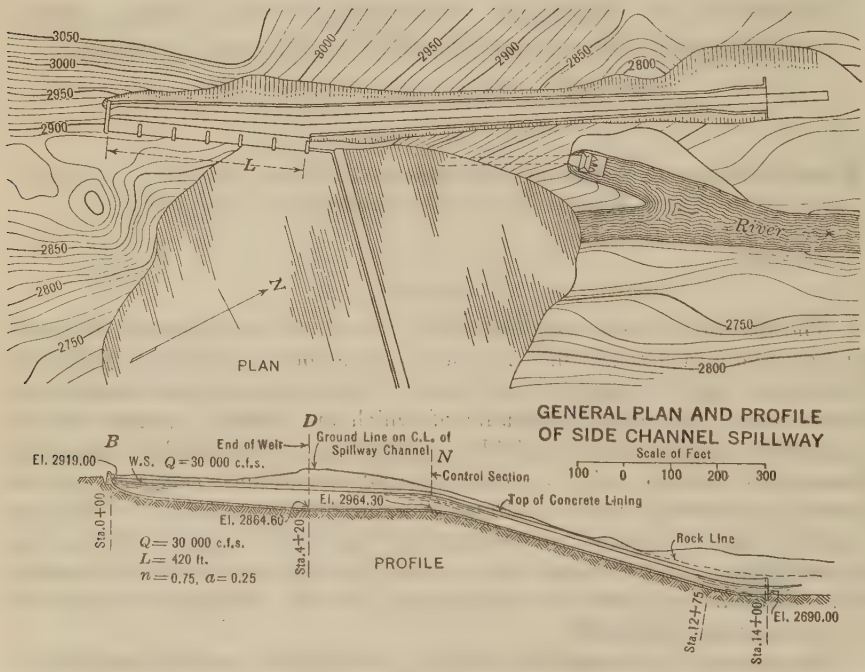

Fig. 1.

rately, form a complicated whole. The ultimate economy of construction depends on the form and dimensions of the spillway channel, its location, both in plan and elevation, its hydraulic properties, and other factors. The hydraulics presents a special problem, due to loss by shock and other irregularities caused by the constant addition to the flow in the channel of the water coming in over the spillway crest. Although this type of structure is very inefficient hydraulically, physical conditions sometimes make its use desirable.

It is best suited to spillway discharges of moderate quantities. The determination of the quantity of flood discharge to be provided for is beyond the scope of this paper. It will be assumed that the required spillway capacity is known. The depth of flow over the crest has an important influence on the cost of both the spillway and the dam. Generally, and within certain limits, the cost of the spillway channel is reduced by a short crest with a deep overflow, but if the spillway is of the open or uncontrolled type the cost of the dam will be increased, due to the excessive free-board required. If spillway gates are provided, their cost increases with their height. The factors involved in this part of the problem are too many and too varied to permit of a general solution. The most practical method of solving this problem is to assume a number of depths of overflow and prepare preliminary designs and cost estimates for the spillway, dam, and other related features.

Accuracy of Computations.—The quantity of flow to be provided for in the design of a spillway can be only roughly approximated at best, and extreme precision in computation is not justified. As the preparation of this paper progressed, arithmetical simplifications were developed, and the method of procedure finally recommended differs from that used in some of the typical designs and the reduction of experimental data. However, all computations are based on the same fundamental theories, and sufficient checking has been done to show that the various methods of procedure yield results in sufficiently close agreement for all practical purposes.

Units of Measure.—Although the equations deduced are independent of any particular system of measurements, units of 1 ft. and 1 sec. will be used to avoid confusion of language. The weight of 1 cu. ft. of water will be taken as a unit of force, to eliminate the necessity of multiplying all forces and momenta by 62.5 to convert them into pounds.

Symbols.—The letters and characters used in the formulas are, as follows:

A = area of water prism.
a = arbitrary coefficient of x in velocity equations.
b = inflow per foot length of weir crest.
d = depth of water in channel.
dM, dx, dV, etc. = derivatives of M, x, V, etc.
g = acceleration due to gravity.
H = head on crest (in weir formulas).
$H = d + y$ (in channel-flow formulas).
hv = velocity head.
M = momentum.
M_u = momentum at up stream of two adjacent sections.
M_d = momentum at down stream of two adjacent sections.
$\Delta M = M_d - M_u$, or change in momentum over a short length, Δx.
n = arbitrary exponent of x in velocity equations.
Q = discharge, in cubic feet per second.
Q_1 = discharge at upper of two adjacent sections.
Q_2 = discharge at lower of two adjacent sections.
T = width of channel at water surface.

t = time, in seconds.
V = velocity, in feet per second.
V_1 = velocity at upper of two adjacent sections.
V_2 = velocity at lower of two adjacent sections.
$\Delta V = V_2 - V_1$, or change in velocity in a short distance, Δx.
x = distance along axis of channel.
Δx = distance between consecutive cross-sections of the channel.
y = ordinate to the water surface curve in the channel.

The Hydraulic Theory

Referring to Fig. 1 it will be noted that the flow moves over the crest in a direction approximately at right angles to the axis of the spillway channel. At the moment it comes in contact with the body of the water already in the channel, the incoming water has an appreciable velocity in a vertical plane normal to the channel axis. This transverse velocity is of no assistance in moving the water along the spillway channel.

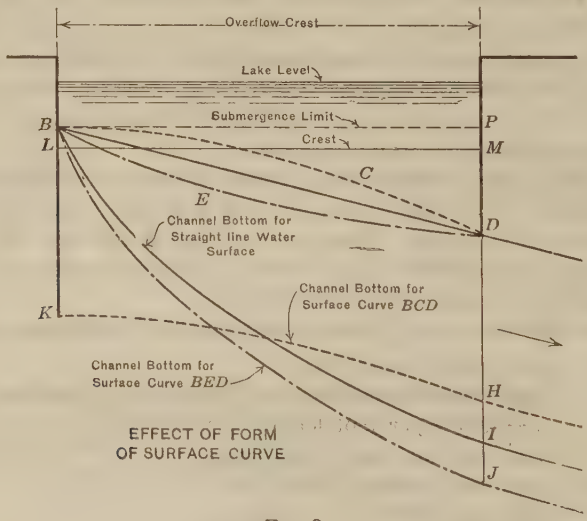

Fig. 2.

The force producing axial motion in the channel is derived from the falling of the particles of water along the water surface curve. The useful fall of any particle is measured by the drop in the water surface below its elevation at the point at which the particle entered the stream. Fig. 2 represents diagrammatically a section along the center line of a side-channel spillway. The water surface is assumed to fall along some curve from the point, B, at the upper end of the channel to a point, D, opposite the down-stream end of the crest. Each particle coming into the channel contributes to the production of velocity and the overcoming of resistances between B and D an amount of energy represented by its effective fall, or the drop in water surface from the point at which it enters, to D. Thus, a particle coming in at B will have an

effective fall equal to $P\,D$, whereas one coming in at D will have no effective fall. The total applied energy down to the point, D, is equal to that produced by the entire flow falling through the average drop for all the particles. If the surface curve from B to D is a straight line, and if the inflow per foot of crest is uniform, the average fall will be one-half the total fall, $P\,D$. If the curve is convexed, upward, as $B\,C\,D$, the average fall will be greater than $\frac{1}{2}\,P\,D$, and if the curve is concaved, the proportion will be less than $\frac{1}{2}\,P\,D$.

Only a part of the average fall is available for the production of velocity head at D. The remainder is used to overcome frictional and impact resistances. The frictional resistances are relatively small and may be neglected or estimated by methods used for other cases of variable flow. Impact is of greater importance.

Application of the Laws of Motion.—Water flowing in a channel must conform to each of the two laws of motion—the law of the conservation of energy and the law of the conservation of linear momentum. The first law is commonly expressed in hydraulics in the form of Bernoulli's theorem, which states that the velocity head plus the static head at any point is equal to the velocity head plus the static head at any other point, plus or minus the intervening "losses." The word "loss" in this sense refers to the transformation of kinetic or static energy into some less available form, such as heat. The energy is not actually lost in the sense of being destroyed. The law of the conservation of linear momentum requires that the momentum of any system of particles can be changed only by the application of an external force, the amount of change being proportionate to the magnitude and duration of the force. This law is commonly expressed in the form: "Force is equal to mass times acceleration." In hydraulics, it is more convenient to make the equivalent statement that "force is equal to rate of change of momentum with respect to time."

Neither of these laws is inherently superior to the other, each having its particular field of usefulness. The results obtained from the proper application of the two laws always correspond. In special cases one or the other may be more readily applicable.

A good example of the special usefulness of the momentum theory is afforded in calculations for the hydraulic jump in a straight uniform channel, where violent surges cause heat losses which make the use of Bernoulli's theorem impracticable. However, the external forces acting on the water, in the direction of flow, are readily isolated, and the amount of deceleration can be computed with precision. The only force to be approximated is the friction between the water and the channel, and this is usually small. After flow conditions below the jump are computed from the momentum equation the loss of head can be found from Bernoulli's theorem. A loss of head, in such a case, is unavoidable, and is caused by the fact that after the fast moving particles coming into the jump and the slow moving particles below the jump collide they must eventually move away with equal velocities.

Necessity for Loss of Head.—The fact that a loss of head is necessary in such a case may be illustrated by the collision of two simple bodies, such as

two billiard balls. In order to eliminate consideration of external forces the balls may be assumed to roll or slide without friction over a horizontal surface. It will also be advantageous first to assume the two balls to move in the same straight line. At the instant of first contact the centers of the two balls are moving toward each other. The materials of the balls at the point of contact immediately begin to be compressed. This compression results in a reaction which accelerates the forward ball and retards the rear ball. The compression increases until the velocities of the two balls are identical, at which time considerable energy has been expended in the compression of the balls. If the balls are perfectly elastic this energy is available, through the resilience of the balls, to force them apart again. If the balls are entirely inelastic no force will be available to separate them, and they will move together with identical velocities. As a result, there will be a reduction in the combined kinetic energy of the two balls equivalent to the elastic energy of the perfectly elastic balls at the instant of greatest compression. The important conclusion results that if all the energy of impact is absorbed the two balls will move away together and, conversely, if the balls are to move away together all the energy of impact must be absorbed.

Momentum and Energy Laws Both Required.—If the elasticity is perfect, the relative velocity of the two balls after impact will be exactly the same as before impact, whereas if they are perfectly inelastic the resultant relative velocity will be zero. With intermediate degrees of elasticity the resultant relative velocity will be determined by the proportion of the energy of impact absorbed.

The individual action of the balls after impact may be determined only by the application of both the laws of conservation of energy and of momentum. There is only one combination of individual velocities that will satisfy both the energy and momentum requirements, and that combination is controlled by the energy absorbed in impact. That part of the energy of impact not absorbed is utilized in the production of relative velocity between the balls after impact, that is, the velocity of one ball with respect to the other. The average velocity can be determined from the equation of momentum, and if the relative velocity is known, the motion is completely determined. If the relative velocity is zero, the actual and average velocities are identical, and in this special case only, the factor representing the energy equation may be dispensed with, the law of the conservation of momentum affording a complete solution.

Impinging Streams of Water.—When two streams of water flowing at different velocities come together and flow away down a common conduit, the two systems of particles eventually intermingle and the particles move with approximately equal individual velocities. Consequently, the energy of impact must be lost, or changed into some form not readily available for the production of velocity. As in the simpler case of the impinging balls, flow for this special condition is completely determined from the momentum equation. This is because the momentum always precisely determines the average velocity, which, in this instance, is also the actual velocity.

The term "average velocity" should not be confused with the "mean velocity" as ordinarily used in hydraulic computations. Average velocity, as here used, is the arithmetical or algebraic average of the velocities of all the particles. The mean velocity as ordinarily used is the average velocity over the cross-section of the channel taken by areas. Unless the velocity is uniform over the entire cross-section of the channel at a given point, these two terms are not identical. Where the velocities vary, more particles pass through an area of high velocity than through an equal area of low velocity, and the average velocity is greater than the mean. The assumption that the velocity is uniform over a given cross-section introduces an error into all ordinary hydraulic computations, as this assumption is never strictly true. This factor is relatively of greater importance for side-channel spillways than for other more usual types of structures, because velocity variations are more pronounced. However, the relation of the actual and average velocities is too complicated to be given practical consideration, and the usual assumption of uniformly distributed velocities will be made.

The effect of this approximation on the hydraulics of impinging streams is interesting. As previously stated, the average velocity is completely and accurately determined from the momentum equation. If the velocity is uniform over the cross-section there will be no relative velocity between particles and all the energy of impact will be lost. If the velocity is not uniform over the section there will be some relative velocity, and a part of the energy of impact will not be lost. However, as shown, the average velocity is greater than the mean velocity, and water-prism areas and depths computed on the basis of the known average velocity will be too small. Thus, although for a given average velocity, the theoretical impact loss computed on the basis of a uniform distribution of velocities is greater than the actual impact loss, nevertheless, the theoretical depth computed on the same basis is smaller than the actual depth.

Hydraulic Formulas for Side-Channel Flow.—A condition of impact and shock loss exists at every point along a side-channel spillway from the beginning to the end of a spillway crest, as from B to D in Fig. 2. Flow in such a case is completely determined by making the momentum after impact equal to that before impact plus any acceleration due to external forces, subject only to the approximations mentioned previously. The same result may be obtained by placing the energy after impact equal to that before impact minus all the energy lost in impact. However, equating the momenta will be found to be more convenient.

Consider conditions at two consecutive sections, a small distance, Δx, apart, somewhere between B and D, Fig. 2. If the weir discharge per unit length is b, the inflow between the two sections will be $b \Delta x$. The velocity and the discharge at the up-stream section may be designated by V and Q, respectively, and at the down-stream section by $V + \Delta V$ and $Q + b \Delta x$. The momenta at the two sections, therefore, will be:

Up stream,

$$M_u = \frac{Q V}{g} \qquad (1)$$

Down stream,

$$M_d = \frac{Q + b\,\Delta x}{g}(V + \Delta V) \quad \ldots\ldots(2)$$

Subtracting Equation (1) from Equation (2):

$$\Delta M = \frac{Q\,\Delta V}{g} + \frac{b\,\Delta x}{g}(V + \Delta V) \quad \ldots\ldots(3)$$

As Δx approaches the limit zero, ΔV becomes infinitesimal as compared to V, and disappears, giving the differential equation:

$$\frac{d\,M}{d\,x} = \frac{Q}{g}\frac{d\,V}{d\,x} + V\frac{b}{g} \quad \ldots\ldots(4)$$

The rate of change of momentum with respect to time being V times the rate of change with respect to x, we may write:

$$\frac{d\,M}{d\,t} = V\frac{Q}{g}\frac{d\,V}{d\,x} + \frac{b\,V^2}{g} \quad \ldots\ldots(5)$$

The rate of change of momentum with respect to time is equal to the accelerating force, which in this case is the component of the weight of the water acting down the water-surface slope. If the discussion is confined to the horizontal part of the velocity and if x is taken as the horizontal distance along the channel, the accelerating force will be $Q\frac{d\,y}{d\,x}$, in which, $\frac{d\,y}{d\,x}$ is the tangent of the water-surface slope. Substituting this force for $\frac{d\,M}{d\,t}$ in Equation (5), and reducing, gives:

$$\frac{d\,y}{d\,x} = \frac{V}{g}\frac{d\,V}{d\,x} + \frac{b\,V^2}{Q\,g} \quad \ldots\ldots(6)$$

Integrating,

$$y = \frac{1}{g}\int_0^x \left(V\frac{d\,V}{d\,x} + \frac{b}{Q}V^2\right) d\,x \quad \ldots\ldots(7)$$

in which, y is the ordinate to the water-surface curve.

Special Formula for Simple New Designs.—If the relations of Q and V to x are known in a given case Equation (7) can be integrated and the form of the surface curve determined. These relations depend on the form and dimensions of the channel, and will be algebraically complicated unless the channel is purposely designed to make them simple. In preparing a new design there appears to be no objection to choosing a form of channel that will simplify the computations, or, what is the same thing, choosing the hydraulics and computing the dimensions of the structure to correspond.

The inflow per foot of spillway crest for the purpose of design will generally be uniform, and the total discharge at any section x distant from the upper end of the crest will be given by an equation of the form:

$$Q = bx \quad \ldots\ldots(8)$$

An equation of the exponential type will be found convenient for expressing the velocity relation, and by properly choosing constants such an equation

can be made to conform to a wide range of physical requirements. The following form is suggested:

$$V = ax^n \quad (9)$$

In Equation (9), a and n are arbitrary constants and V and x denote, respectively, velocity of flow and distance from the upper end of the crest.

Substituting these values for V and Q in Equation (7), integrating, and reducing:

$$y = \frac{a^2 (n+1)}{2 g n} x^{2n} \quad (10)$$

Substituting $a^2 x^{2n}$ for V^2, Equation (10) is simplified to:

$$y = \frac{n+1}{n} h v \quad (11)$$

in which, $h v$ is the theoretical velocity head.

The Preparation of an Unrestricted Design

Economic Factors.—A spillway channel is completely determined by Equations (8) to (11), if its shape and the values of a and n are chosen. The proper choice of these factors is controlled by economic considerations. The discussion of this part of the problem will be confined to a trapezoidel channel

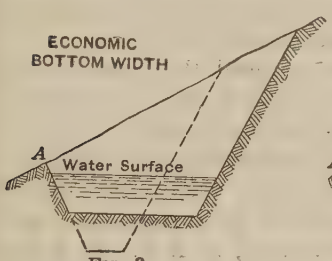

Fig. 3.

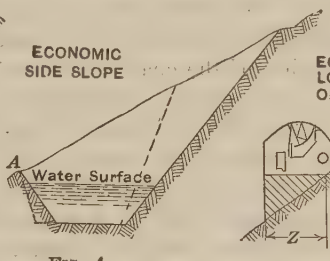

Fig. 4.

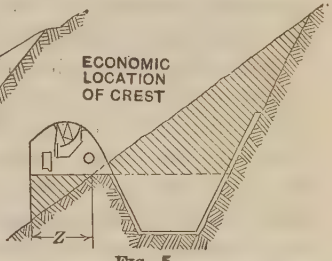

Fig. 5.

on a comparatively steep hillside, which is a usual case. The conclusions reached can be revised readily to suit other conditions.

The effect of the shape of the channel on the excavation is illustrated in Figs. 3 and 4. Safety usually demands that the channel be set well into the original formation. It may be required that the waterway be entirely in rock. If the water-surface elevation, channel side slopes, area of water prism, and location of point of outcrop, A, are fixed, it is evident from Fig. 3 that the excavation is reduced by a narrow bottom width of channel. It is similarly evident from Fig. 4 that, other things being constant, the side slopes should be made as steep as feasible. The minimum practical width of bottom will depend on the equipment to be used for removing the material from the trench. If the excavation is to be done by machinery, a width of 15 or 20 ft. may be required. For team work a somewhat narrower base may be used. The reduction in excavation for extremely narrow widths is not great. The side slopes should be trimmed to the steepest angle at which the materials will safely stand.

In many cases it will be necessary to line the spillway channel with concrete. Other things being constant, the cost of lining, which is an important item, is least when the bottom width is such that the wetted perimeter is a minimum. With steep side slopes this will require an average width of water prism equal approximately to twice the depth of the water. The bottom of the channel may be made somewhat narrower without greatly increasing the amount of lining, but the cost of lining should be considered in the final selection of channel width.

Figs. 3 and 4 are drawn to represent that part of the channel down stream from the crest structure, but the same principles apply to the part of the channel opposite the crest.

With a movable crest of the drum type an additional factor is introduced, due to the necessity for supporting the crest on a concrete base. It will be found advantageous to set the channel back into the hill a certain distance to reduce the quantity of concrete required for this purpose. The distance, z, in Fig. 5, should be chosen to make the combined cost of the shaded part of the concrete and the shaded part of the excavation a minimum. After a tentative bottom profile has been determined, the selection of which will be discussed later, the correct value of z can be calculated for a number of cross-sections, and a theoretical plan of the structure plotted on a contour map of the site. Unless the topography is unusually regular, it will not be possible to fit a practicable structure to the computed points with accuracy, but a location approximating the computed locations may be selected for trial.

After the cross-section of the channel has been selected, the profile is controlled by the values of a and n. Assuming a specified drop in the water surface from B to D, the effect of varying n is illustrated roughly in Fig. 2. If $n = 0.5$ the surface curve will be straight and the channel bottom will follow some such line as $B\,I$. If n is greater than 0.5 the water-surface curve will be convexed upward, as $B\,C\,D$. If n is exactly 1.0 the surface curve will be a parabola and the bottom will be a parallel curve, as $K\,H$. If n lies between 0.5 and 1.0 the bottom line will start at B, but if the value of n is nearly unity, it will drop rapidly nearly to the line, $K\,H$, which line it will cross up stream from H. If n exceeds unity, the bottom line theoretically drops to an infinite depth at the upper end of the channel, then rises rapidly approximately to the line, $K\,H$, which it crosses before reaching H. These statements can be readily proved by making a few trial computations from hypothetical data.

The effect on the profile, of varying both n and a, is shown in Fig. 6. If the value of n is known or assumed, the greatest economy in excavation at any point is obtained by making a such that the total drop from the submergence limit at B to the bottom of the channel at the point considered, expressed as $y + d$, is a minimum. Choosing H to represent $y + d$, the minimum value can be found by an equation, derived as follows:

$$H = d + y \qquad (12)$$

$$= d + \left(\frac{n+1}{n}\right) h\,v \text{ (from Equation (11))} \qquad (13)$$

As $h\,v$ is equal to $\frac{V^2}{2\,g}$ and V^2 is equal to $\frac{Q^2}{A^2}$:

$$H = d + \left(\frac{n+1}{n}\right)\frac{V^2}{2\,g}$$

$$= d + \left(\frac{n+1}{n}\right)\frac{Q^2}{2\,g\,A^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (14)$$

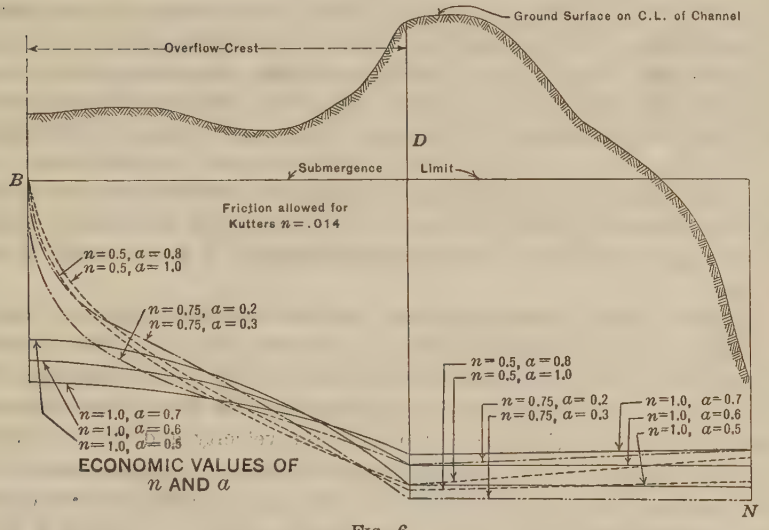

FIG. 6.

Differentiating with respect to d:

$$\frac{d\,H}{d\,d} = 1 - \left(\frac{n+1}{n}\right)\frac{Q^2}{g\,A^3}\,\frac{d\,A}{d\,d} \quad \ldots\ldots\ldots\ldots\ldots\ldots (15)$$

Making $\frac{d\,H}{d\,d}$ equal to zero, the minimum value of H is found to obtain when:

$$g\,A^3 = \left(\frac{n+1}{n}\right) Q^2\,\frac{d\,A}{d\,d} \quad \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

The factor, $\frac{d\,A}{d\,d}$, is equal to T, the top width of the water prism. Inserting this value and recalling that $\frac{Q^2}{2\,g\,A^2} = h\,v$, Equation (16) simplifies to:

$$h\,v = \frac{n}{n+1}\,\frac{A}{2\,T} \quad \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

or, from Equation (11):

$$y = \frac{A}{2\,T} \quad \ldots\ldots\ldots\ldots\ldots\ldots (18)$$

Having chosen a value for either a or n, the corresponding value of the other required to give the greatest economy at a specified point in a given channel, can be found from these equations.

The correct combination of values for a and n to give the greatest economy for the entire structure is not so readily found. A general solution involves the equation of the surface of the hillside which can not be practically expressed algebraically. The problem is best solved by trial.

Anticipating the results of the study, it may be stated that n is a much more constant factor than a, and is more easily guessed. A start may be made, therefore, with an assumed value of n. Having selected the trial value, choose some station along the channel where the excavation is unavoidably heavy and assume that this section will be a controlling factor in the cost of the spillway. Usually, as a safety precaution, the channel must be set well into the hill opposite the end of the dam, with the result that the excavation is heavy near the point, D, Fig. 6. Below some point, N, the channel need be set into the rock only as far as may be required to afford secure sidewalls. The section at D, therefore, influences the economy of construction more than any other single section, and the maximum economy of excavation for a given value of n, will be approximated if $d + y$ is made a minimum at D.

Therefore, unless special conditions indicate that the controlling section is elsewhere, find the economic value of y for the point, D, from Equations (17) and (18) by trial* and the corresponding value of a from Equation (10). The velocity and the water-surface curve may then be found from Equations (9) and (10), or Equation (11). Knowing the velocity and the form of the channel, the depth of flow and the bottom profile at points above D are readily obtained. Below D it is economical to have the bottom of the channel as high as possible without interfering with flow above D. Below N (Figs. 1 and 6), the channel will usually be steep and flow will occur at a velocity in excess of the critical velocity.

The velocity at D, determined as outlined, will be less than the critical. A "control", or point of critical flow, therefore, may be provided at N or between D and N. The control may be anywhere within this reach, but should be a sufficient distance below D to permit the necessary change in velocity to take place gradually. In the examples illustrated, the control is assumed to be at N. Having located the control, the hydraulic computations may be completed and the profile platted down stream from B to the point, N. The grade from D to N may be level, or even reversed.

Comparative Estimates.—As soon as a bottom profile has been completed the principles of Fig. 5 may be applied to several sections of the spillway crest, and the resulting channel platted on a topographic map of the site. A cost estimate for the spillway may then be prepared, which will locate one point on one of the curves in the left-hand part, (a), of Fig. 7. The correctness of the first trial value of a should be checked by assuming additional trial values, with the same value of n, and making more cost estimates. The result will give a number of points from which one of the curves in Fig. 7

* Assume a trial depth, d, and compute the area, A, and the top width, T. From Equation (17), find $h\,v$ and the corresponding velocity, V. Then, if $A\,V$ is equal to the required discharge, the assumed depth is correct. Otherwise, assume a new depth and repeat the process, continuing until an agreement is secured. Having thus arrived at the economic depth, the corresponding value of y is found from Equation (18).

(*a*) may be drawn. The lowest point on this curve will give the correct value of *a* for use with the assumed value of *n*. A new value of *n* should then be assumed, and the process repeated, platting other curves as shown in the diagram, until it is clear that the most suitable combination of *a* and *n* has been found. The curve in Fig. 7 (*b*) is obtained by platting the low points of the curves in Fig. 7 (*a*) against their respective values of *n*.

In the example given it is seen that 0.75 is the best value for *n*, the corresponding value for *a* being approximately 0.25. This value of *a* is somewhat larger than the value corresponding to the value of *y* computed for least depth at *D*. In all usual cases, with a lined channel, this will be true, and trial values of *a* should never be less than are required to give the minimum value of *H* at *D* unless the estimates show smaller values to be necessary.

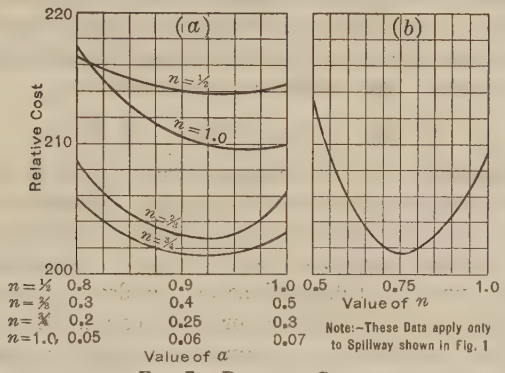

FIG. 7.—RELATIVE COSTS.

Submergence of Crest.—An important matter not yet discussed is the amount the weir can be submerged at *B* without seriously reducing the discharge. It has been the general practice heretofore to assume that Herschel's coefficients for ordinary submerged weirs are approximately applicable. The accuracy of this assumption will be discussed subsequently in connection with the experimental data. The economic importance of this point is apparent from the fact that the bottom profile is obtained by measuring $d + y$ downward from the permissible submergence line. In Figs. 1 and 6 the submergence is assumed to be such that the inflow will not be reduced, that is, according to Herschel, about 0.13 of the head on the crest. This small allowable submergence is chosen in these examples principally to simplify the theoretical discussion by making the inflow per foot constant. According to experiments, submergence reduces the discharge only slowly up to a fairly considerable depth. Furthermore, in a spillway the back-water falls away below the point, *B*. The crest may be submerged at *B* by one-half or two-thirds of the head without seriously reducing the total discharge. Equation (8) and Equations (10) to (18), inclusive, are not strictly applicable to such a partly submerged condition, as the inflow is variable. However, they apply with sufficient accuracy to any ordinary case, and the results may be checked by methods to be given subsequently. It may be desirable sometimes to

assume a heavy submergence, increasing the depth of spill to compensate for the reduced discharge factor. The limit to which this process may be carried can be determined by cost estimates.

Allowance for Swell.—In estimating the free-board required to prevent slopping over the edges of the channel or the top of the lining, allowance must be made for turbulence and "swell" due to entrained air and unequal distribution of velocities. As previously pointed out the average velocity is always greater than the mean velocity, which fact is ignored in the computation of depths and areas. Consequently, the actual depth may be expected to exceed the computed depth by an amount depending on the extent of longitudinal eddies. The volume will be further increased by air drawn into the stream by the infalling water. It is believed that the only information available on this subject is that given subsequently in connection with the experimental data. The average bulking observed for a small model was about 4% with a variation from zero to about 10 per cent. Observations on full-sized structures under normal flow conditions are needed.

Computations for a Restricted Design

Hydraulic Formulas.—The information already given is intended for use in the preparation of new designs not hampered by special limiting conditions. The same fundamental hydraulic principles may be applied to the analysis of an existing channel, or to the design of a channel which must conform to certain prescribed dimensions and grades, or where inflow is non-uniform due to excessive submergence or other cause. Equation (6) can be rewritten to make it applicable, approximately, to finite values of Δx. Equation (3) divided by Δx gives:

$$\frac{\Delta M}{\Delta x} = \frac{Q \Delta V}{g \Delta x} + \frac{b}{g}(V + \Delta V) \quad \ldots\ldots\ldots\ldots\ldots\ldots (19)$$

Multiplying by the average velocity, $V + \frac{1}{2}\Delta V$,

$$\frac{\Delta M}{\Delta t} = \frac{Q}{g}(V + \frac{1}{2}\Delta V)\frac{\Delta V}{\Delta x} + \frac{b}{g}(V + \Delta V)(V + \frac{1}{2}\Delta V) \quad \ldots\ldots (20)$$

As $\frac{\Delta M}{\Delta t}$ = accelerating force = $\frac{\Delta y}{\Delta x}$ times average discharge, Equation (20) becomes:

$$\frac{\Delta y}{\Delta x}(Q + \frac{1}{2}\Delta Q) = \frac{Q}{g}(V + \frac{1}{2}\Delta V)\frac{\Delta V}{\Delta x} + \frac{b}{g}(V + \Delta V)(V + \frac{1}{2}\Delta V) \quad \ldots (21)$$

From which,

$$\Delta y = \frac{Q}{g}\left(\frac{V + \frac{1}{2}\Delta V}{Q + \frac{1}{2}\Delta Q}\right)\left[\frac{\Delta V}{\Delta x} + \frac{b}{Q}(V + \Delta V)\right]\Delta x \quad \ldots\ldots\ldots (22)$$

or:

$$\Delta y = \frac{Q_1(V_1 + V_2)}{g(Q_1 + Q_2)}\left[\Delta V + \frac{b V_2 \Delta x}{Q_1}\right] \quad \ldots\ldots\ldots\ldots (23)$$

or:

$$\Delta y = \frac{Q_2 (V_1 + V_2)}{g (Q_1 + Q_2)} \left[\Delta V + \frac{b V_1 \Delta x}{Q_2} \right] \quad \ldots\ldots\ldots\ldots\ldots (24)$$

in which, Q_1 and V_1 are the discharge and velocity at the up-stream end of the reach, and Q_2 and V_2 are the same functions at the down-stream end. It is interesting to note that when b is zero, $Q_1 = Q_2$ and Equations (22), (23), and (24) reduce to $\Delta y = \frac{V_2^2 - V_1^2}{2g}$, which is the energy equation for ordinary variable flow, neglecting friction. Equations (22), (23), and (24) are identical, except as to form, and may be used interchangeably, as found convenient.

Location of Control.—These equations are not as cumbersome as might at first appear, but before they can be applied, a starting place, at which the velocity is known, must be found. Such a starting place will be located at a point of control, where the depth passes through the critical point, from above to below.

If the channel slope between D and N, Fig. 1, is insufficient to support flow at the critical depth, and below N, more than sufficient, the control will be located at N, and the computation of the hydraulics may be started from that point. If the slope between D and N is greater than is required to support flow at the critical depth, the control will come at D, or at some point above. Up stream from D there is, in addition to the force of friction, a resisting force due to impact. This force has the same effect on the formation of a control as a flattening out of the grade. If the slope of the channel is insufficient to overcome losses and maintain flow at the critical depth immediately above D, then the control will be at D. If the slope immediately above D is more than sufficient for maintaining critical flow, then the control will come at some point farther up stream, where the slope becomes insufficient for this purpose.

The actual location of a control above D is complicated by the fact that the critical depth, the impact resistance slope for critical depth, and the discharge are all variable. If the equation of the critical velocity can be written, the slope can be found from Equation (6), but this can seldom be done. A suggested method of attacking the problem is illustrated in Fig. 8 and Tables 1, 2, and 3. First, compute the critical velocities and discharges corresponding to a number of depths, as shown in Table 1. The hydraulic radii may also be computed and recorded for use in estimating friction losses. From Table 1 values of the critical depths and velocities may be taken, by interpolation, for use in Table 2, which is self-explanatory and gives in Column (13) the drop in water surface necessary to maintain flow at the critical depth throughout the full length of the channel. Starting from an arbitrary water-surface elevation at some station, a profile of the channel, for critical flow at all points, can be platted, as shown by dashed lines in Fig. 8. A tangent parallel to the bottom of the actual channel may then be drawn to the resulting bottom line of the critical depth channel, and the point of control

will be located at the point of tangency. Referring to Fig. 8, it is evident that the slope required to maintain critical flow to the left of Station 1 + 64 is greater than the actual slope, and to the right it is less, which is the condition necessary to the formation of a control. If more than one point of tangency is possible, that one giving the lowest position of the tangent will be likely to control. It is possible to have two or more control points with hydraulic jumps between.

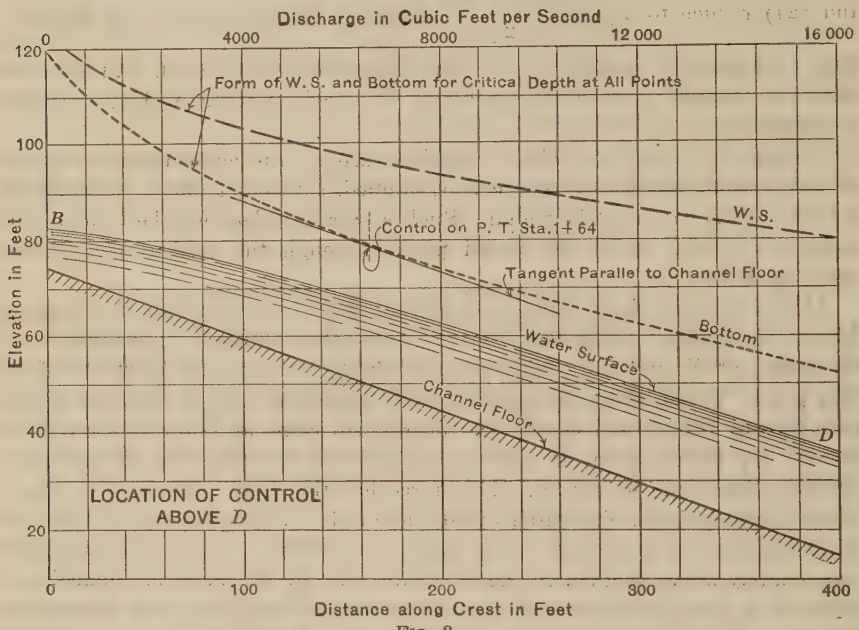

FIG. 8.

The Back-Water Curve.—Having located a control, the back-water curve may be calculated both ways, as illustrated in Table 3, and as platted in the lower part of Fig. 8. Equation (23) is used in the upper part of Table 3 and Equation (24) in the lower part, in order to take advantage of as many constant terms as possible. The accuracy of the computations will depend on the length and number of subdivisions assumed. The number of divisions used in the examples shown could be increased to advantage.

EXPERIMENTS UPON A MODEL STRUCTURE AT BELLVUE, COLO.

In the latter part of December, 1923, the U. S. Bureau of Reclamation constructed a model spillway at the Bellvue Laboratory of the U. S. Department of Agriculture, near Fort Collins, Colo., and conducted a series of experiments for the purpose of establishing, if possible, the correctness of the foregoing theory. The experiments were made by the writer under the direction of J. L. Savage, M. Am. Soc. C. E., Designing Engineer of the Bureau of Reclamation. A large part of the observational work was done by Ivan E. Houk, M. Am. Soc. C. E., and Samuel Judd, Engineer, Bureau of Reclama-

tion. Valuable assistance in operating the laboratory was given by R. L. Parshall, Assoc. M. Am. Soc. C. E., Irrigation Engineer, U. S. Department of Agriculture.

*h_f = friction loss, computation not shown.

The general arrangement and principal dimensions of the Bellvue Laboratory and the model spillway are shown in Fig. 9. The intake to the flume is adjacent to the head-works of the Jackson Ditch, and is controlled by a single 4 by 4-ft. sliding gate. Two 2 by 2-ft. waste-gates are available for additional control, and an 8-in. pipe line, with a gate-valve near the weir pool, may be utilized for the final adjustment of flow.

BELLVUE LABORATORY
EXPERIMENTAL SPILLWAY
DETAILS AND DIMENSIONS

FIG. 9

A 10-ft. Francis weir for measuring the discharge and baffles for stilling the flow are located as shown. Fig. 10 is a general view of the laboratory and Fig. 11 shows the spillway structure.

The spillway crest was of sheet iron rounded to a 9-in. radius, and was approximately 16 ft. long. The trough was of 1-in. planed boards carefully joined on the edges and made water-tight with fiber cement. The leakage was negligible.

That part of the structure carrying the rounded crest, corresponding to the part, *B D*, of Fig. 1, was located above a tight bulkhead across the test flume. In order to simulate conditions from *D* to *N*, Fig. 1, a short length of channel was provided below the end of the spillway crest. This part of the channel was located below the tight bulkhead. A second stop-plank bulkhead below the end of the channel was available for controlling the submergence at the outlet. A 2½ by 2½-ft. slide-gate in the center of this bulkhead made it possible to control the back-water accurately.

The quantity of water which could be passed over the spillway was limited by the flow in the river and by the height at which the flow could be delivered into the flume. Flash-boards were used on top of the diversion dam to increase the head. On account of the lateness of the season, the river discharge was affected by ice, and a steady flow was difficult to obtain.

Hook-gauges for reading depths in the spillway channel were placed in metal stilling-wells anchored to the concrete walls of the test flume. Water-tight connections from the spillway trough to the gauge-wells were made by short lengths of garden hose. Nipples for the hose connections were screwed into holes bored partly through the wooden sides of the trough, reinforcing cleats being used where required. Smaller holes were bored through to the inside surface to permit the passage of water. Five trough-gauges were used, one at each end of the crest and three at equally spaced intermediate points. The up-stream gauge was connected to the end of the channel, on the center line, 8 in. above the floor. The other gauges were connected through the sides, 8 in. above the floor, as shown in Fig. 9. Two additional hook-gauges set in wooden stilling-boxes on the wall of the test flume were used for reading the head on the spillway crest.

Heads on the 10-ft. sharp-crested, rectangular weir were taken with two hook-gauges in wells outside the weir box, as shown on Fig. 9. Discharges were read from a large scale curve platted by Mr. Parshall, and are undoubtedly more exact than would be required for the present purpose.

Observations.—When the structure was put into operation it appeared that a sufficient amount of air was being entrained to reduce materially the weight of the flowing water. It was thought, therefore, that the water depths measured in the stilling-wells might not furnish accurate information as to the actual depth of flow in the channel, and it was decided to take direct level-rod measurements of the surface profile. On account of the disturbed condition of flow, it was not expected that these readings would be accurate, but later they were found to be consistent and reliable.

The conditions shown in Figs. 12 and 13 and Figs. 14 and 15 are typical, respectively, for non-submerged and submerged flows. The level-rod was held

opposite each gauge connection and at such elevation that, as far as could be judged, it was in and out of the water equal intervals of time. Generally, two readings were taken for each station, one on top of the boil shown in the photographs, and one in the depression on the crest side of the channel. In some cases, where the flow was less regular, extra readings were taken near the middle of each section. Level-rod readings were also depended on for determining the back-water level in the pool into which the channel discharged.

The program for making the observations was arranged to eliminate, as far as practicable, personal equation and chance. Tests with varying discharges were run on three settings of the trough, two with a flat bottom slope and one with a considerable grade, as shown on the profiles, Figs. 16, 17, and 18. Fifteen separate runs were made. Preparation for each run was made by setting the head-gates and by-passes to approximate the flow required.

As soon as the depth in the gauge-boxes at the Francis weir became constant, it was assumed that steady flow had been established. The level-rod profile of the water surface was then taken as rapidly as possible, after which the rodman beginning at the up-stream end read all the channel gauges, the Francis weir gauges, and the down-stream and up-stream spillway crest gauges in turn, making three complete circuits. The levelman recorded all readings. The observers then changed duties and repeated the series, reading the gauges first and ending with the level-rod readings. The level of the water in the submergence pool was read only once, after all other readings were completed. Frost in the connections to the stilling-wells for the spillway crest gave considerable trouble, and these gauges could not always be read. The gauge-wells for the measuring weir were outside the structure and were more accessible for clearing out ice. It was necessary each morning to drill the ice out of the connections and to thaw out the wells with hot water or by building fires around them.

Comparative Water-Surface Profiles.—The test was planned primarily as a check on a previously devised theory, and the most advantageous method of presenting the results seems to be in a series of profiles showing measured and computed water surfaces. (See Figs. 16, 17, and 18.) The high, low, and average water surfaces, determined from level-rod readings, are shown. Where available, the results of the trough-gauge readings are also platted. The down-stream part of the channel being on a level grade, the location of the control was not difficult. Where a control existed, it was found theoretically and actually to be close to the outfall end of the channel. In Runs Nos. 3, 9, 10, 12, 14, and 15, the submergence at the outfall was such that the critical velocity was not attained at any point and no control existed. In these cases, the measured water surface in the lower end of the channel was taken as a starting point.

Apparent Swell.—The computed profile generally is of the same form as the average observed profile, lying slightly below it. As noted in the theoretical discussion, it was expected that the measured depths would exceed the computed depths on account of entrained air and swell due to the discrepancy between mean and average velocities. Many factors may influence the amount

of swell. The volume of air taken into the stream probably increases with the quantity and fall of the inflow. The proportion of this air held in suspension probably depends on the volume and velocity of the channel stream. The velocity swell is probably influenced by the same conditions. The data available are neither sufficiently accurate nor sufficiently extensive for developing a law for the determination of the increase in volume due to these causes. The apparent swell for the fifteen runs made at Bellvue is shown graphically in Fig. 19. The points on the graphs were determined by comparing the channel area for the computed depth with that for the average depth from rod readings. Small uncertainties in the rod readings render the results erratic, but there is a general tendency to substantiate the expected results. For example, the weir crest is unsubmerged in Runs Nos. 1 and 8, and the channel outfall is free, allowing high velocities and small storage volume. As might be expected,

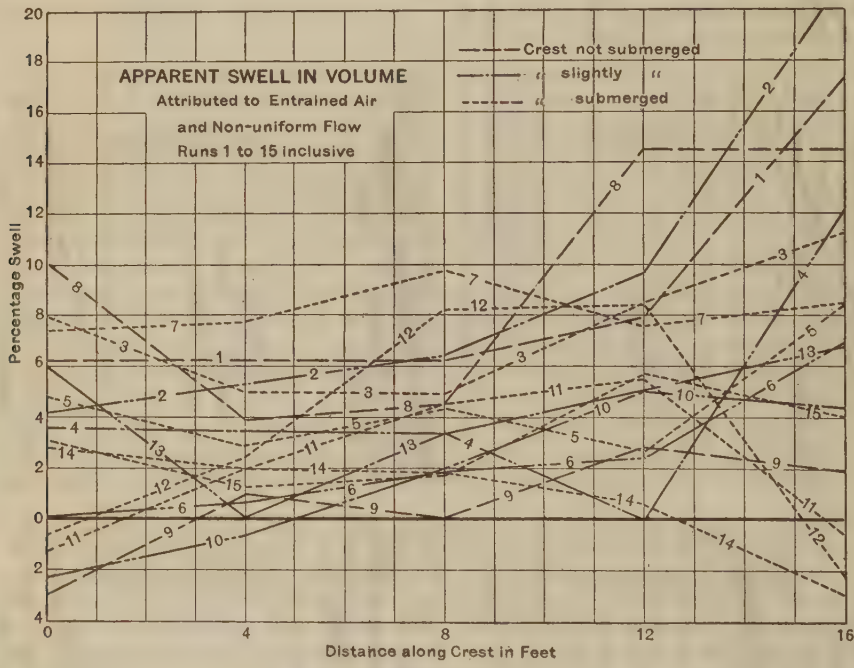

FIG. 19.

the swell is comparatively high. In Runs Nos. 2, 4, 6, and 13, the crest is slightly submerged and the outfall is free. At Station 16, Runs Nos. 2 and 4 show fairly high air contents. Otherwise, these four runs show only a moderate swell. Runs Nos. 5, 7, and 11 show a heavily submerged crest with free outfall. Runs Nos. 5 and 11 show moderate and consistent swells. Run No. 7 is consistent, but higher than might be expected. The crest in Run No. 9 is unsubmerged, but the outfall is obstructed so that channel velocities are low. The swell is small. In Run No. 10, both the crest and the outfall are slightly submerged, and the swell is small. Runs Nos. 3, 12, 14, and 15 are fairly heavily submerged, both at the crest and the outfall, and, in general, show small or

moderate swells. Run No. 13, which probably approximates usual design conditions as closely as any of the runs, shows an average swell of about 5 per cent. The effect of the scale of the structure on the swell is undetermined, and the test results should be applied to actual design with caution.

A Peculiar Air Condition.—An interesting phenomenon was discovered in studying air conditions. A "rope" of air varying in size, but about 2 in. in diameter, was formed approximately at the gravity axis of the water prism, and remained there throughout all the tests, except perhaps in cases of deep submergence. This "rope" ended squarely against the up-stream end of the channel. It increased slightly in diameter and became less distinct toward the down-stream end. If broken up with a hoe, it immediately reformed.

Discharge and Submergence Coefficients for Crest.—It was not anticipated in planning the tests that any valuable data would be obtained on the discharge coefficient of the rounded metal crest, and no special attempt was made to obtain favorable approach conditions. Nevertheless, the results roughly check, in an interesting way, a theory of compound weir discharge previously proposed. According to Bazin's measurements* the lower nappe of the discharge over a sharp-crested weir rises above the crest elevation by an amount equal to 0.112 times the head on the crest. If a crest having the exact shape of the nappe is put under the falling sheet, it may be assumed that the discharge will not be altered. However, the summit of the new crest will be above the original crest level by the previously mentioned percentage of the head on the crest. If for convenience it is desired to express the discharge in terms of the depth on the new crest, the discharge coefficient must be multiplied by $\left(\frac{.1}{1-0.112}\right)^{\frac{3}{2}} = 1.195$. This factor should apply to the coefficient of any discharge formula in which the head appears as the three-halves power, and is theoretically strictly applicable only to a perfectly shaped crest. The crest can be shaped to fit only one flow. For smaller flows, the conditions of a flat-topped weir are approached, and the discharge coefficient decreases. As the depth approaches zero, the crest becomes relatively very flat and the weir tends to act as a control section. The discharge over a control is:

$$Q = \frac{2}{3} H^{\frac{3}{2}} \sqrt{\frac{2}{3} g} = 3.09 H^{\frac{3}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (25)$$

The coefficient in Equation (25) is 0.93 that of the Francis coefficient, 3.33, for suppressed sharp-crested weirs.

In estimating the flow over compound weirs, the use of multipliers to be applied to results from tables for sharp-crested weirs is very convenient. The highest multiplier, if the flow does not clear the crest, is 1.195, and the lowest for a very flat crest, with a rounded approach, is 0.93. Usually, the flat type weir is subject to a transition loss and the multiplier can be less than 0.93 if the approach is not properly rounded. Multipliers for a number of crest forms have been published by the U. S. Bureau of Reclamation.† The highest

* See Parker's "Control of Water", p. 400.

† "Hydraulic and Excavation Tables", p. 96.

value shown is 1.169. Crest multipliers for the test structure are platted in Fig. 20 (*a*) over depths as abscissa, no allowance being made for submergence. The figures to the left of the hyphen at each point designate the number of the run and those to the right show the percentage of submergence at Station 0 on the basis of the computed depths. It will be noted that the points for zero submergence fall quite regularly along a curve joining the theoretical points at the two extremes. The submerged points are distributed in a fairly regular way, but are insufficient in number to permit the derivation of a law governing the effect of submergence.

It was expected that the law of submerged discharge would differ materially from that for a sharp-crested weir. In order to test this assumption the theoretical discharges were recomputed, making allowance for the submergence due to the computed water-surface profile in the channel, in accordance with Herschel's coefficients.* The results are shown in Fig. 20 (*b*). The figures designate the number of the runs. The points follow a definite line, indicating that the multipliers drop away from the theoretical maximum toward the control section value as the head on the crest decreases. There is no characteristic difference between submerged and unsubmerged runs. Run No. 15 is the only one that is seriously erratic. All multipliers are based on Bazin's formula for suppressed weirs, with allowance for velocity of approach, except for the lower theoretical point. Bazin's formula does not extend to a zero depth. Until more complete data are available, it appears that a multiplier of 1.15 may be safely used for a correctly shaped crest, and that Herschel's coefficients for submergence apply with sufficient accuracy to spillway conditions.

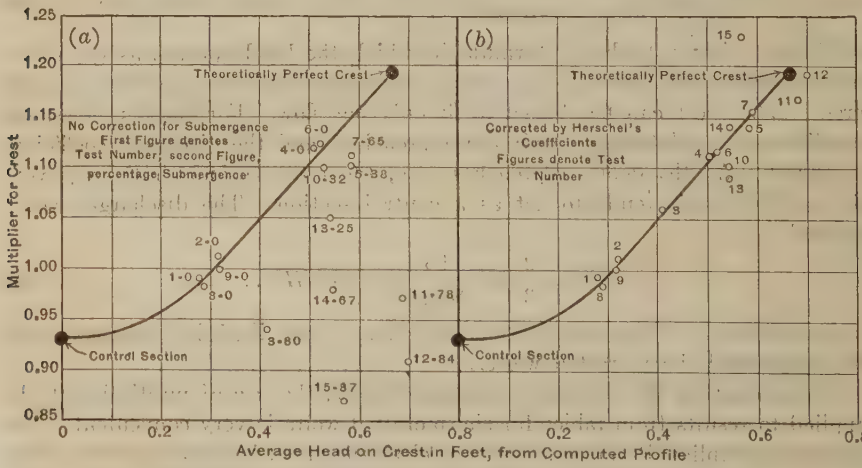

FIG. 20.—CREST MULTIPLIER AND EFFECT OF SUBMERGENCE.

Characteristic runs are shown on Figs. 21, 22, 23, and 24. The effect of submergence on the turbulence of flow is illustrated in Figs. 21 and 23, Runs 13 and 15, respectively. Conditions in these two views are approximately the same, except as to submergence at the outfall.

Experiments at Arrowrock Dam

The 1923 Overflow.—A spillway structure of adequate capacity is rarely required to carry the full discharge for which it is designed. For that reason tests on full-sized installations are difficult to obtain. In the spring of 1923, the Arrowrock Reservoir, on the Boise Irrigation Project, in Idaho, overtopped the spillway by about 10 000 sec-ft. The crest of this spillway is a movable type and might have been lowered to obtain full spillway discharge. However, such a discharge is in excess of any flood ever recorded in the river, even before the construction of the reservoir, and would be considered more or less of a calamity. The designed capacity is 40 000 sec-ft., or about four times the 1923 overflow. The crest gates were not fully lowered, but the water spilled over them in a partly raised position. The resulting conditions were very different from those contemplated in the foregoing discussion, especially in regard to height of fall, turbulence, and air content. However, it was considered desirable to make such rough observations as were possible with simple equipment.

Preparations and Equipment.—The work was in charge of W. G. Steward, Assistant Engineer, U. S. Bureau of Reclamation. Measurements on two different dates were made of the water surface profile in the channel, of the draw-down to the weir, of the upper nappe of the overfalling sheet, and of the surface velocities in the spillway channel.

The general arrangement and dimensions of the spillway are shown in Fig. 25. The crest is divided by piers into six sections, each controlled by a 62 by 6-ft. drum-gate. As shown on the diagram the gate crests were approximately 1 ft. below their maximum height at the time the tests were made.

Before flood stage was reached the gauges were painted on the side of the channel opposite the crest to measure any flow to a depth of 12 ft. The gauges were located half-way between Piers 1 and 2, 2 and 3, opposite Piers 3, 4, 5, 6, and 7, and at 100-ft. intervals below Pier 7. Opposite Piers 1 and 2 there were heavy deposits of sand and gravel, washed in from the hill above, which prevented the painting of the gauges at these points. Wires were stretched across the channel from Piers 1, 2, 3, 4, 6, and 7 for the purpose of running out a trolley to which was attached a weight that could be lowered by a cord to determine the distance to the water surface. A transit was used with the weight and the results were satisfactory, but the work was slow. The wave action on the land bank of the channel was measured partly with a transit and partly by gauge readings. One of the gauges was completely submerged and the others were covered part of the time. The elevation of the water surface on the reservoir side of the channel was determined by a weight suspended over the parapet wall, making allowance for the inclination of suspension. The curvature of the water surface above the weir crest was measured down from the tops of the piers, and the curvature of the nappe of the falling water was measured by an extension lever with a movable weight suspended near the end.

WATER SURFACE PROFILES
May 26 and June 12, 1923

FIG. 25.

The elevation of the movable crests was found by measuring down from the tops of the piers. The velocity of the water in the channel was determined by surface floats consisting of pieces of driftwood or bundles of kindling. The velocity of approach to the weir crest was measured with a current meter.

All measurements were made by Mr. Steward, and a report giving in detail the methods used is on file in the office of the Chief Engineer of the U. S. Bureau of Reclamation at Denver, Colo.

Comparative Profiles.—The observed water surface profiles, in comparison with the computed depths, are shown on Fig. 25. The theoretical profiles shown were not calculated from Equations (23) and (24), but from a previously devised more complicated formula based on the same theory. On May 26, 1923, the water surfaces in the channel were measured along the land bank and along the center line. The agreement between the observed center-line profile and the computed profile is very close; closer, in fact, than would be expected in view of the extreme turbulence. On June 12, 1923, the agreement is not so close, the observed profile coming well above the computed one at all points above the down-stream end of the crest. Below the end of the crest, the computed and observed depths agree quite closely for both sets of observations.

There is an apparent discrepancy in the observed depth for the two dates. The discharge on May 26 was 10 380 sec-ft., and that on June 12, 9 500 sec-ft., yet the observed depths were greater on the latter date. It is probable that the second set of measurements is more reliable. According to Mr. Steward, in the first set the water-surface elevations in the channel were obtained by lowering the weight from the cross-wire to what appeared to be the average surface elevation and then taking the angle to the weight with a transit. There was, he states, a possibility of error in this method due to the continual splashing and wave motion which caused the weight to swing if lowered too far. The weight was more or less hidden by the spray. The second set of measurements was made more carefully, advantage being taken of the experience gained in the first trial. The distance and angle to the weight were measured while the weight was at a sufficient height above the water surface to be out of the spray. The weight was then lowered to what appeared to be the mean elevation of the water surface by paying out additional cord, the length of cord paid out being measured. It will be realized that great accuracy was not possible in either case. An idea of the turbulent conditions of flow is afforded by Figs. 26, 27, and 28.

In computing the theoretical water surface profiles it was necessary to proceed as in the case illustrated in Fig. 8. The control points were near the upper end of the channel. An interesting theoretical situation appears to exist near the down-stream end of the crest in both experiments. It is not possible to follow the flow through to the end of the inflow section without a hydraulic jump. The theoretical jump apparently lies within the observed water prism. There are many complicating influences at this part of the channel, and any attempt to make accurate computations appears useless. Among other things the horizontal curvature of the spillway channel gives the inflow a component velocity in the direction of the channel, and, furthermore, a complete admixture of the last incoming water with channel flow

probably is not accomplished for some distance. The approximate locations of the theoretical jumps are shown on Fig. 25.

Apparent Swell.—At the time the tests were planned it was thought that by observing velocities of flow in the channel an estimate of the volume of entrained air could be obtained. The only available method of measuring these velocities was by means of surface floats. The velocity being variable, it was necessary to time the floats at numerous points along the channel. The number of observers was not sufficient to permit the timing of a single float at all required points. The time of passage from the upper end of the channel to each of the various stations was determined separately by different floats, and the velocities for the various reaches were found by taking differences of these time intervals. No great dependence can be placed on the results. Even if the surface velocity along a given line were definitely known, it would give very little idea of the actual average velocity. A comparison of the mean velocity computed from observed depths with the surface velocity from floats gave apparent air contents of from —4% to +130% of the volume of water. The variations were erratic.

The results are shown in Table 4, as is also the swell obtained from a comparison of the observed and computed water prism areas. It is believed that the percentages of swell shown are higher than need be provided for in design.

* Numbers of observation stations, not distances. (See Fig. 29.) Values show very rough approximations.

Approach Velocity to Crest.—The observed surface velocities and the approach velocities to the weir crest are shown on Fig. 29. The approach velocity measurements were taken on June 12, 1923, from Pier 5. The velocity of approach is affected by the contour of the reservoir floor near the crest and by the position of a log boom up stream from the crest. It is not the same for all stations along the crest.

Shape of Upper Nappe.—An interesting result of these observations is shown on Fig. 30. One of the simplest problems in experimental hydraulics would appear to be the determination of the path of a jet over a sharp-crested

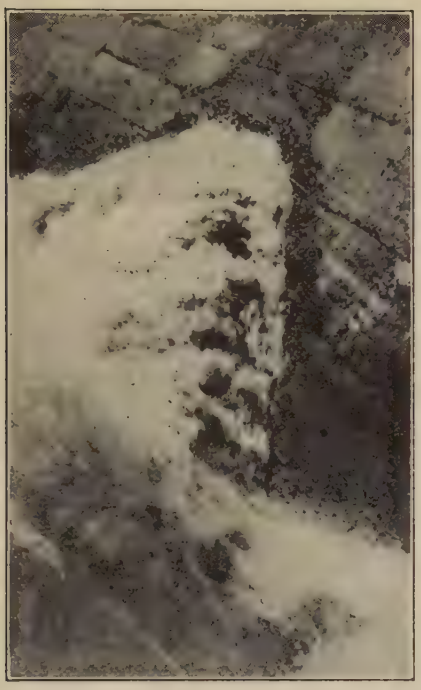

FIG. 26.—ARROWROCK SPILLWAY, JUNE 12, 1923, LOOKING DOWN INTO CHANNEL FROM PIER 1.

FIG. 27.—ARROWROCK SPILLWAY, JUNE 12, 1923, LOOKING UP CHANNEL FROM DOWN-STREAM END.

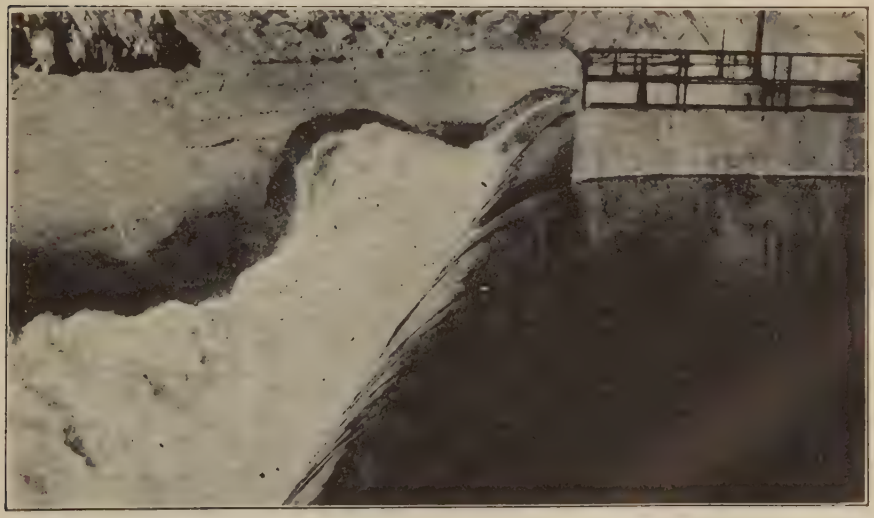

FIG. 28.—ARROWROCK SPILLWAY, JUNE 12, 1923, LOOKING UP STREAM FROM PIER 4.

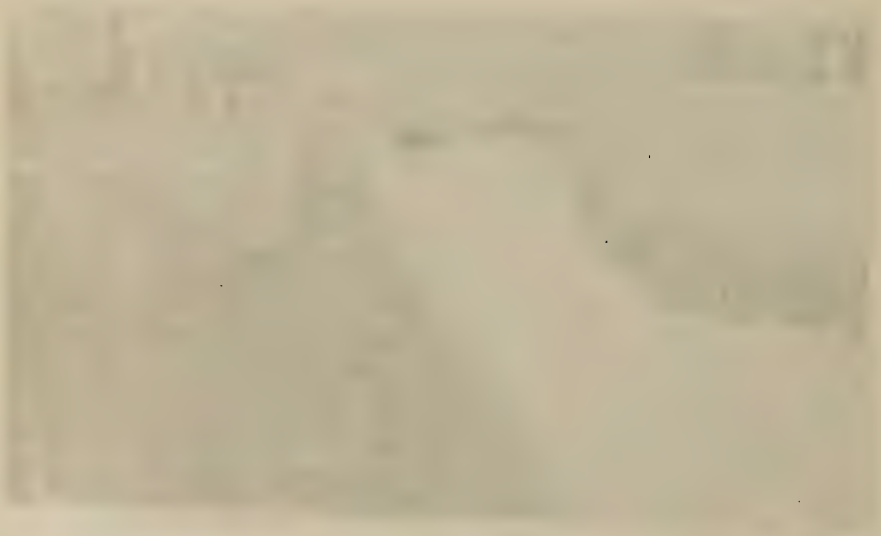

weir, yet practically nothing toward this end has been done. Measurements out to a limited distance were made by Bazin, and various writers have theorized about the subject, generally using these measurements as a basis, with the widely varying results shown in the diagram. The trajectories shown are not all based on identical assumptions, and in order to plat some of them it was necessary to make certain interpretations which may not agree with the original intentions of the various authors. The majority of

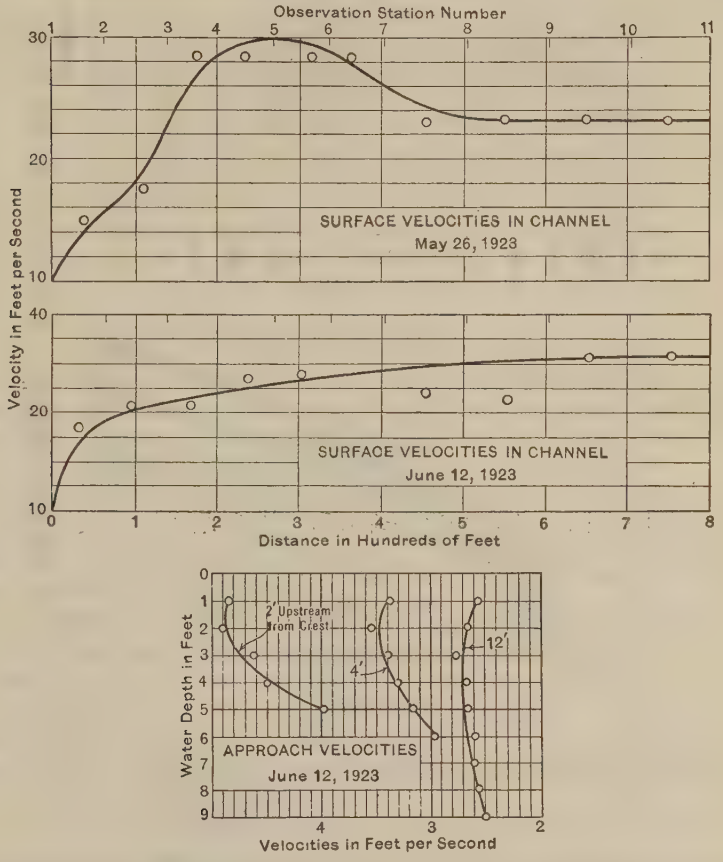

FIG. 29.—EXPERIMENTAL DATA, ARROWROCK SPILLWAY. SURFACE AND APPROACH VELOCITIES.

the curves are based on an assumed sharp crest with a vertical up-stream face. These curves are presented, not as a criticism of any of the theories proposed, but to show the lack of definite information on the subject. Mr. Steward was fortunate enough to obtain measurements of the upper nappe for both measured flows at Arrowrock. The observed nappe for June 12 is shown superimposed upon the theoretical curves for comparison. In order to avoid too great confusion the observed nappe for May 26 is platted separately.

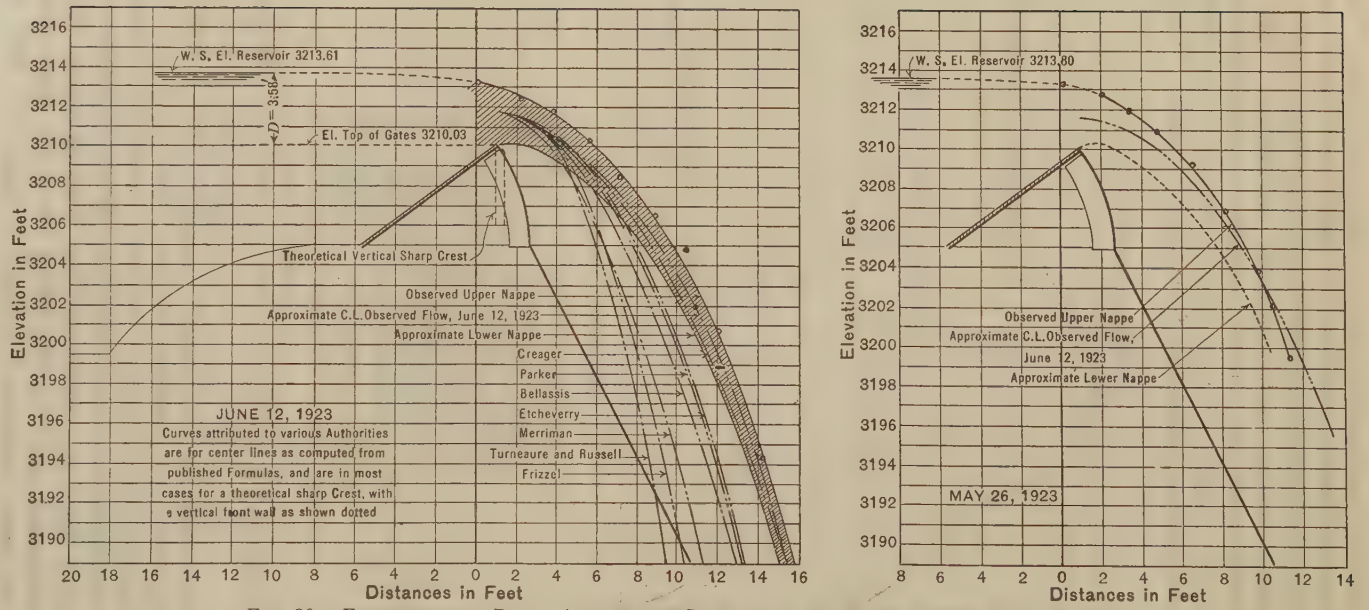

FIG. 30.—EXPERIMENTAL DATA, ARROWROCK SPILLWAY. SHAPE OF NAPPE, MAY 26 AND JUNE 12, 1923.

Although the discharge on May 26 was greater than that on June 12, the trajectory for the latter date is the flatter of the two. The first observation was made at Pier 3 and the second at Pier 5, where the velocity of approach appeared to be greater. Mr. Steward thinks this accounts for the discrepancy between the two nappes. The observed points are indicated on Fig. 30 by circles. The lower nappe curves shown are estimated.

The experimental nappe for June 12 conforms closely to that proposed by Creager, the most conservative of all the theoretical maps. When it is remembered that the economy of an overflow dam is often largely influenced by the thickness required to prevent the jet from leaving its surface, the importance of pursuing this problem further will be appreciated.

Experiments by J. W. Ellms

A situation similar to side-channel spillway flow is found in the design of wash-water troughs for rapid sand filters. A discussion of this problem, by C. N. Miller, Assoc. M. Am. Soc. C. E., has been published.*

Mr. Miller develops a theoretical formula based on the energy equation, and containing an undetermined factor for what he calls friction. This factor, which is expressed as a percentage of the velocity head, includes the friction of the channel and the internal friction, or impact loss.

The mathematical discussion appears to be correct. In order to simplify the formula deduced, the assumption is made that the water surface curve is parabolic, making the average effective fall throughout the trough length equal to two-thirds of the total fall.

It is evident from the general discussion of the problem given in this paper that in many cases this assumption may be incorrect. However, it is probably applicable, within the necessary limits of accuracy, to the particular problems discussed by Mr. Miller.

Applying the theoretically derived equation to some experimental data obtained by Mr. Ellms at the Cincinnati, Ohio, Filtration Plant, a value of 0.75 of the velocity head was found for the friction or impact coefficient.

A coefficient found in this way is applicable only to the conditions under which the experiments were conducted, the loss by shock being dependent on the distribution of velocities throughout the length of the trough, rather than on the velocity at the outlet end.

Mr. Miller's formulas are designed for rectangular channels and are not directly applicable to the results obtained at Bellvue. However, the net loss can be found by subtracting the velocity head from the average fall, which latter is obtained from the water-surface curve. The average ratio of impact and friction loss to velocity head at $x = 16$ ft., for the 15 runs at Bellvue, is about 0.375, or about one-half the value found at Cincinnati.

* "Water Purification," by J. W. Ellms, M. Am. Soc. C. E., Appendix B, 1917 Edition.

DISCUSSION

C. H. Howell,* M. Am. Soc. C. E. (by letter).—The writer believes Mr. Hinds has successfully solved a complicated hydraulic problem of considerable economic importance and scientific interest. To design a spillway properly is often more difficult than to design a dam. This is especially true with very large discharges. A rational method of analysis and design such as this paper presents will be valuable to engineers.

The confirmation of the theory by the Bellvue and Arrowrock experiments will increase the confidence of those using it. As the author states, this type of spillway is rather inefficient hydraulically and is best suited to moderate discharges. The writer's experience leads him to believe that large discharges, exceeding 20 000 to 25 000 sec-ft., can be handled much more economically by spillways with gates placed normal to the channel. The economy increases rapidly as the discharge increases above 25 000 sec-ft. With a gate or gates placed at the upper end of and normal to the channel, the velocity at the gate can be either maintained or increased by a proper slope. The large losses due to impact, inherent in the side channel spillway, are thus avoided.

The side channel spillway, however, lends itself well to the installation of segmental drum crests. These crests, as developed by the U. S. Bureau of Reclamation, are positive in their automatic action. With earth or loose rock dams a large part of the total spillway discharge should have automatic control. The value of the automatic feature of the drum crests may sometimes offset the inefficiency of the side channel spillway.

In designing the Guernsey Dam, on the North Platte River, the Bureau of Reclamation was confronted with the problem of discharging 80 000 sec-ft. past a gravel-fill dam about 100 ft. high. Automatic control for 30 000 sec-ft. was assumed. This is about the maximum discharge in 34 years of record. The side channel type of spillway was tried in various forms and abandoned on account of its excessive cost. The final designs contain some unusual features. The discharge of 30 000 sec-ft. is controlled by two automatic segmental steel drum crests, each 64 ft. long and 14.5 ft. high. These drums discharge into a vertical circular shaft 31 ft. in diameter which, in turn, discharges into a diversion tunnel 30 ft. in diameter. The method proposed by Mr. Hinds was used in designing this structure. This spillway is on the south side of the river. On the north side an open, concrete-lined channel, 34 ft. wide on the bottom and with ½ to 1 slopes, is controlled with one gate which is 50 ft. square in the clear and is the largest in the United States. It is exceeded materially in size, however, by some in Europe. This spillway will pass 50 000 sec-ft. without a raise in the reservoir water surface, and about 70 000 sec-ft. before the dam is overtopped.

H. B. Muckleston,† M. Am. Soc. C. E. (by letter).—The author has not pointed out the great influence which spiral flow in the channel may have on the magnitude of the swell ratio.

---

* Engr., U. S. Bureau of Reclamation, Denver, Colo.
† Cons. Engr., Vancouver, B. C., Canada.

The "peculiar air condition" noted on page 913 was to be anticipated. Owing to the manner in which the increment water is delivered to the channel, the water in the channel tends to flow in spiral stream lines; and any entrained air bubbles, being lighter than the water, naturally seek the region of least centrifugal force, like the oil in a rifled pipe line. Some of the air bubbles are constantly escaping from the free surface; but as more air is being added all along the line, the total air in suspension should remain sensibly constant or even increase somewhat. As soon as the air supply ceases, the "rope" dissipates quickly.

The "rope" is merely visible evidence of a condition which exists all through the mass of water in the channel so long as the flow is spiral. Below the center of the spiral the centripetal tendency due to spiral flow is assisted by the tendency of the bubbles to float; above the center, the two tendencies are opposed, and there will be a region where the resultant tendency is zero. Inside this region the resultant tendency is toward the center. Just as large bubbles rise faster in still water than small ones, so the large bubbles, in the case of spiral flow, find their way more quickly to the center, if inside the critical region, or escape from the free surface, if outside it, than small ones. It is probable that the critical region is farther from the center for large bubbles than for small ones; but, in any event, a condition of spiral flow, by retaining the larger bubbles which would otherwise escape quickly, is favorable to a high content of entrained air and a consequent high swell ratio.

It may be doubted if the effects of spiral flow can be calculated. They are likely to be the greater as the average width approaches the depth and the side slopes become steep. A wide shallow channel, besides being unfavorable to spiral flow, has a greater surface area from which air can escape. If the effects should prove objectionable in a constructed channel, they can be mitigated by building a few shallow ribs on the floor and far wall of the trough parallel to its axis. These ribs will also help in reducing the surges up the far wall.

The author's mathematical treatment of the problem is very neat and the resulting formulas will probably be ratified by experience as closely as engineers have learned to expect in similar treatment of other hydraulic phenomena. The premises do not cover all the conditions, so the formulas will not predict all the results. The calculated surface profile will probably take care of the impact losses, and a few per cent. added to the calculated areas will care for the friction and other losses. The swell due to spiral flow is likely to be high but can not be calculated, and is an additional reason for a generous factor of safety in fixing the dimensions.

I. GUTMANN,* Assoc. M. Am. Soc. C. E. (by letter).—The following is a partial list of dams with spillways of the type discussed in Mr. Hinds' paper:

	Date of construction.		Date of construction.
Solingen, Germany	1902	Rochebut, France	1909
Queille, France	1904	Cold Springs, Oregon	1910
New Croton, New York City Water Supply	1906	Conconully, Washington	1910
Wachusett, Boston, Mass., Water Supply	1906	Croton Falls, New York City Water Supply	1910

* New York, N. Y.

	Date of construction.		Date of construction.
Sweetwater, San Diego, Calif., Water Supply	1911	Klingenberg, Bohemia	1914
Ashokan, New York City Water Supply	1912	Cedar Lake, Seattle, Wash., Water Supply	1915
Mauer, Germany	1912	Morena, San Diego, Calif., Water Supply	1915
Oakley, Idaho	1913	Arrowrock, Idaho	1915
Moehne, Germany	1913		

This list shows that the side channel type of spillway is extensively used in the United States as well as in Europe. In fact, it is usually the most appealing solution in cases where the dam site is in a canyon and a properly located saddle in the rim of the reservoir is not available.

Mr. Hinds' paper presents, as far as the writer knows, the first systematic analysis of this subject in American technical literature. The paper is confined principally to the analysis of one characteristic of flow in side channel spillways, namely, that the total discharge at any section is a linear function of the distance, x, from the head of the channel or, in mathematical terms, $Q = bx$.

It may be stated that the type of discharge expressed by this equation is not characteristic of side channel spillways only. In general, it applies also to the discharge of a drain passing through uniformly porous soil, an infiltration gallery through uniform gravel, etc., and by changing its sign to read, $Q = -bx$, it will give the equation of flow in a channel subject to uniform seepage losses.

Some of the specific and very perturbing problems in the design of side channel spillways are not discussed in Mr. Hinds' paper. The writer has in mind particularly the phenomena caused by the change in direction of flow of the over-falling nappe from normal to axial with reference to the weir. It is hoped that the observations and experiments described by Mr. Hinds will be extended to include studies of the transverse surface curve in the spillway channel, the extent of the effective area of the spillway channel, hydraulic jump, and other phenomena arising from the change in direction of flow.

A. J. Wiley,* M. Am. Soc. C. E. (by letter).—Mr. Hinds has given a complete and clear exposition of the hydraulics of the side channel spillways that have been used in a number of important dams.

Often the spillway is the most difficult part of a dam to design and one of the most expensive to construct. The side channel spillway, as Mr. Hinds correctly states, is best suited for moderate discharges, but it has been used for flood discharges of 75 000 sec-ft. Unless the protected channel is extended to deliver the water back into the river, the concentration of such a large volume in a comparatively small channel, with the resulting high velocities, may cause extensive erosion the deposits from which disturb the river flow below the dam. The channels of the Arrowrock and the Don Pedro Spillways both end a few hundred feet below the dam in a vertical drop over the unpro-

* Cons. Hydr. Engr., Boise, Idaho.

tected canyon slopes from which the water finds its own way back into the river.

The formation at Arrowrock at the end of the channel is a rather soft granite. The erosion was quite rapid at first and the resulting deposits caused a local rise in the river bed. It soon created a vertical fall at the end of the lined channel from which the discharge flows in an eroded channel which joins the river several hundred feet below the toe of the dam. The conditions are stabilized for ordinary flood conditions, and future erosions except for extreme flood discharges will be negligible.

At the Don Pedro Dam, where the drop from the reservoir surface to the river below the dam is about 275 ft., the rock is a very hard diorite with many surface seams. At first there was quite extensive erosion of the large blocks of seamy surface rock with a discharge of 15 000 sec-ft., the deposit of which in the river channel caused a rise of about 20 ft. in the back-water at the dam. In this case, as in the Arrowrock Dam, the conditions soon became stabilized and further erosion will be negligible for ordinary flood discharges.

The spillway of a storage dam discharges only a small part of the river flow, the major part being drawn off through the regulated discharge of the irrigation or power outlets; but it is necessary to make spillway provision for the maximum unregulated flood discharges.

The chief objection to the channel type of spillway is the difficulty of protecting the channel lining against upward pressure. Usually the channel is cut out of the solid rock, beginning, perhaps, 500 ft. above the dam and is about 20 ft. wide and 20 ft. deep. It gradually increases in dimensions until, when it passes the end of the dam, it is, in the case of the Don Pedro Dam, 70 ft. wide and 50 ft. deep. Concrete lining is necessary to avoid erosion at the high velocities obtaining, but the cost of the thickness required to resist the full upward pressure from the reservoir is prohibitive and dependence must be placed on under-drainage to carry off the water that finds its way through the seams in the rock, the quantity of which is uncertain. In the Don Pedro Spillway channel, a part of the floor was raised by the excess of the under-pressure over the relief provided. The concrete lining was replaced and about 450 bbl. of cement were used in pressure grouting the rock floor of the channel although it was from 20 to 50 ft. below the surface of the rock excavation.

In many cases the safest and cheapest spillway is directly over the top of the dam. This form is embodied in the design of the Melones constant radius arch dam, 200 ft. high above the river level. In many storage dams, an important source of revenue is found in the development of water power from the flow as regulated for irrigation. As this is "seasonal" power, it must be cheaply developed in view of its low market value. The lowest development cost usually results from building the power plant directly at the toe of the dam, as at the Don Pedro Dam. At the Exchequer Dam, where the river is raised 325 ft. above its old level, the power plant is built in the river channel at the down-stream toe. A modification of the side channel spillway is made by converting each end of the regular gravity type dam into an overflow section. These two overflow sections take the place of the single long lip, or weir, above

the dam which feeds the ordinary type of spillway channel. The discharge from each of the overflow sections of the dam is carried in a concrete-lined channel, symmetrically located on either side of the canyon, leaving the toe of the dam at the end of the overflow section and discharging into the river down stream from the power house.

Instead of determining the hydraulics of the spillway channel by the method outlined by Mr. Hinds, the writer has been accustomed to use a much less direct method; instead of adopting the most economical shape, he has used a broader and shallower section in which the velocities are relatively low and the danger of uplift under the floor is reduced.

Starting with a considerable submergence of the spillway lip at the upper end, assumed velocities and bottom widths are adopted, increasing by regular increments along the spillway section of the channel. Using assumed side slopes the depth at any point is calculated for the quantity of water at the point with the assumed velocity. The fall in water surface necessary to give the assumed velocity is found by considering that the velocity at the first of any two successive points is reduced at the second point to the same proportion of that at the first point as the discharge at the first point is to that at the second point. The head required to increase the velocity thus reduced up to the required velocity at the second point plus the sum of the velocity heads and friction heads of the first point plus the friction head between the two points then gives the total fall in water surface up to the second of the two points. To provide for the increase in volume by entrained air and for the losses caused by shock and eddies, an arbitrary addition of 25% is made to the required flood discharge.

Ivan E. Houk,* M. Am. Soc. C. E. (by letter).—The writer believes that Mr. Hinds' thorough and practical solution of the side channel spillway problem will be of great value to designing engineers throughout the world. So far as he knows, no adequate treatment of the problem has ever before been published, either in the United States or abroad, although some rather brief discussions of the subject have been given in certain foreign books on dams and reservoirs. That no comprehensive treatment has previously been published seems rather strange considering that this type of spillway is not uncommon and that the safety of the dam itself, especially one of the earth type, is contingent on the proper functioning of the spillway.

A few years ago the writer had occasion to inspect the remains of an earth dam the safety of which had been dependent on a side channel spillway. The length of the spillway crest was reasonable for the size of the drainage area involved, but the side channel was not deep enough to carry the water away from the spillway, despite the fact that considerable submergence could occur before the spillway discharge was reduced appreciably. This condition, together with the fact that little free-board had been provided, resulted in the overtopping of the dam and its complete failure. In this one instance, alone, several lives and several hundred thousand dollars worth of property might have

* Engr., U. S. Reclamation Service, Denver, Colo.

been saved if Mr. Hinds' method of analysis had been available for the designer's use.

The unusually high losses that occur in the side channel spillway are due to the impact of the spillway discharge with the flow in the channel, as Mr. Hinds explains. If the topographic conditions are such that the spillway discharge can be led directly away from the apron, into a gradually converging and curving channel, the direction of flow probably can be changed through an angle of 90°, from a direction normal to the spillway crest to a direction parallel with the spillway, with relatively small losses. The large impact losses will thus be avoided and probably some of the velocity head attained in falling over the spillway will be conserved. It is doubtful whether the loss caused by curvature in open channels ever amounts to 100% of the velocity head in the case of 90° bends. At any rate, that was the conclusion reached by the writer some years ago, after making careful experimental determinations of losses in curves in open channels carrying discharges of from 200 to 70 000 sec-ft. at velocities of from 2 to 10 ft. per sec. The controlling factor in spillway location, however, is not the magnitude of the losses in the spillway channel, but the total cost of an adequate structure. In many instances the cost of a side channel spillway, with proper provision for the large losses involved, will be less than that of any other type.

Figs. 16, 17, 18, and 25, which illustrate the experimental work at the Bellvue Laboratory and at the Arrowrock Dam, might have been improved by showing the actual platted water surface elevations. The photographs in the paper show that in several runs the water surface was comparatively rough, and, therefore, the reader may wonder how accurately the surface curves were determined and how widely the individual observations varied from the smooth curves shown. The writer knows that the curves were accurately determined and that the variation of the measured points from the curves was not excessive, inasmuch as it was his privilege to assist Mr. Hinds in the Bellvue experiments. The matter is simply mentioned for the benefit of those who may be interested.

The Engineering Profession undoubtedly will accept Mr. Hinds' solution of the side channel spillway problem, as it stands. The theory is based on one of the best established laws of physics; the results of the laboratory experiments at Bellvue show substantial agreement with the theoretical formulas; and the results of the field tests on the full-sized structure at the Arrowrock Dam remove all doubt as to whether the theoretical formulas found to be applicable to small-sized laboratory models will apply to full-sized structures in actual practice.

J. C. Stevens,* M. Am. Soc. C. E. (by letter).—This is a most excellent presentation of an intricate hydraulic problem. If the fundamental basis of the author's mathematical analysis be accepted, that the water overflowing the spillway crest has no kinetic energy in the direction of continued motion, then his conclusions must be accepted for they follow rigidly therefrom. The author states his hypothesis a little more generally in observing that when two streams

* Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

of water at different velocities come together and flow away together the energy of impact is lost.

In order to test the soundness of this hypothesis the Special Committee on Irrigation Hydraulics has arranged for certain experiments at the Hydraulic Laboratory at Berkeley, Calif., that are now (December, 1925) under way. These experiments are under the direction of B. A. Etcheverry, M. Am. Soc. C. E., and B. A. Vanleer, Assistant Professor of Mechanical Engineering, University of California, who is in immediate charge of the Laboratory. It is also hoped that other experiments with the same object in view will be conducted at the Hydraulic Laboratory of the Oregon Agricultural College at Corvallis, Ore., under the immediate direction of H. S. Rodgers, Professor of Hydraulics.

These experiments will endeavor to determine the head lost by impact and eddies when two streams of water intersect at right angles in pipes. Pipes are being used in preference to open conduits because greater heads can be secured and the water is free from entrained air.

The writer submits herewith the mathematical treatment of the hydraulics of intersecting pipes, based on the theory in the paper. If the experiments prove the correctness of the formulas herein the theory may be accepted as sound. Let two pipes flowing full under pressure intersect, as shown in Fig. 31.

Let d = inside diameter of the pipe;
a = area of pipe;
p = pressure head;
Q = flow;
v = mean velocity;
h = velocity head;

r = ratio of initial discharges $= \frac{Q_1}{Q_2}$;

z = ratio of areas, $\frac{A_2}{A_3}$; and

i = energy lost in eddies and impact, for brevity called the eddy loss.

All the quantities are expressed in consistent units; the subscripts in the equations denote the pipe involved.

The momentum of the water in Pipe (1) has no component in the final direction of flow. At the junction the pressures are equal, that is,

$$p_1 = p_2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

The change of pressure is equal to the change of momentum from Pipe (2) to Pipe (3), hence the relation,

$$(p_2 - p_3)\, a_3 = \frac{Q_1 + Q_2}{g}\, V_3 - \frac{Q_2}{g}\, V_2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

which reduces to,

$$p_2 - p_3 = 2\,(h_3 - z\,h_2) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

The equation for lost energy is:

$$(Q_1 + Q_2)\, i = Q_1\,(p_1 + h_1) + Q_2\,(p_2 + h_2) - (Q_1 + Q_2)\,(p_3 + h_3) \ldots (29)$$

Substituting from Equation (28) in Equation (29) and reducing, the loss in terms of velocity heads becomes,

$$i = h_3 + h_2 \left(\frac{1}{r+1} - 2z \right) + h_1 \frac{r}{r+1} \quad \ldots\ldots\ldots\ldots (30)$$

When the pipe diameters are in the ratio 3, 4, and 5, that is, when, $a_1 + a_2 = a_3$, Equation (30) reduces to:

$$i = 2h\,(1 - z) = p_2 - p_3 \quad \ldots\ldots\ldots\ldots\ldots\ldots (31)$$

This is obvious since there is no change of mean velocity, the total change of pressure being used in supplying the eddy loss.

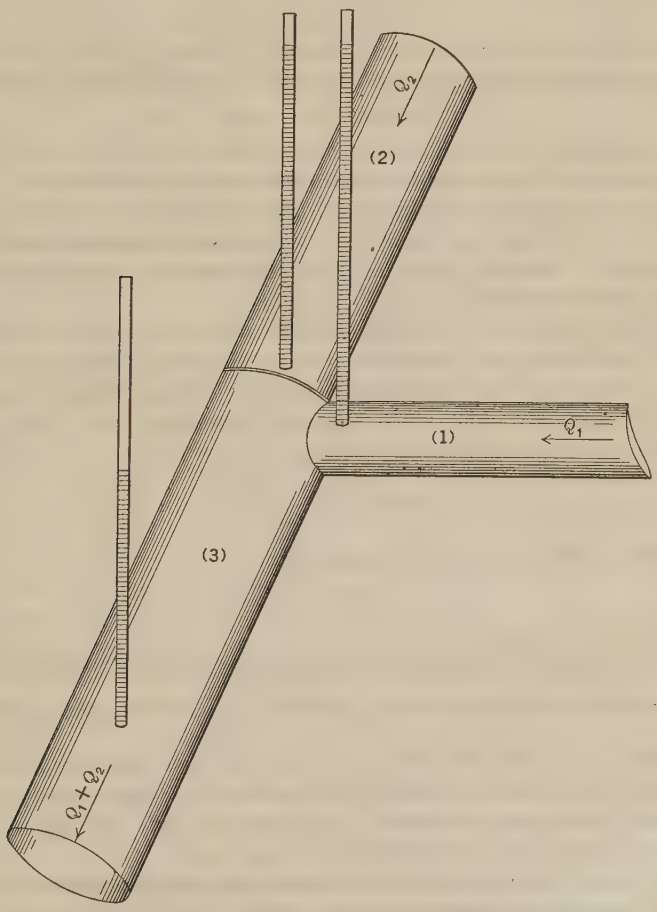

FIG. 31.

If $a_2 = a_3$, Equation (28) becomes:

$$p_2 - p_3 = 2\,(h_3 - h_2) \quad \ldots\ldots\ldots\ldots\ldots\ldots (32)$$

that is, the change of pressure is twice the change of velocity head. In this case the eddy loss is:

$$i = h_3 - \frac{2r + 1}{r + 1} h_2 + \frac{r}{r + 1} h_1 \quad \ldots\ldots (33)$$

When Q_1 is zero, r becomes zero and Equation (30) reduces to:

$$i = \frac{(V_2 - V_3)^2}{2g} \quad \ldots\ldots (34)$$

which is the eddy loss in a sudden enlargement.

If Q_2 is zero, Equation (27) reduces to:

$$p_1 - p_3 = 2h_3 \quad \ldots\ldots (35)$$

and the eddy loss is:

$$i = h_1 + h_3 \quad \ldots\ldots (36)$$

which gives the loss in a right-angle bend. If Pipes (1) and (3) are of the same size the velocity is constant and the loss is twice the velocity head, or,

$$i = 2h = p_1 - p_3 \quad \ldots\ldots (37)$$

This is comparable with Equation (31) under conditions of no change in velocity, the entire drop of pressure going to supply the eddy loss.

These formulas do not take account of friction losses. In order to isolate the eddy losses the friction losses must be calculated separately and deducted from the drop in pressure between the junction and the point below it where the average pressure in the pipe is a maximum.

The writer knows of no reliable experiments on the losses in right-angle bends, although there are a number on curves in pipes. The experiments by Mr. W. H. Archer* show that the loss in sudden enlargements is very close to that indicated by the well-known formula, Equation (34). He found the actual losses to be more nearly represented by the formula:

$$i = 1.098 \frac{(V_2 - V_3)^{1.919}}{2g} \quad \ldots\ldots (38)$$

and that the coefficient, B, in the expression,

$$i = B \frac{(V_2 - V_3)^2}{2g} \quad \ldots\ldots (39)$$

varied with entrance velocity, V_2, and the ratio of areas, from 0.75 to 1.2; and that, for velocities of 6 ft. and more, and for $z = \frac{1}{2}$, or less, the coefficient, B, is less than 1, showing that the actual loss in such cases is less than the theoretical. Mr. Archer attributes this to the "dead" water at the point of enlargement acting as a diffuser. Professor F. W. Medaugh, of Johns Hopkins University, takes† issue with him in this.

If the "dead" water, or eddies, in sudden pipe enlargement or in a right-angle bend, can act as a diffuser then the eddies in a side channel spillway can perform the same function and all the energy of impact is not lost as the author assumes. The Committee awaits the results of the experiments at Berkeley

* *Transactions*, Am. Soc. C. E., Vol. LXXVI, (1913), p. 999.

† *Engineering and Contracting*, January 10, 1923.

and Corvallis, previously mentioned, with interest, hoping that they will throw light on this fundamental principle.

In this connection the writer observed that curved metal vanes had been placed on the crest of the side channel spillway of the Sweetwater Dam near San Diego, Calif., the object being, of course, to give the overflowing water a down-stream direction and thus reduce eddy losses that would otherwise occur. It would be interesting to know whether any measurements have been made of the efficacy of these vanes.

Mention may be made of the tests on models of the side channel spillways of the Burrinjuck Dam* on Murrumbidgee River in New South Wales. These were originally designed to pass a flood of 40 000 sec-ft. While the dam was under construction in 1916 a flood of about 65 000 sec-ft. passed over the works. Because of this, models were built and tests made to ascertain whether increased capacity could be secured within the limits of practicable construction. As a result the south spillway was lengthened and then both spillways were deepened more than the original plans indicated, to take a flood corresponding to that of 1916 under a head of 10 ft. on the two spillways. In May, 1924, the greatest flood of record occurred. The water rose until the head on the spillways was 19.3 ft., the parapets of the dam being overtopped 3.3 ft.† The paper does not contain sufficient data to enable comparisons to be made of the model tests and the author's analysis.

The Committee also hopes to secure in due time actual tests on the side channel spillway of the Rimrock Dam of the U. S. Bureau of Reclamation, on Tieton River, Washington, and also on that of the Lake Fordyce Spillway of the Pacific Gas and Electric Company of California.

Julian Hinds,‡ M. Am. Soc. C. E. (by letter).—It is pleasing to note that the hydraulic principles proposed for the design of side channel spillways are generally accepted, with only a sufficient spirit of misgiving to insure the continued study of the problem. The explanations and improvements offered form a valuable addition to the paper.

The discussion by Mr. Muckleston of the "air rope", and his statements in regard to the effect of spiral flow, are interesting. From the statements made it might be inferred that the spiraling of the water around the axis of the channel, caused by the initial transverse velocity, is likely to increase the volume of flow materially. This probably should not be definitely accepted without proof. The statements in regard to the retention of air seem reasonable, and the spiral flow probably does tend to hold a part of the entrained air in the stream. However, it also promotes a rapid intermingling of particles, and tends to give a more nearly uniform axial velocity at any cross-section. A wide shallow channel would show a poor velocity distribution, which might more than offset the advantage resulting from the ready release of air. These spirals, or other equivalent trans-axial motions, are necessary for the temporary storage of the non-usable kinetic energy of the initial transverse motion,

* "The Spillways of Burrinjuck Dam," by Henry Harvey Dare, *Minutes of Proceedings*, Inst. C. E., Vol. CCXIV, Session 1921-22, Part II.

† *The Illustrated London News* of July 18, 1925, contains photographs of this flood.

‡Engr., Bureau of Reclamation, Denver, Colo.

while it is being converted into heat. In a compact channel it is probable that the spiral action is more uniformly distributed to all the water particles, and is less violent. Under normal operating conditions there appears to be no tendency for the water to surge up the back wall of the channel.

The question raised is important and should be carefully considered in all future experimentation. Special attention should be given to "velocity swell" in the proposed laboratory tests in pipes. The fact that the mathematical treatment applies to the average velocity, and not to the mean velocity, as ordinarily computed, must be kept constantly in mind.

Mr. Wiley also advocates a wide shallow channel, for mechanical reasons. A deep gash through the foundation adjacent to the end of the dam is without question objectionable. With a deep channel the structure supporting the spillway crest, which separates the channel from the reservoir, assumes formidable proportions, and an elaborate drainage system is required to avoid destruction of the channel lining by uplift. Some advantage may also result from the lower velocities that prevail in a wide channel. In addition a wide thin sheet of water is likely to be less destructive at the point of final discharge than a concentrated jet. Considered from this point of view, the channel should always be made as wide as conditions permit. However, if the hillside is steep the cost of a wide channel is likely to exceed greatly the cost of the protective measures necessary to make a deep channel safe. The cost of a wide shallow channel at a location, such as that existing at the Tieton Dam, on the Yakima Project, Washington, for example, would be prohibitive.

Apparently the method used by Mr. Wiley for computing the hydraulics of the channel will give results essentially identical with those obtained by the writer.

The partial list of side channel spillways given by Mr. Gutmann is interesting. The Don Pedro Dam, in California, the Tieton Dam, in Washington, and the McKay Dam, in Oregon, are notable additions to the list.

Mr. Houk and Mr. Howell both offer alternative plans designed to escape the losses involved in the side channel spillway. Mr. Howell would use a deep, narrow, spillway notch, directed down stream, and controlled by a large Stoney gate. Mr. Howell's opinion that this is in all cases more economical than a side channel type is doubtless justified, and the advantages of a Stoney gate installation should be investigated wherever that type of control is considered adequate. The writer would not consider a Stoney gate spillway safe for the condition of a high earth dam in a heavily timbered region like that surrounding the Tieton Reservoir, for example.

Mr. Houk's suggestion that under favorable circumstances an advantage may be gained by curving the channel is believed to be sound. However, curvature of the main channel will not necessarily avoid impact loss, but by providing a means for reaction against the earth may make it possible to utilize a part of the energy of the transverse velocity.

It is possible that confusion sometimes results from the usual and convenient practice of speaking and thinking of eddies as causing losses of head. Under certain conditions it is impossible to maintain a balance between

kinetic energy and static head without violating either the laws of motion or the law of conservation of energy. The situation is met by converting a part of the kinetic energy into heat. This transfer can not occur instantly, and the condemned kinetic energy is stored temporarily in transverse motions which disappear as the water "warms up." The eddies are thus the result rather than the cause of the loss of head.

Mr. Stevens, near the end of his discussion, makes the following statement:

"If the 'dead' water, or eddies, in sudden pipe enlargement or in a right-angle bend, can act as a diffuser then the eddies in a side channel spillway can perform the same function and all the energy of impact is not lost as the author assumes."

There are many secondary hydraulic problems in connection with side channel spillways which have not been solved, and for which no data are available. As pointed out in the paper, and in several of the discussions, there are many factors that require further study. However, there is no question as to the existence and approximate magnitude of the impact losses. To question the fact that all the energy of impact is lost is equivalent to questioning the validity of Newton's laws of motion. The mathematical application of the laws of motion to the particles composing a stream of water is simple, but a physical conception of the resultant reactions is difficult. Perhaps some simple illustrative device will be discovered before the study of impact losses is finally dismissed.

Mr. Stevens' statement that his Equation (34) gives the eddy loss in a sudden enlargement, is not self-evident, and, so far as the writer knows, has never been rigidly proven. The so-called proofs usually given involve the assumption, or its equivalent, that the average unit pressure on the shoulder of the enlargement is equal to the unit pressure in the smaller pipe. The fact that under certain conditions the observed and computed losses do not agree is in all probability due to the inaccuracy of this assumption, rather than to any "diffusion" produced by "dead" water.

In discussing the testing of impact losses in pipes, Mr. Stevens proposes to combine the impact and sudden enlargement problems. This is believed to be undesirable. Either problem alone is sufficiently difficult. His Equation (27), and all others dependent thereon, are based on the assumption that the pressure against the shoulder of the enlargement is equal to the pressure in the incoming pipes, the strict correctness of which is not apparent. It is believed that the enlargement should be eliminated from the tests, unless it is desired to extend the study to both these effects, which are distinct. It is believed that the tests at Berkeley, Calif., mentioned by Mr. Stevens, contemplate a main line pipe of uniform diameter.

The interest shown in this paper is gratifying. It is hoped that other discussions of the problem will be prepared for publication after the results of laboratory tests now under way are made public.

Paper No. 1588

PERMISSIBLE CANAL VELOCITIES*

By Samuel Fortier† and Fred C. Scobey,‡ Members, Am. Soc. C. E.

With Discussion by Messrs. H. B. Muckleston, Elbert M. Chandler, Robert S. Stockton, R. A. Hart, R. A. Hill, Jerome H. Fertig, E. S. Lindley, Andrew Weiss, J. C. Stevens, Carl Rohwer, Ivan E. Houk, and Samuel Fortier and Fred C. Scobey.

Synopsis

The use of relative high velocities reduces the cost of canal per unit length. The limit of velocities permissible is somewhat less than velocities that will erode a canal bed. The determination of permissible velocities is not possible from data on transporting velocities or mere non-silting velocities. The presence or absence of colloidal matter is of prime importance. The opinions of irrigation engineers as determined from their experience are given, as well as deductions from available data and the final recommendations of the Special Committee on Irrigation Hydraulics.

Definitions.—Limiting velocity is taken to mean the maximum permissible value of the mean velocity. Although it is obvious that for any water prism the highest velocities are much in excess of the mean velocity, yet the only figure sufficiently tangible, under all conditions, for design and operation is the mean velocity.

Note.—This paper constitutes the Final Report of the Special Committee on Irrigation Hydraulics on this subject, reference to which is made in the Progress Report of that Committee for 1924, *Proceedings*, Am. Soc. C. E., March, 1925, Society Affairs, p. 137.

* Published in *Proceedings*, Am. Soc. C. E., September, 1925.

Silt is not considered as a specific gradation in soil sizes, but as a general term for all material brought into a canal by "muddy" waters. It is usually thought of, even in this sense, as different from sands and gravels. In other words, the "bottom load" is not included in the term as herein used.

Velocity and Canal Length.—As the discharge is the product of area and mean velocity, it follows that the area of the water prism, and, therefore, the approximate area of the channel, must vary inversely with the mean velocity. As the cost of construction per unit length depends on the area of the channel, it is usually desirable to make the mean velocity as high as the material will withstand. The cost of construction also varies with the length of the channel. By increasing the grade of the channel the velocity of water therein is increased and the water prism diminished, but the distance between the irrigable land and the diversion point is increased. If the point of diversion is fixed, a higher diversion dam will be required in order to command the same area of land. This phase of the question requires a comparative study for each location, whereas the purpose of this paper is to indicate maximum feasible mean velocities.

Non-Silting Velocities not Necessarily Scouring Velocities.—The subject of limiting velocities for open channels has usually been treated under a heading combining the silting and scouring of channels. It has been considered that for each depth of water there is a certain velocity below which silt will be deposited and above which silt will be eroded from the bed of the channel. In the opinion of the writers, two phenomena only slightly related are thus confused. The power of flowing water to maintain a movement of separate soil, sand, or gravel particles, has been confused with the power to break the bedding of a canal bottom and ravel off particles of that bed and transport them to places of lesser velocities where they may be deposited. In their opinion there is no sharp line of demarcation between the velocities that can no longer maintain silt in movement and those that will scour a canal bed. It is believed that there is a broad belt of velocities between these two "critical" velocities, within which silt already loosened or brought in through a head-gate will remain in suspension while the bed nevertheless will remain undisturbed as regards scour. It is easy to show the absurdity of accepting the laws of silting as giving the immediate answer to the laws of scour.

Kennedy's Formula.—Certain of the canals of India, served by heavily silt-laden streams, were known to have reached a condition of permanent channel régime, neither silting nor scouring. In 1895, Mr. R. G. Kennedy offered his well-known formula*:

$$V_0 = C\, d^{0.64}$$

in which, V_0 represents the "critical" mean velocity, in feet per second, of a water prism, d ft. in depth, and C is a coefficient. This so-called critical velocity is that for which there was no silting or scouring of the channel. The value of C is usually quoted as 0.84, but this coefficient was applicable for

* *Minutes of Proceedings,* Inst. C. E., Vol. CXIX (1895).

fine sand silt only; other coefficients for heavier materials range up to 1.09 for coarse silt or detritus from hard soils. Using the coefficient, 0.84, Table 1 may be developed.

TABLE 1.

Depth, in feet.	1.	2.	3.	4.	5.	6.	7.	8.	9.
Velocity, in feet per second.	0.84	1.30	1.70	2.04	2.35	2.64	2.92	3.18	3.43

A glance at Table 1 shows the fallacy of accepting these velocities as the lower limit of scouring velocities. Mean velocities of 2.5 to 3 ft. per sec. for general conditions are considered as most desirable in irrigation canals of the United States, yet Table 1 would indicate that a canal 6 ft. deep is the shallowest which would not show scour at the desirable velocities mentioned in that table. Yet even the velocities as tabulated are further modified, according to Bellasis,* who quotes rules attributed to Kennedy to the effect that:

"Near the hills [Northern India] where the bed is of shingle the velocity may exceed V_0. A few other soils will stand 1.1 V_0. In ordinary channels any excess over V_0 will give much trouble lower down. * * * If soil is very poor, especially if the depth of water is more than 6 or 7 ft., the velocity should be less than V_0, say, 0.9 V_0, so as not to cause falling in of the banks * * *."

A comparison between the figures in this quotation and the values of V_0 in Table 1 shows that the velocities resulting from such procedure would not be acceptable to engineers designing and operating canals in the United States. They would be considered much too low.

Dubuat and Gilbert on Transporting Velocities.—Reference to the earlier writings of accepted American authorities shows that they applied the findings of Dubuat to the determination of the permissible velocities for ditches and canals. These velocities are usually less than one-half the velocities now accepted by irrigation engineers. Dubuat made certain determinations of the transporting power of water. In the words of Gilbert "what he really investigated was chiefly competence for flume traction." The "competent bed velocity" as ascertained by Dubuat for various materials is given by Gilbert† as shown in Table 2.

TABLE 2.

	Velocity, in feet per second.
Potter's clay	0.27 to 0.35
Coarse angular sand	0.7 " 1.1
River gravel:	
Size of anise seed	0.35 " 0.53

Although the velocities along the bed of a flume, such as that used by Dubuat, would be less than the mean velocities, still the difference would not be sufficient to account for the great difference between the figures of Table 2 and those given by various authorities as determined from actual practice.

Material Easily Transported Is Difficult to Scour.—Additional evidence against confusing the movement of particles by flowing water with the scouring action of that same water is contained in the following: The finer the soil particles, the slower may be the velocities that will maintain the particles in suspension. In actual practice it is found, as noted in the suggestions given hereafter, that canal beds in stiff clays, classed by soil experts as being composed of particles of 0.005 mm., or less, in diameter, will withstand mean velocities approximating 4 ft. per sec., yet clear sand coarser than granulated sugar will be scoured at velocities of about one-half that, or 2 ft. per sec.

Colloidal Matter.—Some alluvial silts or loams will erode quite easily, when a canal is new, whereas some, of apparently the same size gradation, will not. The difference lies mostly in the presence or absence of effective colloidal matter. Colloids, as applied to soils, give the properties of plasticity, cohesion, toughness when wet, and hardness when dry, that are essential to an erosion-resisting soil. This point is so important that the writers quote extensively from that well-known authority on Western soils, Hilgard:*

"'Colloidal' Clay.—In connection with soils, clay may be defined, in the most general terms, as being the substance which imparts plasticity and adhesiveness to soils when wetted and kneaded, and which, when heated to redness, loses this property completely and permanently, becoming hard and coherent in proportion to the degree of heat to which it is exposed.

"In common life, however, the name is applied to the whole of any naturally occurring earth which on wetting and kneading assumes a reasonable degree of plasticity and adhesiveness. When the latter property becomes nearly or quite insensible, the earth is designated as a 'loam', more or less 'clayey' according to the amount of the pure, plastic and adhesive material associated with the mineral powders and sand that form the bulk of most soils. * * *

"It has of late been attempted to extend the meaning of this word (plasticity) to the behavior of all powders when wetted with water. But the adhesive plasticity of clay stands almost alone, in that (aside from contraction) it preserves in drying the form into which it may have been molded while wet, even when struck, whereas other powdery substances similarly treated at once collapse back into the original powder. The exclusive use of clay in modeling offers the typical example of plasticity as generally understood. The addition of any powdery substance, however fine, diminishes the plasticity of clay. * * *

"Causes of Plasticity.—In any case the property of plasticity and adhesiveness is restricted to the particles so fine that they fail to settle, in the course of 24 hours, through a column of pure water 8 in. high, while some are so extremely minute that they will not settle for many months, and even for several years. Such turbid 'clay water' may sometimes be found existing in nature, in moist, secluded places, for weeks after the subsidence of the

* "Soils," by E. W. Hilgard, N. Y., 1906, pp. 59 *et seq.*

overflows of rivers whose water is exceptionally free from dissolved mineral matter. * * *

"When separated from the water and dried, the jelly-like substance ('colloidal clay') shrinks as extravagantly as would so much boiled starch, into hard, shiny crusts or flakes, which when struck in mass are sometimes even resonant, and bear more resemblance to glue than to the clay of everyday life. Like glue, too, but much more quickly and tenaciously, the dried colloidal clay adheres to the tongue, so as to render the separation painful; when wetted it quickly bulges with great energy, and in a short time resumes its former jelly-like condition. When moistened with less water it assumes a highly plastic and adhesive condition, so that it is difficult to handle and almost as sure to soil the operator's hands as so much pitch."

With this understanding of soil colloids, it is easily seen that great changes may take place in a canal bed after a period of use under the influences of various types of waters. This explains the thought expressed in some of the answers to questionnaires, that old, well-seasoned canals will stand much higher velocities than new ones.

Effective Colloids.—The presence in the water of an electrolyte, such as calcium or carbon dioxide, will flocculate the colloids and partly or completely annul the property of creating cohesion. Therefore, effective colloids are those free from the influence of an electrolyte.

Types of Bedding.—The property of a canal bottom to withstand scour is due to beds of different types, of which the following are examples:

1.—Very fine silty or clayey particles so puddled together that there is distinct cohesion present; a homogeneous mass—the more colloidal matter present, the greater will be the cohesion.

2.—Graded materials, the finer filling the voids of the coarser; ranging from the finest silts to coarse gravel. Such a bed becomes very firmly compacted and will withstand velocities that would erode a bedding composed of any of the constituent particles alone.

3.—Non-cohesive particles, without grading as to sizes. The unit particles may be of "sugar" sand or of cobble-stone size; if free from colloidal silt or graded sizes a canal bed in such materials may come nearest to following what Gilbert terms the laws of "competent velocities."

Original Channel Material Usually Altered by Age.—A study of these types shows that the particular one to which any given canal will belong may or may not be determined at the time of construction. The type may not be determined by the materials excavated for the canal. It is finally determined only after years of use. Two examples will make this clear. The first is indicative of changes caused by the character of the water diverted from the river. The second example will develop under clear mountain waters carrying little or no silt, and is due to the character of the material through which the canals are excavated.

In the Imperial Valley of California many of the large laterals were excavated in a light sandy soil that would have scoured when the canals were new at a velocity of 2½ ft. per sec. The extremely fine silt particles brought in from the Colorado River prior to 1910 compacted and puddled

this sand and plastered it with a coat of slick colloidal mud, so that it would withstand velocities in excess of 5 ft. per sec.; yet the individual particles of this slick mud were so fine that they would remain in suspension at very low velocities, except when the water was "overloaded" with silt—in times of flood on the Colorado River in June and July. All experienced canal operators know the trick of holding muddy water above one check structure after another until the mud has painted over the sides and bottom of a new canal, reducing seepage losses and making the bed of the canal less susceptible to scour.

Many of the mountain valley canals of Colorado, Utah, and other Rocky Mountain States were constructed in loamy gravel soils. The present bottoms of these canals show little indication of loam. At the extreme edges, grass, roots, and low velocities combined have built up vertical banks of fine material, but the bottoms are of well-graded gravel, ranging from pea size to cobble-stones, but all so well compacted and fitted together that a high velocity is feasible, far above that which originally washed out all the loam particles until a gravel paving resulted.

Effect of Velocities on Plant Growth.—The problem of plant growth is an important one in the operation of irrigation canals and deserves special treatment. It is, however, influenced by factors other than canal velocities. More particularly these factors comprise water temperatures and turbidity and character of soil.

Few aquatic plants thrive in the absence of sunlight, therefore, canals carrying turbid waters are seldom bothered with plant growth. In clear-water channels some species thrive in velocities much greater than the channel soil will stand. Other species grow only in sluggish velocities. If, therefore, the highest permissible canal velocities as determined from the standpoint of erosion are provided, all that is possible will have been done to prevent trouble by plant growth as far as fixing velocities are concerned.

Difficulty of Securing Specific Data.—Thus far in this discussion the writers have endeavored to establish the fact that the determination of eroding velocities is a matter of empirical observation on erosion, not on silt deposition, to the time when a particle is broken off from the bed of the canal, the cohesion due to colloidal matter being overcome or the mechanical interkeying of various elements being disturbed. After that takes place, the data of Dubuat, Kennedy, Gilbert, and others may apply. The actual determination of these empirical data has never been attempted, as far as the writers are aware. That is, it has not been considered feasible to increase slowly the mean velocity in a canal of a definite material and thus determine the actual mean velocity at which scouring commenced. The only data available are the facts that certain canals have scoured under relatively high velocities. The magnitude of these high velocities is known from measurements of the canals, but the exact high velocity that started the scour has never been determined. Undoubtedly, a higher velocity is required to start scour than to continue it when once started. Likewise, it is known that certain canals do not scour even if the mean velocity is two to three times

those velocities suggested by Dubuat or Kennedy. It still remains to be determined how much higher a velocity this particular canal would stand before scour commenced.

Hence, at present, the best knowledge of scouring velocities comes from personal deductions as to the performance of individual canals and not from direct experimental work. With this understanding in mind, the Society's Special Committee on Irrigation Hydraulics submitted questionnaires to a number of irrigation engineers whose experience qualified them to form authoritative estimates of the maximum mean velocities allowable in canals of various materials. The questionnaire, as submitted, follows:

"QUESTIONNAIRE ON PERMISSIBLE CANAL VELOCITIES

"This list of questions is submitted by the Special Committee on Irrigation Hydraulics of the American Society of Civil Engineers in order to ascertain the results of experience as to the permissible mean canal velocities in various types of soil under normal operating conditions.

"The Committee will appreciate the results of your experience and observation on this subject.

"1. Name?

"2. To what irrigation system or systems do your answers apply?

"3. What in your opinion is the maximum mean canal velocity permissible without eroding each type of soil according to the following classification:

	Ft. per sec.	Ft. per sec.
Alluvial silts		
Fine loam		
Fine sandy loam		
Fine sand		
Volcanic ash		
Coarse sand		
Fine gravel		
Coarse gravel		
Stiff clays		
Shales		

"4. If the soils with which you have had experience do not fall plainly in the above classification can you give such permissible velocities with a description of the soils to which they apply?

"5. Do you find that canal velocity has any marked effect on the growth of mosses and aquatic plants and, through them, on erosion?

"6. If you have made actual determinations of highest non-scouring velocities with mechanical analysis of soils, or if you have made an investigation of aquatic plant growth as affected by velocity of water the Committee will appreciate a copy of the results or reference to where they may be found, if published."

Opinions of Irrigation Engineers.—Constructive replies and suggestions were received from the following list of engineers, to whom the Committee acknowledges its indebtedness:

Herbert D. Newell, Assoc. M. Am. Soc. C. E., Superintendent, Klamath Project, U. S. Bureau of Reclamation, Klamath Falls, Ore.

C. N. Perry, M. Am. Soc. C. E., Consulting Engineer, Los Angeles, Calif.; formerly Chief Engineer, Imperial Irrigation District, California.

Fred D. Pyle, M. Am. Soc. C. E., Engineer Manager, Vista Irrigation District, Vista, Calif.; formerly Irrigation Engineer, Imperial Irrigation District; Irrigation Manager, North Platte Project; Project Manager, Uncompahgre Project of U. S. Bureau of Reclamation; and General Manager, Columbia Irrigation District, Washington.

J. L. Lytel, M. Am. Soc. C. E., Superintendent, Yakima Project, U. S. Bureau of Reclamation, Yakima, Wash.

W. H. Code, M. Am. Soc. C. E., Consulting Engineer, Los Angeles, Calif.

Jerome H. Fertig, M. Am. Soc. C. E., Los Angeles, Calif.; formerly Construction Engineer, Bitter Root Irrigation District, Montana; Construction Engineer, Uncompahgre Project, U. S. Bureau of Reclamation; and, later, Construction Engineer, Ochoco Irrigation District, Prineville, Ore.; Project Engineer, Grants Pass Irrigation District, Grants Pass, Ore.; and Engineer in charge of reconstruction of project, Bitter Root Irrigation District, Hamilton, Mont.

C. E. Atwood, Assoc. M. Am. Soc. C. E., Chief Engineer, The Valier Montana Land and Water Company, Valier, Mont.; formerly Chief Engineer, Valier Carey Act Irrigation Project, Valier, Mont.

M. E. Bunger, Engineer for various companies in Colorado; formerly Hydrographer and Deputy State Engineer, Colorado.

Charles Taylor, Hydrographer, Umatilla Project, U. S. Bureau of Reclamation.

C. C. Williams, Engineer, Wenatchee Reclamation District, Washington.

From these replies Table 3 has been compiled. Much of the value of the comments of the authorities noted would be lost if Table 3 alone were given, hence quotations and excerpts are also appended.

TABLE 3.—PERMISSIBLE VELOCITIES, IN FEET PER SECOND, ON TANGENTS AS SUGGESTED BY IRRIGATION ENGINEERS IN ANSWERS TO QUESTIONNAIRES.*

* A few of these engineers suggested velocities for curves ranging from 0.5 ft. to 1 ft. slower. It would not be practicable to change from one velocity to another as the canal went into and out of curves. It would be better to use one value for straight canals and a slightly lower one for sinuous ones.

Mr. Newell felt that the experience gained on the Klamath Project did not warrant an estimate of maximum velocities allowable, but submitted answers to questions in the questionnaire, as follows:

3. "There has been no trouble from erosion on any of the canals of the Project. Generally the velocities here used are comparatively low. The velocities listed are taken from the highest current-meter measurements of 1924.

4. "The soils encountered in canals of this Project are fine sand and a chalk that is intermediate between a stiff clay and a shale. Velocities as given below were in fine sand:

Canal.	Quantity, in second-feet.	Velocity, in feet per second.	Soil.
A	750	1.80	Fine sand
B	115	1.26	" "
C	531	1.35	" "
D	155	1.98	" "
E	18.6	1.10	" "
F	31.3	0.95	" "
C–G	249	1.03	" "
Div. Chan.	305	1.67	" "
C-4	92.3	1.62	" "

Mr. Pyle offers particularly valuable suggestions in the following:

"The velocities given are average only and are not proposed as proper to meet the various soil conditions without careful study. In general, an excess of grade controlled by checks is preferable to a flat grade, as the condition can be remedied in the first instance and cannot be in the second.

"Some soils are very light, mushy and easily eroded when new canals are being used for the first time and will set and toughen after several years' use so as to stand 50% more velocity than they would the first year. In fact, very few canals will stand velocities the first few years that they will after 10 years' use.

"Other soils such as volcanic ash and clays will erode gradually but almost constantly forming large holes in the bottom which create boils in the water. I filled a number of these while with the Columbia Irrigation District with sandy loam covered with about 3 in. of fine gravel.

"The nature of the silts carried by the water affects the erosion as some fine silts penetrate and toughen the bottom and sides of the canal, while some coarse silts tend to start erosion.

"The amount of silt carried affects the erosion as on the Imperial Irrigation District canals, where very little erosion takes place at times due to excess of silt which prevents the water from picking up more, while at other times as the water clears it will pick up silt previously deposited and commence eroding.

"In many instances a canal will run satisfactorily for a number of years without eroding, when something will occur to break the natural lining of the canal with the result that swirls and boils are formed which increase the erosion until considerable damage may result.

"Generally erosion commences on the outside of curves, around obstructions or where the current is deflected against the banks. In the last instance we are not always able to decide just why the current changes from one point to another. Back currents are very dangerous when once started and should be controlled as soon as possible."

Mr. Lytel submits a table showing the highest velocities found on some of the canals on the Yakima Project and brings out again the point that these may not be the limiting velocities. These figures are given in Table 5. He

then submits an estimate of limiting velocities included in Table 3, with the following explanatory remarks:

"We find that the velocities given afford very satisfactory service, but may be increased or decreased very considerably without damage to the banks or the depositing of silt. The Yakima River is comparatively free from silt, so a great deal of attention has not been given to the silt problem in connection with the designing of canal sections.

"The figures shown in Table 5 give the velocities at gauging stations on a number of the canals along the Yakima River to which we deliver water in bulk.

"All of the stations shown in Table 5 are on tangents. The velocities given are those which are found at our regular gauging stations on the canals and at the points given. Greater velocities in several cases would probably be possible without injury to the canal section. Lesser velocities in most of the cases would be possible without silting. We have no information as to the velocities on curves, since all our gauging stations are located on tangents. In any study of this kind it is practically certain that special gaugings are necessary. Our hydrographic work has been necessarily confined to the stream measurement work necessary for the establishment and maintenance of the various gauging stations.

"On account of the erosion of the canal banks in the main Sunnyside Canal, we have some silt in the water in the lower part of the system, but not in sufficient quantity to give trouble in handling the water or increase the expense of maintenance to any extent.

"On account of the lack of silt in the water of the Yakima River, this valley is not a very good place to secure information on velocities in canals built in different material with reference to the carrying or depositing of silt, but I thought such information as our records contain might be of some use."

Mr. Code is quoted as follows:

"The writer's experience in operating canals from the Salt River for a period of 10 years prior to the building of the Roosevelt and Granite Reef Dams taught him that with mean velocities materially under 2.5 ft. per sec. there would be deposits of silt on both sides and bottom of main canals and laterals, and all canals and main laterals built under his direction during this period were designed as far as practicable with hydraulic functions insuring approximately such maximum velocities during flood seasons. At other times there was little silt carried in the water and when the low water period occurred, our canals would be running small heads of clear water."

Mr. Atwood makes plain that the velocities given opposite his name in Table 3 are the highest found and may not be the highest attainable:

"The velocities given have been taken from our measuring stations where no erosion occurs and where the canals have given very satisfactory results from an operation and maintenance standpoint. We have not made a study of the maximum permissible velocities."

Pertinent remarks from the answers of Mr. Bunger are:

"If the water running through fine loam contains material in suspension that tends to deposit there will be no erosion until such a velocity is reached that no deposition will take place and I know of instances where that velocity was 3 ft. per sec. with no erosion.

"I have found on the inlet ditch to the Model Reservoir near Trinidad, Colo., where the water carries silt in suspension, that erosions take place in shale with a velocity of 6 ft. per sec. while in the outlet ditch where the water is clean no erosion takes place in the same character of shale with a velocity of 6 ft. per sec.

"The velocities I have given for the above soils are therefore based on a moderately clear water.

"I have made no actual determination of highest non-scouring velocities and soil analysis with a view of publishing them, but as Hydrographer and Deputy State Engineer in the State Engineer's office at Denver, Colo., I have rated hundreds of ditches located in all kinds of soils and know the velocities that cause some of them to scour and in others that do not, and as engineer and manager for different ditch systems, I have had occasion to measure velocities of water in various soils and shales and know at what velocities erosion takes place in them."

Mr. Taylor is quoted as follows:

"Fine to medium sand: The highest velocities in use through canals in this type of soil, shown by water measurements, are mean velocity, 1.7 ft. per sec. for Q equal to 45 sec-ft., and a mean, V, on tangents. The physical condition of the original soil was 60% passed through screen 74 mesh to the inch.

"At the above velocities erosion will show in places where submerged débris or weeds have lodged.

"Without having made actual tests, I think the above are the highest permissible mean velocities for the above type of soil.

"The coarse sand on the Umatilla Project through which some of the original canals were built, was so porous, and the losses were so great, they had to be lined. Some of this sand passed only 40% through screen 74 mesh to the inch."

Mr. Williams gives his experience with Wenatchee soils:

"The soil encountered on this project falls mainly into two general classifications: (*a*) heavy clay loam, and (b) sandy loam. The experience here has been that the first classification will stand velocity up to 3.0 ft. per sec., without serious erosion, and that the second classification erodes badly on curves at velocity of 2.0 ft. per sec. In stiff clays, coarse gravel, and shale, we have had no erosion. With very fine loam and silt, we have erosion to a considerable extent with velocity of 2 ft. per sec. The velocities on the project in unlined canal range from 2.0 to 3.0 and above observations are based solely on experience within these limits."

In addition to answers to the questionnaires, much excellent material is found in the writings of recognized authorities on irrigation engineering.

From the first great book on irrigation engineering by an American author, the late P. J. Flynn, M. Am. Soc. C. E.,* the writers quote at length (note his comment as to Dubuat and compare with the statements of the writers in the early paragraphs of this paper):

"If this slope is too great, the bed of the canal will be torn up, and the foundation of all bridges, drops and other works, will be endangered. The canal bed will be cut down and retrogression of levels take place, until the velocity of the water has adjusted itself to the cohesion of the material through which it flows. * * *

"The maximum mean velocity is not, however, so easily fixed. It must, in the first place, vary with the nature of the soil of the bed. A stony bed will stand a very considerable velocity, while a sandy bed will be disturbed if the velocity exceeds 3 ft. per sec. Some gravel beds will bear a high velocity. Good loam with not too much sand will bear a velocity of 4 ft. per sec. * * *

* "Irrigation Canals and Other Irrigation Works," by P. J. Flynn, San Francisco, 1892, p. 32.

"In computing the slope for the Ganges Canal, Sir Proby Cantley used the formula of Dubuat. This formula was often used at this time, but is now known to be unreliable, especially for large canals.

"It is better to give too great than too small a velocity, as, in the former case, measures can be adopted to protect the side slopes, or falls can be made in the canal and the longitudinal slope, and, therefore, the velocity reduced. In the latter case the deposition of silt will necessitate an annual clearance of the canal, at great expense, and the loss of ground along the canal banks on which to deposit the spoil."

In his chapter on maximum and minimum velocities, Etcheverry* recognizes the fact that the velocity necessary to start erosion is much higher than that required to maintain loosened particles in motion. After quoting other authorities he gives a tabulation (reproduced as Table 4) of suggested maximum mean velocities that does not permit of a direct place in Table 3, as the categories are different.

In speaking of farm ditches in particular (hence, those of shallow depth), Fortier† says:

"In fine sand or sediment a flat grade is required to prevent scouring. A mean velocity of 1 ft. per sec. is sufficient for such material. In hard gravel or hard clay or in a mixture of these, a velocity of 3 ft. per sec. can be used without eroding the bottom. In ordinary materials, ranging from sandy or gravelly loams to clay loams, a grade may safely be adopted which will produce a mean velocity of 2 to 2½ ft. per sec."

TABLE 4.—Maximum Mean Velocities Safe Against Erosion.

(By Etcheverry.)

Material.	Mean velocity, in feet per second.
Very light pure sand of quicksand character	0.75– 1.00
Very light loose sand	1.00– 1.50
Coarse sand or light sandy soil	1.50– 2.00
Average sandy soil	2.00– 2.50
Sandy loam	2.50– 2.75
Average loam, alluvial soil, volcanic ash soil	2.75– 3.00
Firm loam, clay loam	3.00– 3.75
Stiff clay soil, ordinary gravel soil	4.00– 5.00
Coarse gravel, cobbles, shingles	5.00– 6.00
Conglomerates, cemented gravel, soft slate, tough hard-pan, soft sedimentary rock	6.00– 8.00
Hard rock	10.00–15.00
Concrete	15.00–20.00

In order to show examples of relatively high velocities in irrigation channels, Table 5 has been compiled.

Deduction from Available Data.—After a careful study of all the data presented and in the absence of experimental data bearing on the subject, the Committee recommends the values given in Table 6 for maximum permissible mean velocities. The figures given are for canals with long tangents

predominating throughout their lengths. For the same canals in sinuous alignment a reduction of about 25% is recommended. Likewise, the figures are for depths of 3 ft. or less. For greater depths a mean velocity greater by 0.5 ft. per sec. may be allowed. The velocity in canals carrying water free from muddy silts, but bringing a powerful abrasive from the river, should be reduced 0.5 ft. per sec. Basalt ravelings are probably the sharpest scouring agency carried by any of the Western streams, and many of the streams from the Northwestern lava beds will contain this abrasive although the water may appear to be quite clear. Canals from streams more or less silt-laden through the year, like the Rio Grande or the Colorado River, may be designed for full-load mean velocities from 1 to 2 ft. per sec. greater than would be permissible for the same material or new excavation, served by clear water from a reservoir. Deep canals conveying water with clean sand will develop destructive sand boils which would be absent in the same canal with clear reservoir water. In short, the character of water conveyed must be considered as well as the materials through which the canal is first excavated. In theories of "loading", clear water is best fitted to take on a load of scoured material and a water carrying a partial load of sharp abrasive is better equipped to start erosion.

Explanation of Table 6.—The general basis of Table 6 is a tabulation of original soil materials in their order of ability to withstand erosion under usual conditions; that is, conveying relatively clear water, for the greater part of the season, either from a mountain stream or from a reservoir. In soil gradations finer than gravels, it is recognized that the resistance to erosion depends on the cohesion between individual particles. For the gravels—fine, coarse, and cobbles—the resistance is by virtue of weight, shape, and density of units, aided by the mechanical obstruction afforded one unit by its mixture with others. There is no element of cohesion due to viscosity, plasticity, or stickiness, such as is found in clay. In graded materials, loam to cobbles in size, such as are found on the Piedmont benches and alluvial fans of Colorado, Utah, and other mountain States, the canal bottoms become firmly bedded after a few years. At first, there being little plastic colloidal matter, the finer grained soils are washed free and carried farther down stream, to be deposited on the inside of curves or precipitated where velocities are reduced above check structures. At the same time, the gravel is moving slowly down stream, until finally a bed is developed in which voids are filled by smaller material, much on the order of proportioning concrete aggregates. This graded bed is quite stable, entirely because of mechanical intermixture and not because of plastic cohesion, although as indicated in Column (3) of Table 6, the fact is recognized that the admixture of effective colloids will make the bed all the more tough and tenacious, increasing its resistance to erosion. The shales are taken as smooth, soft rock, resistant to erosion by clear water, but not so resistant when a sharp abrasive, such as sand or gravel, is carried by this water. (Note comment by Mr. Bunger, page 949.)

TABLE 6.—Permissible Canal Velocities.

Original material excavated for canal. (1)	Velocity, in Feet per Second, after Aging, of Canals Carrying: Clear water, no detritus. (2)	Water transporting colloidal silts. (3)	Water transporting non-colloidal silts, sands, gravels, or rock fragments. (4)
Fine sand (non-colloidal)	1.50	2.50	1.50
Sandy loam (" ")	1.75	2.50	2.00
Silt loam (" ")	2.00	3.00	2.00
Alluvial silts when non-colloidal	2.00	3.50	2.00
Ordinary firm loam	2.50	3.50	2.25
Volcanic ash	2.50	3.50	2.00
Fine gravel	2.50	5.00	3.75
Stiff clay (very colloidal)	3.75	5.00	3.00
Graded, loam to cobbles, when non-colloidal	3.75	5.00	5.00
Alluvial silts when colloidal	3.75	5.00	3.00
Graded, silt to cobbles, when colloidal	4.00	5.50	5.00
Coarse gravel (non-colloidal)	4.00	6.00	6.50
Cobbles and shingles	5.00	5.50	6.50
Shales and hard-pans	6.00	6.00	5.00

For each grade of original material shown in Column (1) the fact is recognized in Column (2) that the final condition of a canal bed must be quite largely determined by the material through which it flows and likewise the fact that there is little or no mechanical abrasive in the water. The figures in Column (3) refer to water that contains effective colloidal silts, such as the waters from the Colorado River or Rio Grande. These silts will settle to greater or less extent under relatively high velocities. The difference between colloids and colloidal silts should be noted. The first will remain in suspension, even if all velocity be eliminated, for a long period of time, even years. The silts will precipitate under reduced velocities, and possess sufficient colloidal matter to form a plastic, highly cohesive mass. Obviously, such water will have a marked influence on the final character of the canal bed for all gradations up to the shales where the original material is more resistant than any deposit of silts. In Column (4), the figures indicate that waters conveying abrasive sand or gravel will make some materials more resistant by furnishing the constituents needed for a graded bedding. On the other hand, shales or slick tough clays are themselves resistant, and this resistance is reduced when a powerful abrasive is contained in the water.

Conclusions

1.—The laws of hydraulics governing the movement of loose silt and detritus in open channels are only distantly related to the laws governing the scouring of a canal bed and are not directly applicable.

2.—The material of seasoned canal beds is composed of particles of different sizes and when the interstices of the larger are filled by the smaller, the mass becomes more dense, stable, and less subject to the erosive action of water.

3.—The velocity required to ravel and scour a well bedded canal in any material is much greater than the velocity required to maintain movement of particles of that same material before becoming bedded or that have been raveled off by higher velocities than the bed would stand.

4.—Colloids in either the material of the canal bed or the water conveyed by it, or in both, tend to cement particles of clay, silt, sand, and gravel in such a way as to resist erosive effects.

5.—The grading of material running from fine to coarse coupled with the adhesion between particles brought about by colloids make possible high mean velocities without any appreciable scouring effect.

6.—Irrigation canals may be designed for the velocity that is permissible when seasoned by age, as the demand for water grows with the age of the canal and the maximum mean velocity grows with the supply necessary to satisfy this demand.

7.—Power canals are likely to be placed under peak load as soon as feasible after completion. For this reason a more conservative velocity should be chosen, otherwise scour may take place before seasoning.

8.—Canals, when new, may be operated with velocities less than the maximum permissible, by the use of check structures.

9.—A slight excess of velocity is preferable to insufficient velocity. Check-drop structures will correct a slope causing erosion, but there is no method within reasonable cost by which velocities may be increased.

10.—In the past, engineers have been led astray by too close an adherence to the results of experimental data on the transporting action of water on such materials as clay, silt, sand, and gravel, considered separately rather than on cohesive or mechanical combinations, and in consequence many canals have been designed and built on too flat slopes with correspondingly low velocities.

11.—The growth of aquatic plants is only partly connected with velocities. Canals designed for the highest permissible velocities, from the standpoint of erosion, will be as free from plant growth as design alone can effect.

DISCUSSION

H. B. Muckleston,* M. Am. Soc. C. E. (by letter).—This paper attacks a problem which is in great need of serious consideration. Its principal difficulty lies in the definition of the various soils. Such designations as "sandy with admixture of clay", "clayey loam", "dark uniform clay loam", and others in Tables 5 and 6 may convey varying ideas to different engineers, depending on the soils with which they have had experience. The man familiar with the loams around Winnipeg, Man., Canada, would consider the loams of Alberta as light to the point of being floury, whereas the Alberta man would consider the Winnipeg soil extraordinarily tough. Yet the designation as "dark uniform clay loam" might very well fit either material. This is not in disparagement of the authors' work, but to show the difficulties in the problem they have undertaken to solve.

The engineer who is faced with the necessity of deciding on the upper limit of permissible canal velocity for a project is confronted at the outset with the fact that he knows very little about the soils he will encounter in the excavation. No matter how numerous his test pits or borings, they can reveal little about the real character of the soils in which the canal will be dug. When the canal is entirely in an alluvial river valley there may be some assurance that the soils will be reasonably constant over an extended area, but for a canal in bench lands, particularly glacier-made lands, the character may change materially in a few hundred feet. In the writer's experience, a canal designed for a mean velocity of 2.5 ft. per sec. was badly eroded in some stretches, while in others, possibly in the next quarter-section, silting took place to such a degree as to become a nuisance. The difference in the soils was not especially noticeable on examination, but it must have been considerable in fact.

The authors are quite right in insisting that silting and scouring are phenomena of entirely different natures and following radically different laws. They involve fundamentally different processes. In the one case the force opposing is gravity; in the other, it is cohesion or friction. In well-packed, well-graded gravel, the resisting force is almost entirely friction assisted in some cases by the weight of the larger particles helping to hold down the smaller ones. In clays, or in materials containing a good proportion of clay, the resisting force is mainly cohesion. Before erosion can take place the particle must first be detached from its matrix and this can happen only as a result of unequal pressure on opposing sides. This inequality of pressures may be due to an upward current tending to lift the particle, or to a horizontal current tending to roll it along the bottom. If the surface is smooth and impervious, the opportunity for the disturbing currents to act on small particles is limited and a high mean velocity is permissible without scour. This explains the high resistance offered to scour by nicely slicked bed and banks. It also explains why alkali soils erode so easily.

* Cons. Engr., Vancouver, B. C., Canada.

Almost any material will erode if the water carries in suspension particles of considerable size. These particles by their momentum can detach from the bottom other good-sized particles which would not be detached by the water alone.

In discussing the quotation from the late P. J. Flynn, M. Am. Soc. C. E., the authors have mistaken his meaning in the reference to the formula of Dubuat. Mr. Flynn was referring to Dubuat's formula for the mean velocity of water in open channels and not to his formula for permissible velocity. The former was a "horrible" expression used in India until it was superseded by Kutter's formula.

The velocities recommended in Table 6 will be accepted by most irrigation engineers, subject to their own interpretation of the terminologies.

Elbert M. Chandler,* M. Am. Soc. C. E. (by letter).—The collection of records of experience and observation in this paper will be very useful to canal designers. The paper will undoubtedly serve to call attention to and emphasize the desirability of the use of maximum velocities consistent with the physical conditions to be met in any given case, and particularly that, under normal circumstances, the limiting factor in fixing a canal velocity should be the elimination of erosion of a seasoned canal and not the minimum velocity required to prevent the deposit of silt, as has been the case in many instances.

Of course, each particular situation must be analyzed and the conditions met as they arise. For example, in the case of canals diverting water from the Snake River and carrying a moderate but not harmful quantity of silt, circumstances could easily require, not the maximum or limiting permissible velocity, but some velocity less than the maximum that will permit of a continuous slight deposit of silt, such silt deposits being useful and necessary to reduce seepage losses.

There are certain kinds of aquatic growth that thrive only in water having a very high velocity. The writer has noted the odd situation of no aquatic growth in the canal, but long strings of such growth in an adjacent regulating spillway having a continuous velocity well over 10 ft. per sec.

Another factor to bear in mind is that many circumstances will justify in initial construction a concrete lined canal, not only because of the reduction of seepage losses, but of the decrease in the cost of excavation owing to the use of a smaller sectional area. This possibility should always be studied when considering grades and maximum velocities.

It may not be amiss to call attention to the life work of one of the authors, Dr. Fortier. For more than forty years, he has studied, investigated, and worked to solve the many difficult problems incident to irrigation development. He was the first to emphasize that the work of construction and operation of irrigation works was purely incidental and secondary to the ultimate result—the success of the man on the land. Twenty years ago he was a pioneer in working to improve the methods of irrigation and the opportunities of the

* Civ. Engr., Olympia, Wash.

irrigation farmer. His rôle has not been spectacular, but the actual worth of his services to the irrigated West has been exceeded by none.

ROBERT S. STOCKTON,* M. AM. SOC. C. E. (by letter).—This paper emphasizes certain matters in connection with permissible canal velocities that have come under the observation of experienced operating engineers in this field, but that have not been fully discussed in textbooks. This subject is one into which many factors enter and for which the collection and tabulation of observed field data at a large number of locations as given in the paper are particularly valuable.

It has been noted that a canal carrying water at a velocity near the eroding point on a straight course will actually erode on the curves. It may be desirable to use such a velocity and protect the curves by rip-rap or by superelevation of the bottom to correspond with the increased velocity on the outside of the curve. This latter method is limited in its application but has not been used as much as it should have been.

As a practical matter of economical operation an engineer should be sure that the velocities in small canals and distributing ditches are high enough; on the other hand, in designing large canals he should perhaps lean the other way and be sure the velocity is not too high, if they carry mostly clear water through material where seepage may be an important matter. For very muddy waters, for a low construction cost, and for preventing the growth of water plants, the highest permissible velocity or the highest feasible velocity would be indicated. At many points the soil is in layers and the softest must, more or less, govern the velocity. As pointed out by Fred D. Pyle, M. Am. Soc. C. E. (see page 948), it is usually much easier to remedy a high velocity than to increase a flat grade in a canal. The lighter the soil, the flatter the side slopes must be for stability.

The canals on the Western Section Irrigation Project of the Canadian Pacific Railway, Department of Natural Resources, have been in use from 15 to 20 years. The soil varies from sand to heavy clay, but in most places contains no gravel and might be described as varying between a light sandy loam and a clay loam, all characteristic of the prairie soils east of the Rocky Mountains.

The Main "A" Canal of this System is through an average clay loam soil and is a good example of a large canal in good condition after twenty years' use. The constructed slopes were 1 on 2 and for long distances are in almost perfect condition, except for occasional gullies where storm water has entered from the side. Of course, the section is modified slightly and approaches the parabolic form so pronounced on the canals and ditches in the softer loam soils. The calculated velocity for a depth of 10 ft. and a discharge of 2 048 sec-ft., is 3.2 ft. per sec., with $n = 0.025$. The discharge of the canal has not exceeded about 1 500 sec-ft. and for most of each season runs at half capacity or less, so that conditions are favorable for maintaining the canal section. The Bow River water turned into the canal carries silt for about a month at the high-water period. The grade of the canal is

* Supt. of Operation and Maintenance, Western Section C. P. Ry. Irrig. Block, Strathmore, Alberta, Canada.

0.02% and the typical meter measurements at Chestermere Station are as given in Table 7.

TABLE 7.—Typical Meter Measurements of Main "A" Canal at Chestermere Station.

Width, in feet.	Area of cross-section, in square feet.	Mean velocity, in feet per second.	Discharge, in second-feet.	Depth of water, in feet.	Calculated roughness coefficient.
52.0	116.0	1.25	145	2.70	$n = 0.028$
63.0	254.0	1.90	486	5.10	$n = 0.028$
72.0	459.0	2.74	1 257	7.90	$n = 0.026$

The material would come under the heading of "ordinary firm loam" and the canal would be classified as "carrying water bearing colloidal silts during a part of the season." The condition of the canal substantiates the recommended velocity as shown in Table 6.

The Secondary "A" Canal runs for most of its length through a rather sandy loam and follows the contour closely so that it has a large curvature. Considerable cutting requiring rip-rap work has occurred on this canal, mostly on the curves. The designed velocity varied in the sandy section from 2.5 to 2.7 ft. per sec., but experience indicates that it should have a maximum mean velocity of about 2.0 ft. per sec., for stable banks, and the material should be classed as a fine or sandy loam in Table 6. This canal takes practically clear water from Chestermere Lake but at high stages is turbid from the erosion of its own banks. The meter measurements as given in Table 8, are typical.

In general, it will be admitted that a large number of complex and variable conditions affect the design of canals and ditches as expressed by the permissible velocities of the water and are difficult to place in their true perspective without considerable practical experience. It is of great benefit, however, to try and describe fully all the factors and discuss conditions in order to capitalize the united experience of engineers and express as clearly as possible all the principles involved.

TABLE 8.—Typical Meter Measurements at Bridge 16A, Cairnhill. (Grade, 0.03%; constructed side slopes, 1 on 2.)

Width, in feet.	Area of cross-section, in square feet.	Mean velocity, in feet per second.	Discharge, in second-feet.	Depth of water, in feet.	Calculated roughness coefficient.
27.0	34.3	1.47	50	1.6	$n = 0.020$
31.0	67.0	1.90	127	2.7	$n = 0.022$
41.5	158.8	2.56	408	4.8	$n = 0.024$

It very frequently happens that the cost of construction, plans for enlargement or future canal lining, the requirement for a high velocity to prevent weed growth, or other factors, lead to the selection of different velocities from those most favorable to a condition of no erosion or silting. It is fre-

quently the case that the material through which canals are built changes so often from one class of soil to another, that the only practical course is to meet a probable average condition.

On the Western Section Irrigation Project, it has proved wise to leave many small ditches with excess grade and to utilize the natural channels. The Operating Department has thus been able to take up the excess grade after use has developed its exact amount and determined the location of controlling structures.

The writer has had particular occasion to observe the difference between new and old canals and wishes to commend the emphasis the authors have laid on designing for the more or less permanent condition of the old canal with its compacted banks and growth of vegetation.

R. A. Hart,* M. Am. Soc. C. E. (by letter).—This paper should prove of great value not only in that the various factors relating to the question have been brought together but especially in that the difference between eroding and transporting velocities is so clearly emphasized.

An important consideration is the position of the ground-water table with respect to the water surface of the canal. As long as the latter is higher, seepage is out of the canal, and there is a tendency for the finer materials to be carried into the interstices between coarser particles, thereby permitting a silting-up process. On the other hand, if the ground-water table is higher, as frequently happens, seepage is into the canal and the whole process is reversed.

In localities having a high water-table there is likely to be an accumulation of soluble materials in the soil, in the ground-water, and even in the canal water. The nature of the soluble matter has a bearing on the case. Calcium salts aid in the flocculation of soil, forming a structure that is easily eroded, whereas sodium carbonate, for example, has a deflocculating effect.

With respect to the presence of sodium carbonate the effect of temperature is of possible concern. At 0° cent., sodium carbonate is soluble at the rate of 7.1 parts per 100 parts of water, while at 35° cent., the solubility is 51.0 parts per 100 parts of water. The warmer the canal water, therefore, the greater the extraction of the deflocculating salt.

Small irregularities in grade are of moment as is evidenced by the self-cleaning of clogged tile lines that have a grade too slight to provide an eroding velocity. The cleaning results from local erosion at the toe of the clogged part, due to the higher velocity of the water flowing down the short, steep section. Once eroded, the material is kept moving by virtue of the velocity of normal flow.

R. A. Hill,† M. Am. Soc. C. E. (by letter).—The very careful distinction which the authors make between canals carrying colloidal matter and those carrying only clear water or materials not colloidal in nature is one of especial value and in itself warrants all the efforts spent in gathering and interpreting the data.

* Secy.-Mgr., Western Clay Products Assoc., Salt Lake City, Utah.
† Associate, Quinton, Code & Hill, Los Angeles, Calif.

Consideration of the effect of infiltration of colloidal matter into the sides and bottoms of canals has been disregarded too many times in the development of irrigation projects in the Southwest. Equally unfortunate has been the experience of those familiar only with canals carrying colloidal material when they are called on to design irrigation works for other conditions. As the writer's experience has been very largely with irrigation canals served from silty rivers, he will limit his discussion to this particular phase of canal velocities.

While the conditions found by Mr. R. G. Kennedy in Northern India probably are considerably different from those in America, it would seem that in dismissing his conclusions as fallacious, the authors have overlooked the fact that any relation found reasonably applicable there should likewise, when properly modified, be reasonably applicable to canals in those parts of the United States that have climatic conditions generally similar to Northern India; furthermore, that the so-called critical velocity is really not a single velocity but rather a range of velocities between which neither silting nor scouring will occur.

Where the material being transported by the water in canals is not colloidal in nature the range of velocity between which silting will cease and scouring begin will become smaller as the particles comprising the bed of the channel approximate the size of the particles carried in suspension. In practically all cases, however, the bed of the channel is composed either of colloidal material or of particles materially larger than those carried in suspension. Consequently, it should be obvious that a velocity which will not cause silting need not cause scour or erosion.

While the relation proposed by Mr. Kennedy, that the velocity should be proportional to the 0.64 power of the depth, would be applicable only in rare instances, nevertheless there must exist in any channel a relation between the depth and the permissible velocity. It is generally recognized on irrigation projects where silty water must be handled that a deep channel is far more apt to silt than a channel having an equal mean velocity but a less depth. This recognition on one project took the form of an empirical rule that the depth should be one-thirteenth of the bottom width. Analysis of this "rule-of-thumb" will show that when the depth is increased the hydraulic characteristics will be such, under ordinary circumstances, that the velocity will also increase. On other projects, attempts have been made to follow Kennedy's rule or some modification thereof.

If, for the sake of illustration, it is assumed that water is diverted from a silt-carrying river into two large canals similar in capacity and of equal area, one of which is, however, twice the depth of the other, it will be seen that consideration must be given to this factor of depth. At the head of each channel the same quantity of silt is present at all times. The sides of most artificial channels carrying silty water are rather steep, consequently the bottom width of these canals must be approximately in the ratio of 1 to 2; furthermore, the bottom width will be a large percentage of the wetted perimeter.

In order to prevent this silt from falling by the force of gravity to the bed of either channel, eddies must be created to raise the silt toward the sur-

face. About the same number of eddies of equal intensity would be required to keep the silt in the deeper channel from settling to the bottom as would be required in the broader and shallower channel. As the deeper channel is only one-half the width of the shallower channel, there would have to be about twice as many eddies per unit of wetted area, or the eddies would have to be of double intensity in order to maintain the silt in suspension. These eddies can only be created by the energy of the water in contact with the bed of the channel, consequently, in order to develop twice the number of eddies or eddies of double intensity over an equal area, it must be necessary to increase the velocity in the channel if the depth of the channel is increased.

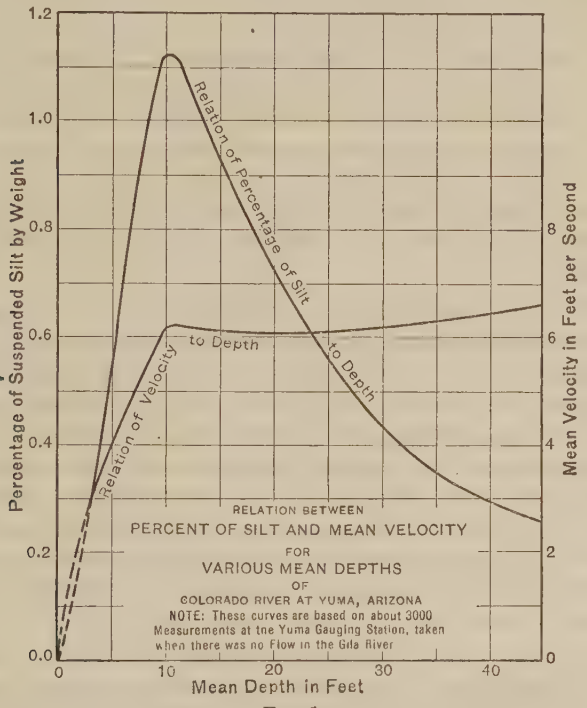

FIG. 1.

Although the most efficient hydraulic section is that in which the bottom width is roughly equal to the depth, no river naturally forms such a channel, the tendency being quite opposite in that the bottom width is usually from 10 to even 100 times the depth. Rivers carrying sediment and flowing between banks of unstable material naturally adapt themselves to a cross-section in which only local silting or scouring will occur as long as the velocity is fairly constant. On such streams bottom scour will commence as soon as the river rises and will continue until a depth has been reached which is sufficient to maintain equilibrium between the tendency to deposit suspended matter and the tendency to erode material from the bed of the channel. As the river recedes the channel gradually refills until equilibrium is again reached at some low stage.

Such fluctuations in the depth of the Colorado River are a most fortunate illustration of the effect of depth on the silt-carrying capacity of a stream. On Fig. 1 is shown the actual relations between depth and mean velocity, and depth and percentage of silt in the Colorado River at Yuma, Ariz. It will be noted that as the velocity increases rapidly the percentage of silt held in suspension also increases rapidly, but when the velocity becomes approximately constant, the percentage of silt steadily decreases as the depth increases. When the mean depth is about 10 ft. the silt content is normally about 1.1%, but when the depth is 30 ft. the silt content is only about 0.4%, although the mean velocity is practically constant throughout this range in depth.

Conversely, if silting of artificial channels is to be avoided, the percentage of suspended matter carried by the water must be held constant, hence the mean velocity must be in accord with some increasing function of the depth of the channel. Since bottom scour cannot take place except at velocities higher than non-silting velocities, consideration must be given to the depth at which the canal will normally be operated, otherwise the maximum velocity ordinarily considered safe against scouring might be insufficient to prevent silting of the deep canals required to carry very large quantities. As pointed out by the authors, bank scour is of little consequence due to the berm which naturally forms.

JEROME H. FERTIG,* M. AM. SOC. C. E. (by letter).—The authors are to be commended on the able manner in which they have presented the subject and their conclusions, and desires to express his accord with their views.

It appears that the column of permissible velocities submitted by the writer in Table 3, is somewhat conservative. This is due, possibly, to the fact that his experience has been largely in the construction of irrigation works and in the operation of such works only during the first year or two. His observation has been that new canals and laterals in earth will sustain without scour only a comparatively low velocity; that pure sand banks will wash quite readily; and that shales containing an excessive quantity of alkaline salts will erode much more easily than those having little or none.

In seasoning new canals it is a good plan to allow the first water turned in to run only a short time. The wetting of the canal will cause the banks to settle and become more compact and by not allowing the water to run too long at the start, the finer particles of the soil will remain and tend to cement the material as it dries. Thus, the banks will become set, as it were. It is also desirable, as stated by the authors, to "check back" muddy water in the canal allowing the silt to be deposited, thus aiding in cementing the banks and making them more resistant against scour and seepage.

It is known, as stated in the paper, "that old, well-seasoned canals will stand much higher velocities than new ones". Therefore, where sufficient grade is available, canals should be designed for the highest velocities the materials will stand after several years of operation, taking into account the probability of self-riprapping and also of silting either by natural silt carried

* Los Angeles, Calif.

into the canal by the water supply or, where the latter is deficient, by sluicing fine material into the water, or by other means. If the velocities are too high, particularly during the first few years, they can be controlled by checks placed at suitable locations, as at drops or turnouts in the canal.

It is often essential to locate canals so that as much land as possible is supplied with water, in which case the engineer is confronted with the question of the minimum allowable velocity rather than the maximum. This, of course, presumes a thorough study of costs of larger canals and the position and elevation of the intake, the latter often being rather definitely fixed because of controlling topography.

E. S. Lindley,* M. Am. Soc. C. E. (by letter).—The authors quote the Kennedy formula for critical velocities, but what is said gives the impression that the original paper has not been fully understood; and it shows an inclination to generalize even outside the field that Kennedy only glanced at tentatively.

Twenty years elapsed before any concrete attempt was made to advance from Kennedy's pioneer work. In a few Panjab technical papers† various aspects of the problem have been attacked, and matters pertinent to the present discussion are given. In the course of these papers and the ensuing discussions, reference is made to most of the work known in the East.

Andrew Weiss,‡ M. Am. Soc. C. E. (by letter).—The excellent report on the subject of permissible canal velocities prompts the following supplementary comment. The determination of the most suitable canal velocities is associated with numerous difficulties, chief of which are:

1.—The abrupt and often frequent variation of the material through which the canal section must be built;

2.—The uncertainties attending the selection of the proper coefficients or friction factors in the design of the canals; and

3.—The fluctuations in demand, progressive and seasonal, for which the system should adequately provide.

The first of these difficulties is perhaps best met by attempting to obtain some suitable velocity best adapted to the general average conditions of the locality, and depending on the use of the proper corrective measures as unforeseen difficulties develop later in the use of the system. Sometimes Nature will assist in shaping the canal bed to meet the needs where such an adjustment is made possible. Thus, in the case of a part of the Interstate Canal of the North Platte Project extending through about four miles of shifting dune sands, the section of the channel changed itself from a bottom width of 22 ft. and a water depth of 10 ft. to a width of approximately 75 ft., with a corresponding reduction in depth and slackening of the velocity until the section became stable without further widening and erosion.

‡ Asst. Director of Reclamation Economics, U. S. Bureau of Reclamation, Denver, Colo.

As to the second difficulty, the growth of grasses and willows along the water edge of the channel may be so abundant as to interfere materially with the velocity of flow unless this vegetation is frequently removed with a corresponding increase in the cost of maintenance; on the other hand, the velocity may be greater than expected by reason of a friction factor less than that assumed in the design of the canal. Measurements of velocity on the Interstate Canal have indicated a value of n in Kutter's formula generally less than 0.020 and, in some instances, as low as 0.017, whereas in the design of the canal the coefficient, 0.025, was used. The result of this was that erosion started immediately when the canal was put into operation, at times with serious consequences. In addition, its discharge was only about two-thirds its rated capacity. The immediate effect of the excess velocity was the development of sand-boils in the canal bed, on the outside of curves, which were followed by the rapid undermining and destruction of the adjacent canal bank. This difficulty is more serious on the larger canals, because of the relatively greater rapidity of the development of these boils and the disproportionately great damages which may result from a breach of the canal.

This difficulty was successfully overcome by the use of check structures in the canal bed, which served as a means to control velocities and proved almost indispensable in regulating the diversions from the canal.

The third difficulty, namely, the fluctuation in the demand for which the system may be constructed, is due to seasonal causes as well as to the conditions which may prevail during the period of development of any system. If such development proceeds slowly on account of agricultural depression or other causes, the system may be only partly used for several years. There are also seasonal variations in the use of any canal system which are especially notable in the Northern latitudes, and which bring about a sharp rise in the demand on the system during June, or more often in July, according to local weather conditions and the variety of crops predominating.

As a result of the observations made on the North Platte Project the following conclusions have been reached:

(*a*) With the fine silt coating resulting from the use of the muddy waters from the direct flow of the North Platte the value of n in Kutter's formula should not exceed 0.020, except on the smaller canals or distributaries on which the growth of long grasses and willows along the water edge may obstruct the velocity of the water to a considerable extent, thereby necessitating more frequent cleanings and consequent larger expense for the proper maintenance of the system. Similar and more serious obstructions may result from the growth of aquatic plants in clear water as noted in the paper. For these reasons the use of the larger friction factor, 0.025 (Kutter's formula), is favored in the design of these smaller canals.

(*b*) Owing to the frequent changes of the structure of the soil through which these canals had to be built, it was best to attempt to obtain some suitable average friction coefficient and resultant velocity. In the case of the larger canals velocities ranging from 2.50 to 2.75 ft. per sec. were sought and, on the distributaries, velocities of about 0.5 ft. per sec. greater.

(*c*) In all cases the best ultimate results were obtained by the use of check structures in the canals and distributaries, these serving the dual purpose of controlling velocities and facilitating the regulation of diversions. It was found to be practically impossible to perform these functions without check structures. By this means provision was made for these uncertain factors and conditions which could not be foreseen in advance of the construction and operation of these canals.

(*d*) In the design of the check structures it is desirable to use a simple method of closure, preferably check planks, all or any part of which may be removed to correspond to the fluctuations in use and the demands incident thereto. By this means the removal of the planks will restore the original canal velocities if such is found desirable during certain periods, as when it is necessary to sluice accumulated material, or after the canal has become seasoned, or when for other reasons it is not desired to maintain these structures in active use.

(*e*) It is usually desirable to adopt a velocity somewhat in excess of the ultimate rate required because after some period of use the growth of obstructing grasses and willows may cause a considerable retardation of the flow, embarrassing shortages in capacity and additional cost of maintenance of the system. This suggests that a reasonable surplus capacity in the design of such channels may be desirable and economical if the cost of operation and maintenance is given due consideration.

The range of velocities indicated in Table 6 appears to be well applicable in all cases with which the writer has come in contact. There are occasional instances where it may be desirable to avoid the higher velocities in order to induce the deposition of silt for the purpose of reducing percolation losses.

J. C. Stevens,* M. Am. Soc. C. E. (by letter).—The authors deserve the thanks of the Engineering Profession for their excellent paper. It summarizes briefly existing knowledge on the subject and offers its final conclusions in Table 6, which the writer believes will become the guide for earth canal design for years to come.

However, a word of caution should be sounded against using such data blindly. A thorough knowledge of the conditions to be met in design and of the materials encountered is essential to the proper interpretation of such guiding data. The authors have presented the results of their intimate knowledge and study of this subject in as nearly a "fool-proof" form as appears possible. Nevertheless, the terms "non-colloidal fine sands", "sandy loam and fine loam", "colloidal silts", etc., must give many engineers great concern. The skill of the chemist will be required in many instances.

It is obviously impossible to standardize soil classifications so that the various designations will have the same meaning for all. Broad experience will yet be a prime essential in order properly to interpret and successfully to utilize the data presented by the authors.

CARL ROHWER,* ASSOC. M. AM. SOC. C. E. (by letter).—A knowledge of permissible canal velocities is an important factor in the design of irrigation systems, particularly where the soil is easily eroded, or the canals carry a large quantity of suspended material. Where both conditions obtain the velocity must be carefully determined to eliminate the possibility of erosion on one hand and sedimentation on the other. Fortunately, as pointed out by the authors, non-silting velocities are not necessarily scouring velocities.

An interesting example of a canal constructed under the conditions mentioned is shown in the view (Fig. 2), of the Fort Lyon Supply Canal in the Arkansas Valley near Rocky Ford, Colo. This canal is about 90 ft. wide, has a maximum capacity of 1 500 sec-ft., is excavated in Fresno fine sandy loam, and carries a large quantity of sand and colloidal silt. The silt remains in suspension in the canal but is deposited on the lands irrigated, amounting to as much as ¼ in. in a single irrigation. The type of silt carried is shown by the view (Fig. 3) of the material deposited in a depression alongside the canal. Under some conditions the sand or bottom load is deposited and under others is scoured out. The characteristic appearance of the sand deposit is shown in Fig. 2. The depressions shown are about 15 ft. in diameter and 3 ft. deep.

TABLE 9.—DISCHARGE MEASUREMENTS ON FORT LYON SUPPLY CANAL.

Date.	Gauge height, in feet.	Area, in square feet.	Discharge, in cubic feet per second.	Mean velocity, in feet per second.	Critical velocity, V_0*, in feet per second.
June 8, 1923	3.44	304.5	681.5	2.24	1.85
" 14, "	1.32	101.5	159.4	1.57	1.00
" 19, "	4.96	452.7	1 142.6	2.52	2.35

* Computed from the formula, $V_0 = 0.84\, d^{0.64}$.

Tables 9 and 10, submitted by Mr. H. D. Amsley, of the Colorado State Engineer's Office, give the flow characteristics of the canal based on current meter measurements and the gauge height record at the rating flume near the head. The quantities given are for the conditions in the rating flume, but they may be assumed to apply to the canal proper because the rating section does not differ materially from the canal section.

TABLE 10.—MAXIMUM GAUGE HEIGHTS, FORT LYON SUPPLY CANAL.

Date.	Hour.	Gauge height, in feet.
June 8, 1923	4:00 A.M.	4.75
" 16, "	6:00 P.M.	5.15
" 19, "	9:00 A.M.	5.00

On June 8, 1923, the depth in the flume for the gauge height, 3.44 ft., varied from 2.02 to 3.44 ft., and on June 19, for a gauge height of 4.96 ft., from 4.90 to 5.00 ft. This shows that more than 1.25 ft. were scoured from some parts of

FIG. 2.—FORT LYON SUPPLY CANAL, NEAR ROCKY FORD, COLO., AUGUST 13, 1924, SHOWING ERODED AREA.

FIG. 3.—SILT DEPOSIT IN DEPRESSION ALONGSIDE FORT LYON SUPPLY CANAL, NEAR ROCKY FORD, COLO., AUGUST 13, 1924.

the flume in that interval, and as the conditions in the canal are similar it is reasonable to assume that scouring occurred there also. During this time, as shown in Table 10, the gauge height did not materially exceed the values for which the discharge is given, therefore, the velocities were probably never materially higher than the maximum indicated in Table 9.

The values of the critical velocity, V_0 (Table 9), computed from Kennedy's formula, $V_0 = 0.84\, d^{0.64}$, in which, V_0 is the critical velocity, in feet per second, and d, the depth, in feet, of the canal, show that the mean velocity of the canal was always greater than the critical velocity. This indicates, as was found, that the tendency was toward scouring rather than silting at the time. However, the accumulation of sand shown in Fig. 2 indicates that at other times considerable sand is deposited, but the established regimen of the canal indicates that from season to season as much sand is scoured out as is deposited.

Ivan E. Houk,* M. Am. Soc. C. E. (by letter).—The paper presents several good ideas and many valuable data, and the authors are to be congratulated on the clear and comprehensive manner in which they have handled the subject. Their discussion of the effect of colloidal silts in increasing scouring velocities is both interesting and valuable; and the practical ideas and data,† submitted by engineers in charge of irrigation projects, should prove of great value in future designing work. The velocities to be permitted in canals are primarily dependent on the nature of the material through which the canals are located, a condition which is susceptible of almost infinite variation. It is believed that, with the present knowledge and available data, detailed descriptions of the materials through which certain canals have been built, together with the actual velocities found feasible therein, are more valuable than generalized recommendations, such as are given in Table 6.

It is not clear to the writer where there has been any confusion, fallacy, or fundamental error in the work and discussions of other engineers, particularly the British irrigation engineers who have had long and valuable experience in such matters. They have frequently pointed out a wide difference between non-silting and scouring velocities. That they have discussed deposition and erosion in a more or less combined manner, is true; but it seems perfectly logical to do this. In designing a canal to be located through extensive silt deposits it is important to adopt velocities that will neither silt nor scour; and it is perfectly proper to consider such phenomena at the same time even if they are fundamentally different operations. However, experimental determinations of non-silting and eroding velocities are matters which undoubtedly should be considered separately.

It is believed that the experiments, experience, researches, and discussions of many Far Eastern irrigation engineers, including Kennedy, Willcocks, Buckley, Parker, Bellasis, and others, are well worthy of careful study by any one interested in the problem. Although their experience may not agree exactly

* Engr., U. S. Reclamation Service, Denver, Colo.

† See pp. 946–950.

with that of Western engineers, it should not be so briefly dismissed. It is believed that the difference between their experience and that of irrigation engineers in the United States is due to the differences in the materials through which the canals are located, rather than to any fallacy or fundamental error in their conclusions. Their studies and experiments, in some cases at least, may have been made on canals where no colloidal silt was present. There probably are many locations in the United States where Kennedy's laws are more applicable than the recommendations of the authors. The writer knows of several power canals in the East where the velocities recommended by the authors could not be permitted.

It might also be pointed out that the effect of the channel depth is not considered in the final recommendations of the authors. Although the writer has never attempted to express his observations by formulas, he has observed, and always considered, that higher velocities can be permitted in deep channels than in shallow channels, as has been maintained by many writers. On the Miami Valley flood prevention work at Dayton, Ohio, velocities as high as 10 ft. per sec. were considered allowable as extreme maximum values in straight channels having gravel or cobble beds, where the depths were 20 ft., or more. Of course, such high velocities could not be permitted in irrigation canals through similar materials. They would not have been considered on the Miami Valley work except as ultimate possible limits to occur only for a few hours' duration, but even under such conditions the writer would not consider them safe for channels 5 ft. deep. In curved channels on the Miami Valley work concrete slab paving was placed on the outer banks, and flexible concrete block mattresses on the bottom, adjoining the outer banks, wherever the mean velocity exceeded 6 ft. per sec.*

In the high-water surveys of the 1913 flood in the Miami Valley,† made during the summer after the flood, it was noticed that unusually high velocities can occur over alluvial soils when the depths are comparatively great and the flow comparatively uniform, without causing appreciable scour. Several instances were observed where mean velocities as high as 6 ft. per sec. occurred over alluvial fields along the main channels, with mean depths of about 15 ft., without causing any noticeable erosion. Cornstalks from the preceding year's crop were still in place after the flood had passed. In one instance a velocity estimated at 11.5 ft. per sec. occurred over fields flooded to a mean depth of 24.6 ft., where the flow conditions were unusually uniform, without causing apparent scour. Immediately below, where the velocities were practically the same, but the flow conditions greatly disturbed, a new channel about 100 to 150 ft. wide and about 10 ft. deep, was eroded. The material in both places consisted of an alluvial surface soil underlaid by a yellow clay containing some sand and gravel.

Although the velocities just mentioned were calculated from surveys made after the flood, they are not believed to be appreciably in error. The surveys were carefully made, and the calculations, using the Kutter formula, were

checked by independent computations based on measured head at contracted openings, as described in full in the report previously noted. The more valuable observations, together with some later data obtained where the velocities were measured with a current meter, are given in Table 11. Velocities measured with a current meter are indicated by asterisks.

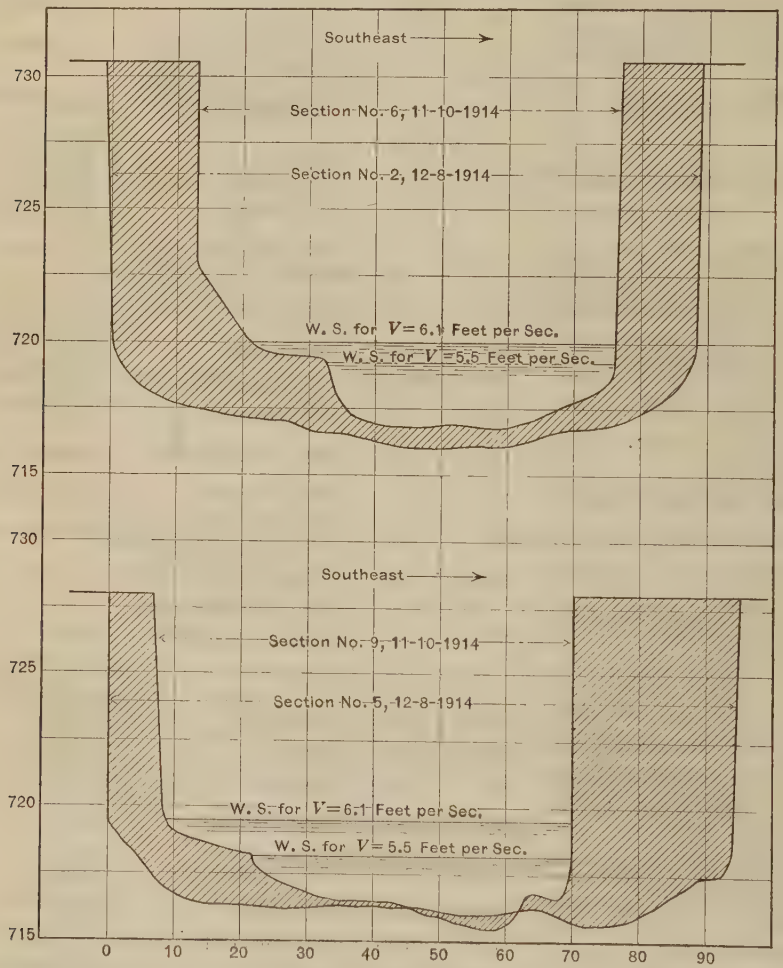

FIG. 6.—CROSS-SECTIONS OF MIAMI RIVER CUT-OFF CHANNEL, DAYTON, OHIO, SHOWING SCOUR CAUSED BY INCREASE IN VELOCITY FROM 5.5 TO 6.1 FEET PER SECOND.

The observations on the Miami River cut-off channel, which make up the last three items in Table 11, are probably worth some discussion. Fig. 4 is a view of the cut-off looking up stream along the channel, from a point near the lower end. The material forming the bed and sides of the cross-section above the place where the man is standing was clean sand and gravel; below this place it was a tenacious yellow clay. Fig. 5 is a close view of the gravel, taken on the berm which appears at the left of Fig. 4. The folding rule and

engineer's scale indicate the sizes of the particles. Although 2 to 3-in. stones constitute the greater part of the surface material, finer particles, fairly well graded, were beneath the surface. This material seemed to be fairly typical of the river-bed gravel found in other parts of the Miami Valley.

When the first set of current-meter measurements were taken, showing a mean velocity of 5.5 ft. per sec., the clay section was eroding continuously, whereas the gravel section was stable. The gravel seemed to be just on the point of moving, but no sand or pebbles were being transported in suspension and no movment along the bottom could be detected. Fortunately, the clay section was down stream from the gravel section so that the water above the clay was perfectly clear. When the second set of meter measurements was taken, four days after the stable conditions had been changed by a slight rise in the river, the mean velocity was 6.1 ft. per sec., only 0.6 ft. per sec. greater; but the gravel was being rapidly eroded. Pebbles of considerable size were being carried in suspension near the surface of the water, as could be determined by placing the sounding rod only a short distance into the water. Thus, it was definitely proved that this material began to erode at some velocity between 5.5 and 6.1 ft. per sec. probably nearer the lower value, when the depths were between 2 and 3 ft. The shaded portions of the cross-sections in Fig. 6 indicate the total cross-sectional area eroded during the four days. Taking into account the length of the cut-off, about 600 ft., rough calculations show that approximately 100 cu. yd. per hour were being transported.

On the basis of the cut-off experiments the writer believes that the maximum permissible velocities of 4.00 and 5.00 ft. per sec., given in Table 6 for limiting values to be used in straight channels where the beds are "coarse gravel" and "cobbles and shingles", respectively, and where the water is clear, could be raised to 5.0 and 5.5 ft. per sec., respectively, especially since very few canals designed for such velocities will be less than 2 or 3 ft. deep. For large canals, 10 or 15 ft. deep, the writer believes that still higher velocities can sometimes be permitted, possibly 7 or 7.5 ft. per sec. in emergencies. What really happens in a canal located through gravelly materials, subjected to relatively high velocities, is that the finer particles are washed out until the bottom is literally paved with the larger stones; so that the larger stones protect the finer particles below from further scour.

Samuel Fortier* and Fred C. Scobey,† Members, Am. Soc. C. E. (by letter).—The writers wish to express their appreciation of the additional constructive information contained in the discussion. From comments in the discussion there appear to be two main points that may be enlarged upon, namely,

1.—Kennedy's theory and formula and its relationship to "permissible canal velocities"; and

2.—Soil classification particularly as influenced by colloidal material in a dispersed state, contributing to plasticity.

* Senior Irrig. Engr., Div. of Agricultural Eng., Bureau of Public Roads, U. S. Dept. of Agriculture, Berkeley, Calif.

† Senior Irrig. Engr., U. S. Dept. of Agriculture, Berkeley, Calif.

The flow of water in canals may be said to consist of three phases of velocity in its relationship to the movement of soil particles:

(*a*) Non-silting velocities, or in the words of Kennedy* himself, "critical non-silting mean velocities", further explained by the statement:

"Thirty channels were selected, all known to be more or less in permanent régime, and all having self-silted and similar sand beds. Evidently each of them was fully charged with silt, since each had the option of picking up more sand from the bed or dropping any overcharge."

(*b*) Transporting velocities—those which will move down stream particles already detached.

(*c*) Scouring velocities—those which will erode a well-aged canal bed.

Phase (*a*) implies a condition of equilibrium in the flow of a silt-laden canal—a water completely loaded with silt for that particular velocity and depth of channel, and neither taking on more silt nor depositing what it has. Likewise, the implication exists in the Kennedy quotation that the bed silt which might be taken on as a load is quite free to join the silt being transported—that it is not firmly bedded down, as defined on page 944. It is readily seen that any particular soil unit from the finest of clay particles to cobble-stones, could be more easily picked up for further transportation within a short time after it last came to rest than after it had either adhered to adjoining bedded particles or had become interkeyed with adjacent units.

Phase (*b*) differs from Phase (*a*) in that it deals with a water that may not be already loaded. In other words soil particles that would not be moved under Kennedy's specifications would be transported under the same velocity conditions by a water not already loaded to capacity. This phase applies only to soil particles that are perfectly free to move—either particles journeying down stream that have never become part of the settled bed of the canal or particles that have been raveled off from the bed due to velocities under Phase (*c*). Gilbert differentiates between material moved by "stream suspension" and that moved by "stream traction".

Phase (*c*) covers velocities that will scour a canal bed which has become well-seasoned under lesser velocities. These are the velocities that "permissible canal velocities" may be allowed to approach, but not to equal. For other given conditions they are higher than the velocities in Phases (*a*) and (*b*).

The writers have the utmost respect for the work of Mr. Kennedy and feel that his theory and formula, adjusted by the proper coefficients for the waters and silts under consideration, should be the basis for all canal design where silted waters are encountered. Their objections are directed at various writers who misapply his formula in discussing scouring velocities.

There is the implication that below a certain velocity for a given channel and given soil conditions silting takes place and above it scour occurs. This may sometimes be true for the traction of loose particles. The writers' contention is that the well-seasoned bed will not scour under a velocity well above the silting velocity limit.

* "Hydraulic Diagrams for Channels in Earth, Giving Discharge, Mean Velocities, and Silting Data," Second Edition, 1907, p. 1.

In a similar manner transporting velocities have been used as criteria for scouring velocities. One of the most quoted authorities on hydraulics (Merriman), in discussing velocities to be used in the design of irrigation canals, states:*

"The following statements show approximately the velocities which are required to move different materials:

0.25	ft.	per	sec.	moves	fine clay.
0.5	"	"	"	"	loam and earth.
1.0	"	"	"	"	sand.
2.0	"	"	"	"	gravel.
3.0	"	"	"	"	pebbles, 1 in. in size.
4.0	"	"	"	"	spalls and stones.
6.0	"	"	"	"	large stones.

"The mean velocity in a channel may be somewhat larger than these values before the materials will move, because the velocities along the wetted perimeter are smaller than the mean velocity."

It is doubtful whether "somewhat larger" could be construed to mean from fifteen to twenty times as great for clay as is indicated in Table 6. Likewise, Merriman's list would indicate that a greater velocity is permissible in a canal with a sand bed than in one with either clay or loam or "earth", whereas sand alone will be eroded by lesser velocities than any other type of soil particles. Even pure sand will bed and pack down until it requires a higher velocity to move it than the "transporting velocity" which could move the same sand down a flume of such material that the sand could not start to "bed down". The amount of the "bedding down" is indicated in the difference between 1.00 ft. per sec., in Merriman's list, and 1.5 ft. per sec. given in Table 6.

Considering velocities that will scour a well-set canal bed, the following statements regarding soils must be taken as general only. The soil types are so varied and blend from one gradation to another and from "light" to "heavy", and through so many mineral and chemical modifications, that there are cases where general statements do not hold. For instance, ordinarily sand is not regarded as having plastic properties such as are usually associated with clay and probably it seldom occurs in a cohesive state in a canal bed. However, in a previous condition, such sand may have been mixed with colloidal material that would cause more or less cohesion between the sand particles. In its progress down a river or canal such a sand would probably have much of the colloidal material removed by attrition. It is suggested by Macy Lapham, Inspector for the Western Division, U. S. Bureau of Soils, that the colloidal matter so prevalent in the waters of the Colorado River may have come in part from the sand particles which are comparatively free from plastic material by the time they reach Yuma, Ariz., and the Imperial Valley, California.

In a paper of this nature, discussion of soils must be confined as nearly as possible to the phases as they appear to engineers, and its lack of detail will allow any soil technician to point out exceptions to the statements made. From the viewpoint of the engineer—particularly the irrigation engineer—it is unfortunate that the soil technicians have chosen the word, "silt", for their

* "Treatise on Hydraulics," Eighth Edition, N. Y., 1908, p. 288.

grade in size of material next above that of clay. When engineers speak of a reservoir "silting up" they mean the reduction of storage by everything brought in by the river. The engineer and the layman nearly always mentally associate silt and water, and this is borne out by Webster, yet some of the great areas of soil of high silt content as classified by soil technologists were not water-laid but derived from loessial deposits, probably wind-laid. On the other hand, "clay" is not immediately associated in thought with water, yet the predominating areas of arable clay soils of the Western United States are water-laid.

To enlarge on the soil materials listed in Table 6, Column (1): Fine sand, sandy loam, and silt loam are listed as non-colloidal. There seems to be little question as to sand. It is composed of hard distinct units that ordinarily have no cohesive attraction one for another. There are exceptions, as mentioned before. Any resistance to scour exerted by a canal bed of sand, other than the weight of the particles, lies in whatever interkeying has taken place since the last disturbing condition.

As to the various modifications of "loam" there may be more uncertainty. The word, "loam", whatever the modification, with the possible exception of "clay loam", conveys the conception of friability. It must be of a low plastic property or it would not be a loam. A loam does not "clod up" when plowed, and when a lump is moistened the tendency is for it to break down into a rather non-sticky mud. A dry lump of loam crushes freely under a boot-heel. Clods of silts or clays give back a resounding resistance when struck with a shovel. However, such clods may rapidly break down in water if the colloids are in a flocculated state. The fact is to be accented that in soil-particle sizes there is no such gradation as "loam". It must exist in a mixture. Sandy loam is rather more sandy than clayey. Clay loam indicates the predominance of clay rather than sand, and so on.

The next category is "alluvial silts when non-colloidal". Alluvial silts may or may not yield a slick sticky mud when wetted by canal water flowing in an excavation in such silts. The criterion of identity is based largely on the state of the colloidal matter in the silts. If the silts were laid down or filtered out in seepage while containing "effective colloids" as defined on page 944, the particles are in a dispersed—extremely fine—status; while if they were deposited as aggregates or flocculated units, they do not have the plastic attributes described by Hilgard, as quoted by the writers. In an unpublished paper on the silts of the Colorado River, J. F. Breazeale, Associate Bio-Chemist of the U. S. Department of Agriculture, points out that a silt may change back and forth many times in its progress from the upper benchlands of Colorado, Wyoming, or Utah, and from the "bad lands" of New Mexico and Arizona. This change is a physico-chemical reaction between the silt particles and the particular waters that are encountered as the silt travels down stream. This reaction is from a dispersed (effective) to a flocculated state, and *vice versa.*

"Volcanic ash" or "lava ash" is popularly applied to much of the finer grained soils of agricultural value east of the Cascade Range, in the States of Washington, Oregon, and Idaho. The term, "volcanic ash", is a misnomer

as this soil contains little or no volcanic ash material associated as to its origin with volcanic activity. It is mainly a wind-laid accumulation and derived from desiccated sediments of old lake beds and from the finely textured weathered particles of the basaltic lava flows. When wetted it forms a slick mud, but without the plastic characteristics of the clays. It is friable when the moisture is dried out of the mud. However, when wetted, as in a canal bed, this material—intermediate in size between the loamy soils and the plastic clays—will withstand velocities slightly greater than soils that are distinctly loamy and, therefore, friable in character.

The foregoing discussion on the characteristics of colloidal and non-colloidal materials will suffice to explain the terms, "very colloidal", as applied to stiff clays and, "when colloidal", or "when non-colloidal", as applied to graded material that may have fine silts or even particles of "clay" size or less that are effectively plastic if in a dispersed state, but are not plastic if in a flocculated state.

Taking up the individual discussions in the order in which they appeared: Mr. Muckleston senses the difficulty in soil determination as already described. He also mentions the same problem later found in the discussion of Mr. Weiss, that is, the fact of rapid changes in soil types within such a short distance that no adjustment in velocities would be feasible. He suggests that alkali soils erode easily. This is true for most alkalis found in the West with the exception of black alkali (sodium carbonate). (See discussion by Mr. Hart.) Other alkalis, being powerful electrolytes, flocculate colloidal matter so that it no longer has the property of forming sticky, extremely cohesive, canal beds.

Mr. Chandler brings out a point that perhaps should have been emphasized in the paper. This paper deals only with maximum permissible velocities—velocities just short of those that will erode a canal bed. Of course, there may be other factors, such as the need for silting of porous channels, which will entirely change the problem so that the velocities desired are just less than Kennedy's critical velocity or may involve transporting velocities, as already mentioned under Phase (*b*).

As to aquatic growth that seemed to flourish in high velocities, the writers have noted moss in chute-drops where the velocities approached 40 ft. per sec., and, furthermore, this moss was literally alive with small worms, some sort of larval growth. It is suggested that the "swell" of water of such high velocity, carrying almost 30% by volume of entrained air, gives the additional oxygen that makes this flourishing growth possible.

The writers appreciate the additional data contributed by Mr. Stockton. Few engineers have had the operating experience under many conditions that has been his lot. For about twenty years he has operated canals in the Mountain States and the Province of Alberta. His comments are authoritative. Mr. Hart makes an excellent point that has previously been overlooked although it involves most obvious hydraulics. If a canal loses by seepage there is a current available to carry silt and sand down into the original bed material, making it tough and well graded by filtration alone. If the water-

table is such that the flow of ground-water is inward no such current is available and there is less tendency for a canal bed to become well set by the grading of material, especially by the introduction of the fine plastic clays.

Mr. Hill misunderstands the writers when he states that they dismiss Kennedy's formula and theory as fallacious. Kennedy's theory is accepted. When misused the results are fallacious. Kennedy's first edition of "Hydraulic Diagrams for Channels in Earth, Giving Discharges, Mean Velocities and Silting Data, etc." appeared in 1895. Presumably the second edition, written in 1907, contains his retrospect after twelve years of applied use of his formula. In his title he mentions "silting data". A careful perusal of this second edition discloses that in no place does Kennedy confuse his critical velocity with a velocity that will scour a well set canal bed. The writers do dismiss as fallacious the findings of later writers who have misinterpreted Kennedy's silting data, applied it to scouring data, and offered limiting velocities for earthen canals based on such silting data. They regret exceedingly that any statements in the paper could be construed as disagreement with Kennedy's theory in general.

Thus far in this paper and discussion no mention has been made of canal depth as a function of the permissible velocity. As pointed out by Mr. Hill, it is certain that depth would enter the problem in any case where sand bottom exists. The scouring velocity and transporting velocity might approach the same figure, and fluctuating pressures would cause disruption of the canal bed by developing "boils".

It is rather difficult to reply to Mr. Lindley. It is regretted that he was not more specific regarding the Kennedy theory. Evidently, he, like Mr. Hill, misinterpreted the paper as disparaging to Mr. Kennedy and his work. The citations given by Mr. Lindley have not been located. It is to be regretted that the valuable reports and professional papers of the irrigation engineers of India, Egypt, and South Africa, are not more generally available in the United States.

The data in the contribution of Mr. Rohwer is similar to that of Mr. Hill in that it applies to silting velocities or transporting velocities rather than to limiting canal velocities. His photograph (Fig. 3) of cracked silt deposits along the Arkansas River, is typical of other rivers as well. Exactly the same condition exists in the Palo Verde and Imperial Valleys of California, the silt coming from the Colorado River,* and in the valley of the Rio Grande.

Mr. Rohwer's Fig. 2 does not appear typical of an erosion condition. Nearly all true erosion, or more properly "corrosion," shows ragged, nearly vertical slopes, at least on one side of the excavation. The tables given to show the movement of sand as the velocity increases apply to the transportation of a sand prism typical of many canals served by water from the eastern side of the Colorado Rockies. The true beds of these earthen canals are seldom exposed to view. This condition also exists in many of the concrete lined canals of the citrus region of Southern California. Here the concrete bottom

* See discussion and views of Colorado River silt, by Harry T. Cory, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), pp. 1223 *et seq.*

is often covered with a traveling load of sand ranging from isolated patches to dunes more than 1 ft. thick.

Mr. Houk adds a great deal of pertinent data, particularly as to the fact that higher velocities may be permitted in deep channels, for the same type of bed material. It is a question whether some of his cited figures may be applied directly to irrigation and power canals. One of the primary assumptions in the paper was that the canal bed should be well aged. For newly made canals an entirely different set of velocities would apply. Such velocities would not enter into the calculations of the designer unless the canal were to be used immediately at or near peak load and there was no possibility of checking the water by proper grade correction. Some of the velocities cited by Mr. Houk as scouring the channel in alluvial material recently inundated by a severe flood would undoubtedly not have been so effective in a well bedded canal gradually seasoned. On the other hand some of his velocities cited as without scouring effect, may have had too little time. It is probable that inundating floods, in their first stages, pick up a tremendous quantity of trash, too heavy for suspension but not too heavy for bottom traction. Such a condition would cause a great lag at the bottoms of the vertical velocity curves. It is conceivable that mean velocities of 10 to 15 ft. per sec. might have bottom velocities of only 4 or 5 ft. This would be particularly true over the usual inundated area, grown over with more or less brush and weeds. Given sufficient time, this protecting cover would be worn off and effective scour would develop.

The reason for not including the element of depth is the lack of data as to an increase in permissible velocities for an increase in depth. Mr. Houk mentions the work of several of the best known Far Eastern irrigation engineers. It is true that their writings yield much light on the subject of canal velocities, but all of them do not differentiate between these velocities as has been done in this paper. Specifically, Kennedy, as already mentioned, is dealing with non-silting velocities over a bed of shifting material. He may have written on other phases of velocity. Willcocks mentions scouring and silting velocities in several places; not under a specific heading dealing with either of these subjects. Regarding scour, he says:

"The laws of scour are not quite the same as the laws of transport, but are analogous. Here the scour depends on the pressure which the water is able to effect on the particles, on the size and weight of the particles, on the surface exposed to the water's action, and on the tenacity with which one particle clings to the next. Smoothness or roundness in the particles will diminish the pressure, but will decrease the tenacity. A mixture of various sizes of silt will probably diminish the surface on which the water can bear, and will decrease scour."

Again, in writing of silts, he says:

"In November and December the water is comparatively clear, and if advantage is taken of this clear water it can be utilised to scour out the deposits of fine mud in the canals before the mud has had time to harden and consolidate."

Evidently, Willcocks was under no misapprehension as to the various types of velocities to be encountered. It is to be regretted that he did not devote

a chapter exclusively to the subject of canal velocities, bringing together his scattered material on this general subject. It may be noted in his second quotation that he senses the writers' premise of aging in a canal bed.

Buckley does not confuse the various phases of velocity and he has a table of permissible canal velocities that agrees quite closely with a similar one developed years before by Clibborn and that also agrees within reason with Table 4 (Etcheverry), and Table 6, Column (2). Bellasis writes of silting velocities and transporting velocities only. Parker* in a large volume that goes exhaustively into some phases of irrigation and other hydraulics, treats of silting velocities and transporting velocities but makes no mention of those classed under the title of this paper. He must have had the writings of Clibborn, Willcocks, and Buckley as well as those of Kennedy and Deacon (on transporting velocities). He may have been convinced that permissible velocities were synonymous with those of one of the other phases mentioned at the beginning of this discussion.

Paper No. 1589

FLOOD FLOW CHARACTERISTICS*

By C. S. Jarvis,† M. Am. Soc. C. E.

With Discussion by Messrs. Robert Follansbee, O. W. Hartwell, E. C. La Rue, N. C. Grover, B. Okazaki, L. K. Sherman, George G. Honness, L. M. Winsor, H. V. Hinckley, Hardy Cross, E. W. Lane, Gerard H. Matthes, Ford Kurtz, Charles W. Comstock, Thaddeus Merriman, Weston E. Fuller, H. de B. Parsons, Robert E. Horton, Merrill M. Bernard, C. D. Purdon, and C. S. Jarvis.

Synopsis

The characteristics of flood flow that may have either general or special application and therefore must be considered in any preliminary studies for protecting a given locality are briefly stated, not by way of defining probable flood limits for individual cases, but of indicating methods of deduction that must be followed.

The available data that seemed reliable and valuable have been listed and platted to give a visual representation of the range of discharge per square mile for maximum recorded floods. Where possible, the portion of the maximum flow which represents the average annual maximum flood on each stream, has been indicated.

A method of attack is explained by which problems in several Central and Western Districts have been solved satisfactorily, both as to prevention of floods and protection of property.

In addition, there has been assembled in convenient form for reference a variety of representative basic and auxiliary data that are best portrayed diagrammatically.

* Presented at the meeting of May 6, 1925.

† Care, U. S. Bureau of Public Roads, Washington, D. C.

The important public service which the Engineering Profession owes society in analyzing each local situation and in inaugurating or even restricting improvements as the future safety of the community may demand, is especially emphasized.

Design of Structures to Cross Drainage Systems

An engineer endeavoring to design economical and safe bridges or similar structures is confronted with a maze of factors influencing the problem—scores of formulas and tables of data, hundreds of examples that serve as warnings, and thousands that appear satisfactory. Where records concerning the stream flow are lacking, he must rely on a study of the water-shed and channel, the alluvial bars and embankments, the drift lodged along canyon walls and in crevices, and the indefinite memories of observers. In general, he will be unable to reconcile the data thus gathered; and then remains the question of assigning proper weights to the various fragments of evidence.

Following such deductions, an important Western railroad company located nearly 100 miles of line along a valley floor, safely above the reach of the maximum assumed floods, only to experience its destruction within a few years. It was rebuilt on a higher line that would be safe against three or four times the maximum flow originally assumed. Similarly, various highway structures on which Federal aid was sought, had provided only one-half or one-fifth the proper capacity and during the torrential floods of 1923 some waterways that had been regarded as adequate proved able to carry only a small fraction of the maximum flow.

Proper design depends on knowledge of (1) the possible maximum flood; (2) the probable duration and frequency of its destructive stages; (3) the average yearly peak; and (4) the damage that will be likely to accrue from a channel overflow; as the fourth factor is a function of the first or the second, the importance of wisely forecasting the probable flood crests warrants patient labor and investigation.

Causes of Floods

Floods result from (*a*) intensive rainfall; (*b*) prolonged storms that produce a combination of swollen tributaries; (*c*) rapid melting of snow such as accompanies warm rains; or (*d*) sudden release of impounded water. Even the last named may operate without human agency, as, for instance, when an ice dam breaks, or when a landslide forms a temporary impounding dam, to be cut through after the main stream has gathered greater volume and power. Too often floods are traceable to errors of judgment, or perhaps to the demand for economy, as in the cases of restricted spillways, reduced free-board for dams of the non-overflow type, and infringement on the river channel by permanent improvements.

Destructive Stages

The highest flood stage of a stream ceases to be destructive when the endangered elements are either placed beyond its scope or protected from the

violence of the current. The beneficent habits of the Nile would undoubtedly have been known as "destructive floods" if the ancients had established their homes and perishable property in the area subject to inundation, if they had arbitrarily encroached with levees on the required effective channel, or if occasionally the high flood stage had occurred at harvest time instead of during the planting season. Thus, the elements of unpreparedness and helplessness of victims overpowered by a relentless force distinguish a calamity from an awe-inspiring display of latent power in proper control.

Within the past decade communities, after suffering property losses of several million dollars, have expended similarly large amounts for positive insurance against a recurrence. Just such calamities seem to be essential occasionally to crystallize public opinion in preventing channel encroachments that menace property and human lives. It is most regrettable that unscourged communities, exposed to the same peril, exhibit a hesitant attitude toward investigations based on new advances in the science of flood protection.

Rainfall Intensity and Resulting Run-Off

If 1 in. of rainfall runs off uniformly in 1 hour, then each acre will yield 1 sec-ft., or each square mile will yield 640 sec-ft. If the shape and slopes of the drainage basin, the lengths of the various tributaries, and the direction of movement of the storm unite to favor the worst combination, then the yield at some point might be a multiple of this rate. In most cases, due to absorption, percolation, and detention, the percentage that runs off is so low as to neutralize this cumulative effect of synchronous crests at junction points; yet there are apparently authentic records of yields from small areas mounting to 1 000 or even 4 000 sec-ft. per sq. mile, continuing at such stages for only a few minutes, but meanwhile causing incredible damage.

In precipitous localities, especially those denuded of timber, undergrowth, and sod, the first storms that fall after a period of drought seem to yield a greater percentage of run-off than subsequent ones; a sudden penetration of moisture is resisted by the parched and dusty surface. Perhaps the outer inch or two of soil may be saturated and partly eroded, leaving the greater depths entirely dry. The undercutting of such banks along the gullies adds to the weight and momentum of the moving mass, and even retards percolation into the gravel and sand beds along the channel. The first small rivulet, preceding the main body like a pilot, may lubricate the trough so as to increase the natural velocity of the rising torrent, and may finally be overtaken by the flood wave. The great resistance of a rock-strewn channel retards the lower parts of the moving mass, and the upper volume then flows over and descends in front of the retarded portion in a rotary motion; thus, the crest, laden with logs and drift, is comparable to a huge Juggernaut as it crushes obstructions along its path. The content of sediment, fine unctuous clay, gravel, stones, and boulders, picked up from the stream bed according to their relative mobilities, serves to increase the specific gravity and destructive battering power of this first wave, and acts like a moving dam holding this shifting force in reserve, and quickly mounting to greater heights if the progress of the front line is checked momentarily. If the barriers hold, the lateral banks

will be overtopped and the divided flood, disarmed of its heavy weapons, will seek out or carve for itself new channels. Examples of the effects of such mountain torrents are shown in Figs. 1 to 5. The value of such occurrences as warnings to communities similarly situated may even exceed the amount of damage caused if only steps are taken either to prevent a recurrence, or to control, guide, and dissipate the threatening crests.

Diverse Flood Flows

Between the combined avalanche and flood flow here described and the well ordered habits of other rivulets, especially those that have their sources largely in springs, or in snow deposits well protected against sudden thaws, there exists an endless variety of conditions. A north slope, a deep rocky gorge that entraps heavy drifts and provides security against direct sunlight, or topographic features such as mountain peaks on the windward side, serving alike to deflect the "chinooks" and the moisture-laden air currents, cooling them, and transforming the potential rain into snow, may modify run-off habits. As a result some main tributaries have flood problems of limited scope —rarely turbid and never departing far from mean flow—whereas others vary from a dry-channel condition to a peak exceeding that of the main river.

Such is the Gila River in Arizona; in its dry-channel stage it represents between 50 and 400 sec-ft. of underflow,* while as a maximum, its record has exceeded the Colorado River floods above the junction at Yuma, Ariz. The first severe storms in the summer of 1923 wrought havoc to railroad and highway traffic in various Western States. When a destructive flood crest tore out structures on up-stream tributaries of the Gila and approached the highway bridge at Florence, Ariz., a warning alarm was spread; but this flood never attained dangerous proportions nor even reached the first flood channel at this station, as the underground storage nearly absorbed it. A subsequent flood approaching with no higher crest was deemed of less importance and therefore was unheralded; yet it interrupted traffic at some of the lower crossings, because the underground storage space was already filled.

Rainfall Variants

Just as mountains lying across the path of moisture-laden atmospheric currents deflect them upward with a consequent chilling and condensation, so a sharp canyon or rift in a mountain range often causes an induced upward draft as through a chimney, elevating the warm moist air of the valleys to an altitude where the cold temperature results in copious rainfall.

If the convection currents moving upward have a velocity in excess of about 20 miles per hour, the condensation is blown back and scattered much like spray from a garden hose pointing into a violent wind; when the distribution is uneven some areas near the center of disturbance receive a double portion, while others are deprived of their normal supply. A notable example was the record-breaking rainfall in Central Texas, September 7 to 11, 1921, when 23.98 in. fell in 35 hours at Taylor, somewhat to leeward of the storm

center, while Elgin, only 18 miles southward, and actually nearer the center of disturbance, recorded only 4 in. The area receiving more than 5 in. was nearly elliptical, the major axis extending along the pronounced Balcone fault zone for nearly 200 miles, from San Antonio to the Brazos River; Elgin in the midst of 15 and 20-in. rainfall areas had its portion depleted to increase Taylor's abundance, doubtless by the action here described.*

Run-Off Variants

The variations due to the presence or absence of vegetation; to the surface texture and condition; to the probability of sudden thaws, as from warm rains, or of intense precipitation on frozen ground; to the possibility of bank and flood-channel storage; to the direction of travel maintained by prevailing storms; to the altitude, temperature, annual rainfall, special topographical or meteorological features; and to the area, shape, and slopes of the drainage basin—all these variations must be considered in a given problem. The influence of the area appeals to the writer as the logical basis for a general formula, with the effect of the other variants grouped in the numerical coefficient corresponding to Kutter's or Chezy's C.

Determination of Basic Run-Off Formulas

A careful study of diagrams on which are platted data for the yield, q, in second-feet per square mile of drainage area, as ordinates against the drainage areas, M, in square miles, as abscissas, indicates the relation:

$$q = \frac{C}{M^{\frac{1}{n}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which C and n are constants.

If there is required, not the yield per square mile, but the total discharge from the basin, designated Q, it will be necessary to multiply each member of Equation (1) by M, that is,

$$q\,M = \frac{C\,M}{M^{\frac{1}{n}}}, \text{ or } Q = C\,M^{\frac{n-1}{n}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

which is one of the most convenient forms for practical field use.

Another easily applied formula results from dividing each member of Equation (2) by the assumed mean velocity to be attained at the section considered; the left-hand member will be the prescribed area of waterway, a, in square feet. Assuming a velocity of 10 ft. per sec., for example, and reducing C correspondingly to C', there results:

$$\frac{Q}{10} = a = C'\,M^{\frac{n-1}{n}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

This fundamental form is followed, with slight variations, by many of the widely used and satisfactorily tested formulas for run-off or for area of

* "The Floods of Central Texas in September, 1921", *Water Supply Paper No. 488*, U. S. Geological Survey.

waterway, with n taking values between 1.5 and 6 generally, giving rise to expressions, such as $\sqrt[6]{M^5}$, and others much more complicated.

The bewildering number of factors, constants, and variants which have been so ingeniously devised to make the various formulas fit the needs of given conditions, apparently should be capable of reduction to a common denominator, so to speak, a means of translation without mastering each nomenclature or becoming an adept in the use of each of the various forms.

In devising a proper formula for run-off, the Myers type will be tentatively selected for modification or extension, and correlated with the recorded flood run-offs, as platted on Plate IX. In the Myers formula $a = C\sqrt{A}$, in which, A equals the area of the drainage basin, in acres, and C is a coefficient varying from 1 to 4. Transforming the area into square miles:

$$a = C \times 25.3 \sqrt{\frac{A}{640}} = C \times 25.3 \sqrt{M}$$

This agrees with Equation (3) if $C' = 25.3\ C$ and $n = 2$.

Trying a value of C equal to 40, giving the product of $C \times 25.3$ as approximately 1 000, and assuming the velocity to be 10 ft. per sec., the resulting equation becomes:

$$Q = a\ V = 10\ 000\ \sqrt{M}$$

The resulting graph for Q (Plate IX) is found to lie above all the platted points representing flood run-off rates except two, and to conform closely with the enveloping curve, thus justifying the assumption of C as 40 for a maximum.

Similarly, for the lower limit, the path of the point, $Q = 100\ \sqrt{M}$, conforms well with the general slope, and lies above only 5% of the more than 1 000 platted flood run-off rates. This treatment suggests the idea that the modified Myers formula might be considered as $Q = R\ \sqrt{M}$, in which, R is the expected rate of run-off, in second-feet, from 1 sq. mile, varying between 100 and 10 000.

To determine the required cross-sectional area of bridge opening, the allowable velocity would be used as a denominator, and,

$$a = \frac{R}{V}\sqrt{M} = S\sqrt{M}$$

in which, S is the coefficient for the sectional area of waterway.

Another method of comparing discharges would be according to the percentage, p, of the maximum for the corresponding area obtained from the modified Myers formula, $Q = 10\ 000\ \sqrt{M}$, which percentage is readily scaled for any point platted, as shown on Plate IX; in that case the coefficient, R, in the previously given equation becomes $10\ 000\ p$; and $S = 1\ 000\ p$, if $V = 10$. Thus, the Colorado River below the Gila junction at Yuma would rate 5%; the Nile would be expressed as 4%; the Amazon, 50%; the Mississippi at Cairo, 21%; the Ohio at Paducah, Ky., 32%; the Gila both at Yuma and Florence, Ariz., 10%; the Salt River, prior to its control by storage reservoir, at the mouth and at Roosevelt, Ariz., 27%; Salado Creek, Texas, 117%, the highest rate platted; the Miami, Dayton, Ohio, 50%; Otay, Lower Otay Dam (causing failure), Calif., 40 per cent.

FIG. 6.

There may be other formulas just as capable of extension and modification to cover the entire field, but it will be difficult to find one more readily applicable, and agreeing with the platted run-offs more consistently than the modified Myers formula. In Fig. 6 is graphically illustrated the relationship between the best-known expressions for run-off.

In some cases a first approximation of run-off for a given district may be obtained by the use of data from Plate IX, or from Table 2 (Appendix I), which is the same information in statistical form. As opportunity affords, further computations may be based on all the usual factors, representing expected rainfall intensities and duration, percolation, evaporation, detention, bank storage, slopes, forestation, tillage, elevation, shape of drainage basins, the time elements, geological formations, and other tangible influences.

Variable Factors

Among the considerations too often neglected, and so variable and elusive as to have escaped notice in standard formulas, are the following.

1.—Inherent Similarity.—Flood problems for small drainage areas may be essentially the same in various districts, even under widely dissimilar climatic conditions. If it be recognized that extreme rainfall and run-off rates for the arid and the humid regions of the United States, and, in fact, for nearly all known regions, are nearly identical, then there is a common basis for estimates. Whether in desert regions or on the coastal plains, however, the resulting run-off varies, being increased in violence by steep slopes and confluent crests from denuded areas, or reduced by detention, evaporation, percolation, and under-flow.

Vital differences do exist as regards the frequency, duration, and extent of such violent storms, thus justifying the classification of the resulting floods as "frequent" or "occasional" for one district, while they are regarded as of rare occurrence for another. The latter case encourages the appropriation and partial occupation of the channel for productive purposes.

2.—Periodic Maxima Expected.—The time element, so useful in connection with flood frequencies, is too often a basis of error. The popular notion is to place the probable occurrence of the 100-year maximum flow at a number of years hence, and, similarly, with the 20-year expected maximum. Either of these is as likely to occur during this year or next as in any other two years of the designated periods. This fact is well illustrated in Table 1, showing the time intervals of great floods.

3.—Factors of Safety.—On most American streams the records are altogether too meager to establish a fair approximation of the maximum flood to be expected in a century or even in a period of two decades. If there is any basis in fact for the theory of storm cycles, the platted curve representing the magnitude of expected floods would doubtless show harmonic variation, with nodes and slight inclinations as well as steep slopes. If the period of observation includes only one of the phases, there is a probability of a large error. Therein is the most potent argument for a physical examination of the watershed, channel, and modifying influences existing or to be provided.

§ "Hydrologic Record, Mississippi River Floods," by E. N. Chisolm, Jr., Captain, Corps of Engrs., U. S. A., M. Am. Soc. C. E., *Engineering News-Record,* January 18, 1923, p. 112.

As an example, the City of Pueblo, Colo., and the Denver and Rio Grande Railroad Company previous to 1921 had made ample provision against maximum recorded or expected floods, based on the average annual crests, or on the possibility of local storms of the cloudburst type affecting small tributaries concurrently; but the demonstrations of June, 1921, placed this problem in another category. At that time (Fig. 7), there was a sustained violent storm over an area in excess of 1 000 sq. miles for at least 10 hours.

While making provision for increased channel capacity at Pueblo, engineers were astonished to find that the flood might have been of nearly double severity had the storm center been located a few miles farther westward. For this and other reasons, it was recommended that the old channel with a capacity of 40 000 sec-ft. (fully five times the average yearly maximum for the preceding 30 years) be replaced by one including a wide spillway, the combined capacity to be 175 000 sec-ft. The actual observed peak was 105 000 sec-ft.

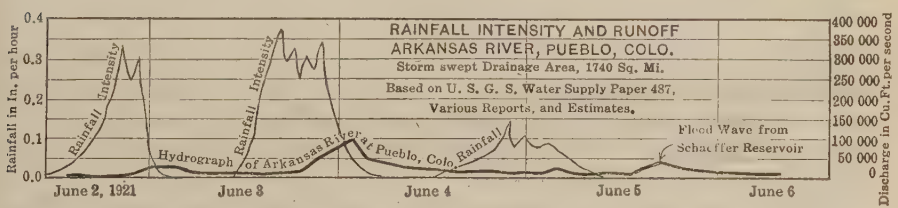

FIG. 7.

As another instance the spillway at the Lower Otay Dam, near San Diego, Calif., was overtaxed in January, 1916, the run-off being eight or ten times the quantity for which it was designed according to the known habits of the water-shed at that time. Such calamities emphasize the need for larger factors of safety to take care of these supposedly remote happenings.

4.—Flood Height vs. Discharge.—Where protective works are established or contemplated without storage the flood height is more important than the actual discharge passing the station. It is well established that a given stage

of a rising flood in a silt-laden stream represents a greater flow than the same height during recession. In Fig. 8 are graphically shown some of the reasons for this phenomenon. It has been claimed for the Colorado River channel at Yuma, that for each foot of rise on the gauge it scours an equal depth from the bottom. Evidently, after the peak has passed another cycle begins, the velocity being retarded, the silt burden depositing, the gradient and the hydraulic radius decreasing, thereby causing further retardation and deflection of currents laterally as if in quest of new material to transport. Although the tendency during the rising phase is to scour the channel bottom and induce central flow, the receding torrent is inclined toward lateral excursions. This often accounts for the fact that the main damage to alluvial farms occurs after the main crest has passed and the patrols have slackened their vigilance.

It remains an open question whether the tragedies too frequently recorded of passenger trains plunging from trestles into swollen streams are due to derailment or to inadequate inspection of the substructure. How is the track walker or inspector viewing the rising flood surface only 1 ft. or 2 ft. higher than the normal stream surface, to know that the channel may have scoured several feet deeper, possibly undermining the piers or piling?

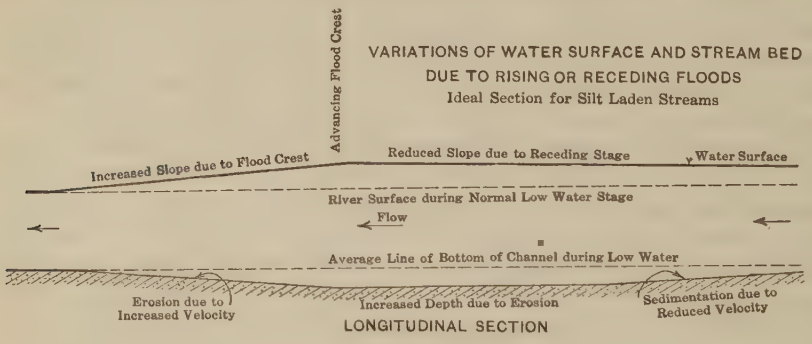

FIG. 8.

While Sir William Willcocks was on a tour through America after his notable success at the Assuan Dam on the Nile, he stated that the 15-ft. gauge height on a rising Tigris flood represents 180 000 sec-ft. of discharge; the 20-ft. stage if at the peak represents only 120 000 sec-ft.; and the 15-ft. stage during recession corresponds to 90 000 sec-ft.*

5.—Maximum Stage as Compared with Twenty-four Hour Average.—The importance of determining maximum flood rates instead of or in addition to the average for 24 hours, is well illustrated by the Pueblo flood (June 3, 1921), where the 24-hour rate was only 110% of the full channel capacity, while the maximum flow, lasting less than 1 hour but accountable for the main loss and damage, was more than twice as great.

In dealing with small areas it must be borne in mind that the maximum flood crest—sometimes coincident with the initial wave—and the return to normal flow may occur within a few hours. For this reason the collected data

* *Engineering Record*, June 27, 1914, p. 723.

for Table 2 (Appendix I), and Plate IX, deal with maximum rates wherever available.

6.—The Wooded Channel.—The regulating influence of great storage dams, such as those built by the U. S. Reclamation Service and enterprising irrigation districts, extends beyond the limits usually assigned. When they begin to function, the improvement of farms near the stream, where the alluvial soil is generally the most productive and at the same time most mellow and exposed to lateral erosion, increases the hazard of flood damage if maximum stage should recur. Even if the reservoir is full to the spillway floor at such a time it is effective, acting as a detention and regulating basin; and it has been conceded on some projects that the 6 to 10 ft. of storage depth above the spillway crest is as important as the entire capacity below that level. Additional depredations surely would have been made by the Colorado River in the Imperial Valley, California, had not the Roosevelt Dam been regulating the Salt River, the Gila's main tributary, when the Gila experienced a record flood in January, 1916, far exceeding any known discharge of the Colorado above Yuma.

If, however, a storm and flood period is protracted, the increased flow over the spillway or the necessity for the operation of emergency outlets to save the main structure, may overcome the natural equalizing effect and transmit the destructive flood stage to the lower river. In that case it would be discovered that the channel capacity has decreased as compared with the years when unrestrained floods limited the growth of vegetation. The islands and bars formerly denuded would have such a well established covering of quick-growing trees as to resist and retard the maximum flood—perhaps even collecting driftwood barriers—forcing the water to seek higher levels. Carefully conducted gaugings* on typical channels have established the fact that for a wooded course Kutter's n increases to nearly double that obtaining for cleared areas.

7.—Structural Design Limits and Flood Peaks.—Granting that the economics of design would not justify doubling the expense to prevent interruption of bridge traffic two or three times a century, it still remains for the Engineering Profession to define just where the excess flow shall be accommodated. The U. S. Bureau of Public Roads anticipates conditions by the following specification:†

"Waterway.—The waterway shall be adequate for the passage of ordinary flood water and drift at a velocity not exceeding the average velocity of the stream in the vicinity of the bridge and shall be adequate for the passage of extreme flood water unless other provisions are made for same. By ordinary flood water is meant the stage that is likely to occur once in ten years."

To cross the numerous intermittent flood channels that are in service only a few hours or days each year, the Bureau and several States have adopted standard dips or spillways, consisting of undulations in the highway grade with suitable cut-off walls to prevent erosion or undermining. Comparative unit costs of waterway area provided by various types of drainage structures, indi-

* *Engineering News-Record*, October 12, 1922, p. 599.

† Superstructures, General Clauses, Standard Specifications, U. S. Bureau of Public Roads, as revised July, 1921.

cate the great economy of the dip or spillway. Although it is conceded that this form of construction has its limitations, especially in connection with railroads and large drainage channels, it is believed that there is a broad field for its use in providing for the maximum flood stages that are beyond the economic range of other structures.

8.—The Definite Function of Spillways.—The moment a flood overtaxes its definite channel is the beginning of either a minor episode or a great tragedy. If the rising surface is confined by inadequate artificial embankments until relief is secured only by the formation of crevasses, then the benefit sought by the levee system is more than nullified by the destructive velocity of an impounded flood suddenly released. It would be far better to allow the gradual overflow and less violent inundation of the adjacent lands; perhaps the enrichment of the soil due to an occasional quiet sedimentation would go far toward repairing the loss and inconvenience, if only the land owner has planned his crops and plantings, his permanent improvements, and his pastures for livestock so as to insure their safety or the minimum damage from such an expected overflow.

Sir William Willcocks, already quoted, evidently gave his own views of what should be done to control the Mississippi River more effectively, when he described the best practice of the ancients. He was altogether appreciative of the wonderfully effective work of the Corps of Engineers, U. S. Army, and of the civilian personnel, and reiterated the idea that an occasional relief through crevasses is inevitable unless some form of multiple spillway along one bank or both shall begin to function automatically whenever the flood stage passes the limit for which ample provision has been made.

The alarm following the moderate but protracted floods of 1922 that passed the Arkansas Junction and registered the greatest flow ever recorded at Carrollton, La., is really a commendation for effective construction and maintenance of a great levee system, and gives point to the argument of Sir William Willcocks for automatic spillways, regulated overflow channels, and valley storage. Examinations of the actual projects on the Mississippi will disclose that all the foregoing features are contemplated in some degree; but where a stage higher than 50 ft. continues for 50 days, as occurred even at Cairo during that year, the use of farm lands for storage almost amounts to their abandonment.

Applying the principles herein enumerated to projects under civilian control, it would seem like a measure of safety to compute the profile of an assumed or estimated flood crest, which should be some multiple of the present channel capacity, in many cases double or treble. If the resulting lateral flow would overtax structures under highways, railroad embankments, or other barriers, the question would be to determine the possibility of their sudden failure, and the changes required to provide a safe automatic discharge with minimum damage.

When destructive floods occur at other times than during the planting or growing season and consist of sharp crests carrying much sediment, there are strong arguments for not only allowing but insuring the action of wooded channel spillways, thus providing against scouring velocities. The recurrent

quiet sedimentation on the overflowed lands would add fertility and cause them to rise at least proportionately with the river delta.

Review of Flood Problems Desirable

As a result of floods during recent decades and especially during 1923, a re-appraisal of the attendant dangers should be made for many of the river channels.

After a flood the stricken community is confronted with the problem of abandoning the inundated area in whole or in part, or of insuring it against future damage. This latter solution may be accomplished either by positive control—that is, regulation of maximum crests—or by adequate protective works. Conditions may favor (1) regulation by detention basins, ordinary reservoirs, or those purposely located to favor outflow through underground channels; (2) diffusion of the water as by spreading it over detrital cones, gravel bars, or coarse sandy areas to replenish underground storage; (3) establishing timber cribs or other barriers as overfall dams to break the continuous gradient, to check a rolling initial wave and temporarily arrest the heaviest burden; (4) planting willow and timber copses to entrap sediment; or (5) diffusing the surplus by spilling it into pasture or woodlands. All these methods are based on retardation. The case may demand the widening, rectification, and clearing of the channel to promote accelerated flow, or it may warrant a combination of the two general methods—truly, a wide field for investigation. The number of possible solutions of such problems forms a maze through which the proper path is difficult to discover, requiring the best talent and the most mature judgment that experience and special training can develop.

Need for Unified Control

So complex and interlocked are the community interests to be served in the control of streams that there is scant opportunity for the rough and ready, independent, private initiative which pioneers had to develop in order to survive. According to present paternalistic policies, it seems imperative that this control become a State or municipal function for small streams, even as it is now administered under Federal jurisdiction for navigable rivers.

The shortcomings of the present methods are forcibly illustrated by a case that occurred during 1923. When a torrential flood had started to ravel the protective rip-rap and eat into city property, a mass meeting was called, at which the State Engineering Department, represented in an advisory capacity, recommended the anchoring of newly cut trees, with branches intact, as current deflectors and retards, and the placing of brush and rock revetment among hurriedly driven piles and stakes. In earlier days this very plan would have been carried out and reported as accomplished before the hour for mass meetings; but in the present case by the time each citizen had extolled his individual plan, the majority sentiment seemed to favor the use of rock because of its durable character. This disregard of sound engineering advice for wasteful emergency measures resulted in the continued progress of erosion, with the loss of all the new rip-rap, several city lots and comfortable homes, an

appeal to the Government for relief, and the acceptance of a plan furnished by a competent specialist requiring a timber pile jetty with brush and rock-filling to cover the scar and prevent further incision.

Opportunity for Public Service

The possibilities of the present situation must appeal to all members of the profession who are experienced and competent in flood protection, that is, the privilege of contributing to community welfare in determining whether great hazards do exist and what special protective measures are required. If thereby local officials are awakened to the reasonable needs, and relief projects are initiated, one step toward safety will have been accomplished; the danger zone of floods will be known and provision will be made for an emergency. If even a small percentage of the annual disasters should be averted, or the loss and damage reduced by wise preparation, the cost and labor involved in such studies will be fully justified.

Conclusion

In this paper, the writer does not assume to solve any particular problem, but merely lists certain data and considerations that are often left unrelated or neglected entirely. His purpose will be accomplished only when the essential suggestions herein recorded, or to be brought forth during the discussion, have resulted in a definite campaign to determine flood dangers and the advisable measures for control. The most positive step yet taken seems to be the studies involving the expected run-off for California streams made by the State Engineering Department.*

Specific acknowledgments have been made wherever practicable in the paper. In addition, the writer has obtained invaluable information from the published writings of the many eminent hydraulic engineers of the United States, most of them members of this Society. These data are included in Table 2 (Appendix I). For the convenience of members and others, the writer has included an alphabetical index, Table 2 (A) (Appendix I), in order that references to streams in Table 2 may readily be found.

Special appreciation is due those who have so generously assisted and encouraged this work, notably Government engineers and officials, State, municipal, and college officers, engineers in private practice, and associates.

* Reference No. (70), Table 2 (Appendix I).

* Table 2 has been revised to include all corrections noted by discussors, by engineers of the U. S. Geological Survey and others, and information obtained subsequent to the original publication in *Proceedings*. Item numbers followed by letters indicate new data. Corrections, revisions, and the necessary re-arrangements have been made.

† Locations as given in Column (8) of Table 2, are abbreviated, as follows: Northeastern United States, N.E.; Southeastern, S.E.; Southwestern, S.W.; Northwestern, N.W.; Mississippi Valley, M.V.; Rocky Mountains, R.M.; Great Basin, G.B.; Alaska, A.; Canada, C.; Hawaii, H.; Mexico, M.; Panama, P.; and foreign, F.

Notes.—In addition to nearly 1 000 maximum recorded or expected flood rates from Table 2, Plate IX includes other points as follows:

From the discussion by the late Emil Kuichling, M. Am. Soc. C. E., of the paper entitled, "Flood Flows", by Weston E. Fuller, M. Am. Soc. C. E. (Reference No. 69), there are platted fifty flood rates designated (F) for European streams not otherwise listed.

In several instances, points with different designations were found to coincide, requiring either a slight displacement or the omission of one or more.

Reference No. 70, *Bulletin No. 5*, "Water Resources of California", includes several streams for which records are incomplete, but the expected maximum flood rates have been carefully estimated; these platted points are distinguished from those regularly listed.

Initials (Table 2), or characters (Plate IX), to designate each country or section have been selected with regard to their suggestive value.

No. (120) *Proceedings,* Am. Ry. Eng. Assoc., Vol. 12, Pt. 3, 1911, p. 504.

NOTE.—Column (8) of Table 2 (Appendix I) devoted to references is entitled "Main Authority." Several conflicting sources have often been consulted; perhaps the date was supplied from one and the most reliable observed data from another. In such a case, the latter authority is the only one quoted.

The quantities in Columns (6) and (7) of Table 2, "Expected Peaks," were in general gleaned from sources other than the ones quoted, except where the reference is No. (70); this California *Bulletin* was found to be better adapted than any other publication examined for giving visual presentation of such hydrographic data. It has been endorsed and adopted as the most desirable form for displaying such information by the Society's Special Committee on Flood Protection Data.

Wherever the U. S. Geological Survey publications contained the data for a given stream they were given preference, as being both the most reliable and the most nearly standardized. The majority of observations tabulated were either made or collected and authenticated by the Hydrographic Branch of that Department.

DISCUSSION

ROBERT FOLLANSBEE,* M. AM. SOC. C. E. (by letter).—This paper contains the most complete tabulation of flood flows that has come to the writer's attention, and the Engineering Profession is indebted to the author for his able treatment of the subject.

The list of maximum observed discharge rates should be brought down to date where possible, especially in the case of records for stream-gauging stations still being maintained, where floods greater than those presented by the author have been recorded.†

During 1922 and 1923, the States of Colorado and Wyoming experienced a number of severe floods, some of which were the greatest ever recorded. These are described in a report of the U. S. Geological Survey.‡

In addition, two other severe floods of previous years which have been recorded, are not included in the author's list. Table 3 shows the maximum discharge of these floods, arranged according to the size of the drainage areas.

TABLE 3.—MAXIMUM OBSERVED FLOOD DISCHARGE RATES.

Stream.	Drainage area, in square miles.	Crest discharge, in second-feet per square mile.	Date.
Skyrocket Creek, at Ouray, Colo.	1.0	2 000	July 20, 1923
Magpie Gulch, near Golden, Colo.	1.5	1 270	July 26, 1923
Missouri Canyon, near Masonville, Colo.	2.4	1 820	June 16, 1923
Hogan's Gulch, at Eden, Colo.	6.1	1 580	Aug. 7, 1904
Bayou Gulch, near Franktown, Colo.	19*	460	July 28, 1922
Redstone Creek, at Masonville, Colo.	21*	325	June 16, 1923
Tough Creek in Sec. 28, T. 39 N., R. 94 W., Wyo.	24	62.5	July 24, 1923
Buckhorn Creek, near Masonville, Colo.	40*	262	June 16, 1923
Cherry Creek, near Parker, Colo.	87*	195	July 28, 1922
Paintrock Creek, near Hyattville, Wyo.	164	30.2	July 24, 1923
Salt Creek, below Salt Creek Reservoir, Wyo.	520	61.5	Sept. 27, 1923
Badwater Creek, at Bonneville, Wyo.	794	23.4	July 24, 1923
North Fork, Shoshone, near Wapiti, Wyo.	800	10.1	July 22, 1923
Powder River at Arvada, Wyo.	6 050	15.7	Sept. 29, 1923
Cheyenne River, at Hot Springs, S. Dak.	8 720	17.2	May 12, 1920

* Drainage area affected by storm.

O. W. HARTWELL,§ ASSOC. M. AM. SOC. C. E. (by letter).—The author has made a valuable contribution to the long list of papers on this subject. In the past much has been written about flood flows, and many formulas have been evolved in attempts to predict the size of floods. This problem will be studied again and again in the future, with results increasing in value as the fund of actual flood data increases.

The author has overlooked one source of information which will give him many valuable additions to Table 2. In all the recent *Water Supply Papers*

* Dist. Engr., U. S. Geological Survey, Denver, Colo.

† This suggestion has been carried out by a revision of Table 2 (Appendix I) included in the paper as published.

§ District Engr., U. S. Geological Survey, Trenton, N. J.

of the U. S. Geological Survey the maximum and minimum discharge during the total period of record is published for each gauging station. In the report for any given year may also be found the extremes of discharge for that year.

The author dismisses consideration of the time element too hastily. There are many projects where human life is not endangered and where the cost of various degrees of protection to property must be compared with corresponding losses. Such problems can best be solved by the theory of probability. In this connection, Allen Hazen, M. Am. Soc. C. E., wrote,* in 1914:

"As time goes on, data covering longer periods and more streams may change some of the numerical values; but the underlying idea of treating the recurrence of floods as a matter of probabilities, to be determined by an examination of the records of many streams, will stand."

Ten years have already been added to the continuous records for a large number of the stream-gauging stations which existed in 1914, many new stations having been installed since that time. Furthermore, the accuracy of flood data has been greatly increased through the development of the automatic water-stage recorder and through other improvements in methods of conducting stream-gauging work. It will take 1 000 years to obtain an actual 1 000-year record, but long before the end of this period engineers will be able to determine the 1 000-year probability within a reasonable degree of accuracy.

E. C. La Rue,† M. Am. Soc. C. E. (by letter).—Since the automobile became a dependable means for long-distance travel the demand for good roads has been almost universal. During recent years hundreds of millions of dollars have been expended for the construction of automobile highways in the United States. The cost per mile of many of the hard-surface highways is comparable with that of railroad construction. It is generally conceded that some of this road work has been done without providing adequate structures to take care of transverse drainage. How many engineers make a serious study to determine the magnitude of the floods which may be expected in each running stream or dry wash?

There is much to be said in defense of the engineer. He is not always responsible for the poor location of a railroad or highway, or for drainage structures of inadequate capacity. The author states that "an important Western railroad company located nearly 100 miles of line along a valley floor, safely above the reach of the maximum assumed floods, only to experience its destruction within a few years". Some years ago, the writer talked with the engineer who had charge of the location of this railroad. He had strongly recommended another location to avoid the floods which he, at that time, knew to be dangerous, but was overruled by those who were financing the construction. The estimated initial cost for the location in the valley was less than that recommended by the chief engineer.

The author has presented a simplified formula for computing maximum floods which may be expected from a given drainage basin. Although this is an important step in the right direction, he has left plenty of work for the

* *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 626.

† Hydr. Engr., U. S. Geological Survey, Pasadena, Calif.

engineer who must design the structures, and who must make certain that they will carry the maximum load with safety, that they will not be damaged by the maximum expected floods, and that their estimated costs are reasonable. It will be noted that the author's formula $\left(Q = R\sqrt{M}\right)$, carries a factor which may vary from 100 to 10 000. This formula will unquestionably prove useful in actual practice. However, the engineer must make extensive studies to determine the flood flow characteristics of the streams in the territory through which he must build a railroad or highway. Where the construction of a dam is being considered the studies of flood flows may be confined to its particular drainage basin.

The writer, being familiar with the flood flow characteristics of the Colorado River and many of its tributaries, has applied the author's formulas for the purpose of comparing the calculated values for flood flows with those obtained from recorded data or traditional evidence. It was found that the formulas give erroneous results when used to determine flood flow maxima on the main stream of the Colorado River. According to the formulas the greater the area of drainage basin, the greater the maximum flood. This is not true of the Colorado River. The maximum flood flow at Lees Ferry (drainage area, 108 000 sq. miles) may be 250 000 sec-ft., while the maximum flood at the Laguna Dam (drainage area, 186 000 sq. miles) may be only 200 000 sec-ft. The records show that on this stream the maximum flood flows occur at a point 800 to 850 miles above its mouth (except floods from the Gila River).

The writer believes that the maximum flood that may be expected in a stream with a drainage basin of 1 000 sq. miles, or more, can be estimated with greater accuracy than in streams having drainage basins of a few square miles. The greatest run-off per square mile of drainage area occurs in streams having small drainage basins; however, the frequency of these floods is much less than those which occur in streams having large drainage basins. The engineer has to decide as to how much money may reasonably be spent on structures where the maximum flood may not occur once in 100 or 200 years. It is true that the 100-year flood may occur next year; it is also true that if the structures over every dry wash were built to withstand the 100 or 200-year maximum flood, the mileage of highways to be constructed would be seriously reduced. Where the problem does not involve possible loss of human life, it seems reasonable for the engineer to design flood by-pass structures on a less conservative basis, taking into account the cost of replacing structures which may be destroyed once in 50 years.

The author's graphical tabulation of run-off records (Plate IX) is a valuable contribution to the subject, and he is to be commended for his exhaustive search for the data which form the basis for this diagram. Its accuracy and value are only limited by the flood-flow data which were available. The diagram, perhaps, fails to show the maximum 50-year or 100-year flood for many of the streams due to the lack of available records, but the author has plotted sufficient data to show in a general way the limits of maximum floods that may be expected in streams with drainage basins varying

in size from less than 1 sq. mile to more than 1 000 000 sq. miles. The diagram would obviously be more valuable if sufficient data were available to show the maximum flood that has occurred during the past 100 years on each of the respective streams considered.

The author is unfair to himself, when in his conclusion he says:

"In this paper, the writer does not assume to have solved any particular problem, but merely lists certain data and considerations that are often left unrelated or neglected entirely."

He has suggested a simple formula which may prove to be of considerable value to engineers who must calculate maximum flood flows that may be expected in a given region. The paper as a whole may prove an important factor in furthering the work that should be done to determine flood dangers along streams throughout the country.

N. C. Grover,* M. Am. Soc. C. E. (by letter).—This paper emphasizes the importance of a thorough study of floods, the need for which was anticipated by the Board of Direction of the Society when, in 1922, it created a Special Committee on Flood Protection Data. That Committee, after compiling the records of many floods, has recommended that the Society undertake an elaborate study of flood data and the publication of the results in such form as to afford engineers a satisfactory working basis for handling the many problems of design and construction related to floods.

In the absence of sufficient data to serve as a basis for studying floods by river basins, or even by regions, the author has followed the common practice of showing on a single diagram (Plate IX), the available flood data for a wide area (in this instance, the whole world) and of plotting thereon limiting, average, and regional curves of various kinds that may serve to aid him and others in establishing elevations of highways and railroads and capacities of culverts and other bridge openings and of spillways and flood channels. The diagram has served to generalize the available data and to show how the regional curves are related to all the data and to the limiting curves of the world's floods. He has shown also, by sixteen symbols, the flood data for different regions, but the plotting of so many points on a single diagram has made difficult the separate utilization of the information pertaining to any particular region. He has also presented a diagram (Fig. 6) showing the various flood formulas and, by modifying one of these formulas, has suggested a possible method of approach to the problems that arise in certain fields of engineering.

The results are evidently not wholly satisfactory to the author, as he "does not assume to solve any particular problem but merely lists certain data and considerations that are often left unrelated or neglected entirely." His inability to reach satisfactory conclusions should perhaps have been anticipated, as the only data available are unsystematic and even incomparable, because they include without discrimination both peak discharges and averages for days of maximum discharge. As a net result of reading

* Chf. Hydr. Engr., U. S. Geological Survey, Washington, D. C.

the paper one is left with the feeling that organized engineers, and specifically the Society, should find a better way to serve the profession by providing a rational and adequate basis for treating the many important problems related to floods. Evidently, the author is similarly impressed, as he states in his "Conclusion" that his purpose in preparing this paper will have been accomplished when "a definite campaign to determine flood dangers and the advisable measures for control" has been inaugurated.

Floods are essentially local phenomena in which precipitation is the major factor, even if temperature, in its effect in storing water as snow and ice and, later, in releasing it by melting, may at times be controlling. Other factors also serve to modify the effects of precipitation in varying degrees. Precipitation and temperature vary widely within relatively short distances, so that each of the factors modifying the effect of precipitation in producing floods is strictly local in its application. Floods, therefore, must be studied locally by river systems and sometimes even by tributaries, as well as broadly by continents, in order to reach reliable conclusions. A composite picture of the world's floods will disclose, of course, the limits of floods that are due to the worst conditions of rainfall and run-off, but will not show what may reasonably be expected on any particular stream. Obviously, engineers should not design structures for all rivers on the basis of floods that occur in only a few. The cost would be unwarranted because unnecessary, even if such structures would have the saving grace that they would surely be ample and, therefore, never the causes of physical disaster. Moreover, much legitimate development would be prevented because of prohibitive costs.

California has made a study of the floods on the rivers of that State and has published the results in graphic form.* Similar studies should be made for many rivers in other States by using as the principal source of information the systematic records of discharge collected by the U. S. Geological Survey and supplementing them by all other pertinent data obtainable. This is the first step in the program of the Special Committee on Flood Protection Data, for which it is seeking sufficient funds to warrant the employment of a mature and competent engineer who can work continuously under the direction of the Committee. Following this step the Committee expects, if available funds permit, so to correlate floods with climate, topography, geology, vegetation, and other modifying factors that reasonably accurate predictions of floods may be made not only for the rivers in the United States that have been systematically gauged, but also for the many others for which actual records of discharge are not available.

The writer feels, therefore, that although this paper has direct value in meeting the present needs of engineers for aid in applying the meager available flood data to immediate problems, its greatest value is indirect, for it accentuates the range and importance of flood problems and the unsatisfactory data and methods now available to engineers for solving them. He hopes that its presentation and discussion will assist in promoting a rational study of the magnitude and control of floods in the rivers of the United States

* "Flow in California Streams," *Bulletin No. 5*, Department of Public Works, California.

and the publication of the results in form for ready use, thereby making available to engineers not only the mass of flood data that is awaiting compilation and analysis, but also methods for its application to particular problems. This will change the present unsatisfactory, expensive, and even dangerous procedure into one that will serve as a basis for economic and safe development and that will bring credit to the profession.

B. Okazaki,* M. Am. Soc. C. E. (by letter).—It is well known that where an improved river, in its primitive state, overflows the natural river banks and adjoining lands, the actual maximum discharge at a point down stream from the valley subject to overflow is far less than if the river were diked or "short-cut" to prevent inundation. The natural controlling action caused by the temporary reserve or detention of flood water over the submerged area makes it sometimes necessary to fix the criterion for maximum flood discharge in determining the stability or size of a structure contemplated and the extent of waterway to be provided for probable future floods. The known maximum flood discharge may be greatly exceeded if the river is improved by short-cuts or embankments that do away with the natural flood reserve.

In dealing with a river in its natural state, the writer suggests the need for considering this controlling action due to overflow. As the volume of water temporarily impounded over a large area changes continually, it is difficult to determine the overflow in reserve and the time of maximum intensity, and, likewise, the quantity to be added to the ordinary maximum discharge in order to forecast the probable future discharge after the up-stream portion has been improved.

The writer made a careful investigation of the Ishikari River, which is one of the two largest rivers in Japan and which had long been unregulated. It was found that the known maximum discharge, in July, 1904 (150 000 cu. ft. per sec.) at a place called Tsuishikari, which is about 25 miles up stream from the river mouth and which has 5 600 sq. miles of tributary drainage area, should be doubled, namely, 300 000 cu. ft. per sec., and that the observed run-off of 26.8 cu. ft. per sec. per sq. mile might be increased to 53.6 cu. ft. Therefore, this information should be considered in plans for improvement.

It should also be noted that on the same river for a point called Kamuikotan about 132 miles up stream from the mouth, where the drainage area is 1 400 sq. miles and the impounding action is negligible, the same flood gave a maximum discharge of 129 000 cu. ft. per sec., or 92.2 cu. ft. per sec. per sq. mile.

L. K. Sherman,† M. Am. Soc. C. E. (by letter).—The data which the author has compiled and interpreted, are valuable contributions to engineering progress in the determination of rates of flood run-off.

In forecasting the run-off from relatively small areas the considerations of rainfall, time of flow, and coefficient of imperviousness (such as is used in storm-sewer design) will suffice. In forecasting flood run-off from larger areas, however, the results of actual observation must govern. The usual

* Engr. in Chf., Upper Liao River Conservancy, Newchwang, China.
† Pres., Randolph-Perkins Co., Chicago, Ill.

problem presented is the forecasting of floods from some particular drainage area which has few or no recorded run-offs. Such forecasting must be predicated on analogy with recorded data, such as Mr. Jarvis has presented. The question is how to interpret the existing data so as to apply them to another water-shed.

Referring to observed run-off data, the four principal variants in the rate of flood run-off are:

1.—The size of the drainage area;
2.—The topography and surface characteristics;
3.—The frequency period for which any particular recorded run-off applies; and
4.—The rainfall characteristic.

If the recorded run-off is known for a water-shed identical in all four of the foregoing features with the new location, the problem is solved; but this is seldom the case. In order to apply the recorded data to a special case, it is important to know the relative values of these four principal run-off factors.

Size of Drainage Area.—The effect of this factor on the rate of run-off is quite well established; in larger drainage areas it is relatively small. The run-off rate increases as the area decreases.

Topography and Surface Characteristics.—The effect of these factors has been established only in a general way. In the light of present information, reliable results can be had only by gleaning out and utilizing data based on drainage areas of similar topography and surface characteristics.

Flood Frequency.—In any list of recorded run-off, this factor is the least certain, hence the apparent wide discrepancy in observed run-off from drainage areas almost identical in size, physical character, and rainfall intensities. The author is to be commended in that, where possible, the part of the maximum flow which represents the average annual flood has been indicated in his table of flood records (Table 2).

While it is true that the flood of 100-year frequency may occur within a year or two, there are many cases where it is poor engineering economy, if not impracticable, to build structures for an ultimate maximum possible flood. The extent of the investment in a structure for flood capacity is a matter of a comparative balance between the cost of insurance and that of flood damage.

It is important, therefore, to know the law of variation of flood frequency, not only for co-ordinating flood data, but also for determining the proper frequency to adopt in the design of any particular structure.

Weston E. Fuller, M. Am. Soc. C. E., has developed the law of flood frequencies.* Mr. S. L. Moyer, of Montevideo, Minn., has presented a similar investigation of flood frequency.† Mr. Moyer has developed the expression, $Q = (c - d)e$, for the relation between the rate of run-off and the period of

* *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 564.

† "An Approach to Run-Off Expectancy", *Monthly Weather Review*, November, 1924.

expectancy for such a rate. In the foregoing expression:

Q = the magnitude of flow, in cubic feet per second.

$c\,e$ = the limit to which Q approaches.

$$d = \left(\frac{1}{2\,f} + \frac{4.5}{f + 8}\right)$$

in which,

f = the frequency or interval, in years, between peak flows of a given or greater magnitude.

In Fig. 9 has been platted the curve showing the relationship between run-off and frequency according to the Moyer formula when c and e were each unity. The law of frequency as expressed by Fuller reduced to the Moyer form, which is approximately, $Q = (0.99 - d)\ 0.8$, is also platted on Fig. 9 for comparison.

The dashed curve represents the recorded relation between the amount of rainfall and its frequency at Chicago, Ill. The point for the 22-year rainfall frequency has been platted arbitrarily to coincide with the 22-year point on the Moyer curve.

Both the Fuller and Moyer curves show the relatively rapid increase in the expected rate of run-off with slight increase in the frequency periods up to 10 or 20 years, the lesser increases from 20 to 40 years, and the slowest, almost straight-line, rate of increase after 40 years.

The dashed curve indicates what might be expected—the similarity between run-off intensity frequency and rainfall intensity frequency.

Rainfall Characteristic.—Rainfall is, of course, the prime factor in flood run-off. This factor, however, has the least variant (as between different water-sheds) of any of the four principal factors, namely, area, topography, frequency, and rainfall.

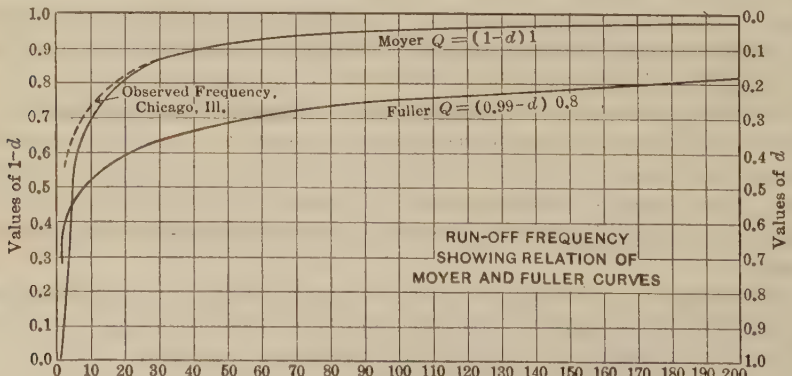

FIG. 9.

For a 20-year frequency, observations at twenty-two stations scattered throughout the United States show a general range within 2 to 3 in. of intensity of rainfall for 60 min. and a range within 7 to 9 in. of intensity of rainfall per hour for a period of 5 min. Meyers* has pointed out that more

* "Elements of Hydrology."

reliable results can be obtained by consideration of the rainfall data from a group of stations within a certain large area than from one particular station.

In the writer's opinion the chief value of a rainfall record in relation to any observed flood discharge, is its aid in determining the probable frequency period applicable to the flood in question.

Flood Height vs. Discharge.—Under this heading, Mr. Jarvis has described interesting phenomena regarding flood waves and the channel regimen of certain streams. The writer has investigated the time of travel of flood waves in open channels.* In many situations a study of the height and velocity of flood waves on existing channels is of value in forecasting flood stages. Such investigation can determine how flood waves and velocities may be modified by changes in the channel section.

GEORGE G. HONNESS,† M. AM. SOC. C. E. (by letter).—The author has performed a valuable service by so forcefully calling attention to conditions only too often neglected in the design of many engineering works and by supplying formulas which may be applied to all localities. These formulas, however, should be used with discretion so as to avoid uneconomical conclusions.

Little can be added by the writer except to furnish additional data which may be considered reliable for Northeastern United States.

On September 29 to October 1, 1924, inclusive, the Catskill Mountain region in New York State was visited by an unprecedented rainfall which led to flood discharges on the Schoharie and Esopus Creeks larger than any theretofore measured. A flood occurred in October, 1869, on Schoharie Creek, which is known to have exceeded the flood of September 30, 1924. At the time of the 1869 flood, it was said to have been the largest in the knowledge of the oldest inhabitants, and, therefore, it seems safe to assert that the flood of September 30, 1924, is the second largest in more than 100 years.

The storm began on September 29 and ended on October 1. For this period, 6.47 in. represented the average precipitation on the Schoharie water-shed above Prattsville (varying from 3.63 in. at Prattsville to 13.32 in. at Elka Park). On the Esopus water-shed above Cold Brook the average precipitation for the same period was 8.63 in., and varied from 5.35 in. at Highmount to 11.51 in. at Edgewood. The bulk of the rain fell on September 29 and 30, during a period of 36 hours.

In Fig. 10 is shown the region under discussion, together with the location of the rain gauges and the lines of equal rainfall for the period. Table 4 gives essential data in reference to the locality and the storm of September 29 to October 1, 1924.

By referring to the isohyetal map (Fig. 10) it will be noted that the storm centered in the extreme southeastern part of the Schoharie water-shed and the northeastern part of the Esopus water-shed. On the Esopus, however, the rainfall was considerably greater, as the storm came from the southeast and the high mountains intervening between the Esopus and the Schoharie

* *Journal*, West. Soc. of Engrs., August, 1923.

† Dept. Engr., Board of Water Supply, New York City, Grand Gorge, N. Y.

Valleys intercepted the moisture-laden winds and caused the higher precipitation on the southern and eastern slopes.

FIG. 10.

TABLE 4.—DETAILS OF WATER-SHEDS AND RECORD STORM.

Location of gauge.	Drainage area, in square miles.	Average yearly rainfall, 18 years, in inches.	Rainfall, September 29-October 1, 1924, in inches.	Maximum discharge, in cubic feet per second.	Maximum discharge, in cubic feet per second per square mile.	Time of maximum discharge.
Prattsville, N. Y., Schoharie Creek.	236	41.3	6.47	29 000	123	9:00 P. M., September 30
Cold Brook, N. Y., Esopus Creek...	192	47.6+	8.63	32 800	171	" "

A masonry dam on a stream draining an area on the eastern side of the mountains, where the maximum precipitation occurred, afforded an opportunity

to estimate closely the maximum discharge of an area of 1.82 sq. miles located between Palenville and West Saugerties, known locally as Whittaker's. This discharge was determined to be at the rate of 508 cu. ft. per sec. per sq. mile.

A determination has been made of the probable effect had the storm been geographically centered over either of the water-sheds. On a conservative basis, it may be asserted that if this condition had obtained, the maximum discharge at Prattsville on Schoharie Creek would have been at the rate of about 177 cu. ft. per sec. per sq. mile, and if at Cold Brook on Esopus Creek, at the rate of about 184 cu. ft. per sec. per sq. mile.

L. M. Winsor,* Assoc. M. Am. Soc. C. E. (by letter).—The author has made a clear and comprehensive statement of this extremely important subject and has presented facts and figures which will be helpful under certain restricted conditions. In the discussion which follows one phase of the question will be amplified and presented according to a somewhat different viewpoint from that of the author.

A distinction must be made between the two types of flood which appear in arid sections, in order to avoid confusion and to obtain a real appreciation of the actual conditions which confront the engineer in designing structures to handle this run-off.

There is a decided difference between the flood that comes as a result of melting snow, or excessive spring rain, and the raging torrent that follows a cyclonic storm in summer—what is generally known and perhaps erroneously termed a "cloudburst." Furthermore, there is as much difference in floods within humid and arid sections as there is in the appearance of the landscape. A flood in a humid country merely means the swelling of a stream beyond its normal volume. In a desert land a flood often means the appearance of a torrent where water had never been seen before.

Spring high water in arid climates is characterized by the swelling of a natural or an intermittent stream over a protracted period. If the flow is augmented by melting snow there is a constant fluctuation between night and day, with a constant rise and fall in total volume from day to day, depending on the temperature and humidity. Practically every mountain stream carries large quantities of drifting sand and gravel at high water, which cause an ever shifting stream bed within the limits of canyon walls, or over the entire surface of gravel cones and alluvial fans built by stream action at the mouth of every canyon. This condition often makes designing for waterways a most intricate problem and one to which run-off formulas have not yet been successfully applied for calculating probable requirements.

In streams of this type drifting gravel becomes the chief factor in designing waterways across highways, railways, and canal systems, or through towns and farming lands. Where attempts have been made to confine such a stream to a narrow channel, the result has invariably been the building up of this channel until it occupies the highest ground in the district, which makes the stream a real menace to adjoining property at flood periods. Under such a condition it is impossible to design bridges or culverts of sufficient capacity. As the stream bed is built up the opening across a roadway or under a canal

* Irrig. Engr., Utah Experiment Station, U. S. Dept. of Agriculture, Logan, Utah.

is filled until finally there is no head-room left. Thus, a stream of a few second-feet in size, if it carries drifting sand and gravel, may cause greater trouble than one of 1 000 sec-ft. that carries only muddy water during flood periods.

The summer flood resulting from a heavy thunder-storm is different in every detail from the spring freshet or high-water flow. Usually, the summer flood reaches its maximum flow immediately. In other words, the very first wave is generally the highest. In extreme cases the breast of such a flood is composed of mud so thick that it cannot flow. It is forced along by the weight of water behind it, and rolls, rather than flows, forward. This is the type of storm referred to by the author, which swept the west slope of the Wasatch Range on August 13, 1923, from Nephi, Utah, on the south, to Brigham City on the north. It struck Nephi at 5:00 P. M. and at 8:00 P. M. had reached its northern limit 200 miles away.

It was not the quantity of water that caused the terrible destruction, but the manner in which it fell. It was such a storm as is frequent in tropical countries where probably 1 in. or 1½ in. of water falls in 10 min. In this case, however, it fell on soil and mountain steeps unprotected by tropical vegetation and unaccustomed to carrying the run-off from such a sudden and severe downpour. The result was inevitable. The entire upper foot in depth of soil in many areas was washed down into ravines and finally into the main canyon leading to the country below. The conglomeration of soil, rubbish, and trees, mixed with a little water made a thick mortar which formed a dam in front of the flood, in places reaching a height of 50 or 60 ft. This dam was rolled forward when the accumulation of water behind it created sufficient pressure. The sliding and rolling mass of earth and débris literally swept the canyon clean of rock and vegetation, and, when released from the canyon walls, spread over the valley below, carrying houses, barns, orchards, livestock, and people to destruction.

The author shows (Fig. 4) a huge boulder, 25 ft. high, which was swept along for 300 yd. In another instance, a large, modern dairy barn filled with hay was carried more than ¼ mile and landed in the main street of Willard, Utah.

In these floods, following the advance wave of mud, rubbish, and huge boulders, there came an after-flow of water which spread the débris to a certain extent; but the actual volume of water was negligible, except where it ponded behind the advance wall of mud.

Needless to say such floods have never been measured, nor will any theory of applied hydraulics as evolved in the laboratory aid in making an estimate as to the type, kind, and size of structure required to handle them. They are calamities which come once or twice in a lifetime under arid conditions, in mountainous regions.

In locating highways through desert regions this problem is ever before the engineer who is acquainted with the real flood conditions. There is no such thing as determining beforehand where or when the next flood will come. In many instances there is no such thing as a defined channel. In certain cases what appears to be a ridge may be the next flood channel. Close observa-

tion in desert regions will reveal the fact, usually, that the ridges at the foot of mountain slopes have been made by water.

Designing for such emergencies is a difficult problem and one which can hardly be accomplished by formulas. It is recommended, therefore, that application of the author's deductions be confined to established waterways and living streams, rather than to desert areas which are subject to heavy summer floods.

It is also important that the engineer who is unacquainted with the character of floods in desert lands, give proper weight to the information available from natives who are familiar with the territory through which roads or canals are to be built.

H. V. Hinckley,* M. Am. Soc. C. E. (by letter).—For some time the writer has had in mind advancing a formula similar to Equation (2), and of the form, $Q = 5\,000\sqrt{M}$. He realizes that the constant, 5 000, might have to be enlarged to apply to possibly forty localities. The use of the symbol, Q, is somewhat objectionable, as no quantity is to be expressed, only a factor in the quantity.

Since the writer has studied the paper (which is both timely and interesting) and, in connection with it, the previous contributions on flood flow by Weston E. Fuller, M. Am. Soc. C. E., and the late Emil Kuichling, M. Am. Soc. C. E., it seems to him unwise to propose definitely the constant, 5 000, at this time because the author's Table 2, covering more than 1 000 records, shows 57 cases where the factor, 5 000, is materially exceeded, of which 23 cases exceeded even 10 000. In studying these data, to offset the inadequate length of observations, a factor was applied to the readings multiplying them by quantities between 1 and 3.40, the member, 3.40, applying to records of one year only or of indefinite and unknown periods. This is in accordance with the recommendation in Fuller's paper.†

For example, Table 5 shows 6 of the 23 cases, in which the author's value of C (10 000) would be replaced by numbers from 21 400 to 37 400. The multiplier, 3.40, was used in each case. It may yet be possible to eliminate discrepancies and make use of the formula, $Q = 10\,000\sqrt{M}$.

The writer believes that the first essential is to have the constant, C, large enough to cover all the absolutely maximum cases, no matter how large it may need to be. Then, as suggested by the author, definite percentages might be adopted to represent certain drainage basins—if it is possible to tell the relation of future floods in different parts of the continent or of the globe.

It seems hardly necessary to mention that an average of the flood flows recorded would be far less than the average actual maximum—if there were such a thing—as fully one-half the values given as maximum floods are not maximum at all except possibly for a day.

On Fig. 11, Line C, by the writer, from studies made for the State of Oklahoma, compared with the lines, M and K (all three lines being for maxi-

* Res. Bridge Engr., Oklahoma City, Okla. Mr. Hinckley died on April 21, 1926.

† "Flood Flows", *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), Table 2, p. 568.

mum second-feet per square mile), shows how the maximum recorded floods have become greater as the records have increased the working data.

TABLE 5.—COMPUTATION OF COEFFICIENT, C.

* Data taken from Table 37 of the paper on "Flood Flows", by Weston E. Fuller, M. Am. Soc. C. E., *Transactions*, Vol. LXXVII (1914), p. 650.

† Discussion on "Flood Problems", by H. P. Eddy, M. Am. Soc. C. E., *Transactions*, Vol. LXXXV (1922), Fig. 45, p. 1526, and Table 5, p. 1528.

The author seems to have his flood values under good control. Nos. 275 and 493 (Table 2), however, apparently give values for the constant, C, of slightly more than 10 000, being 11 683 and 10 029, respectively.

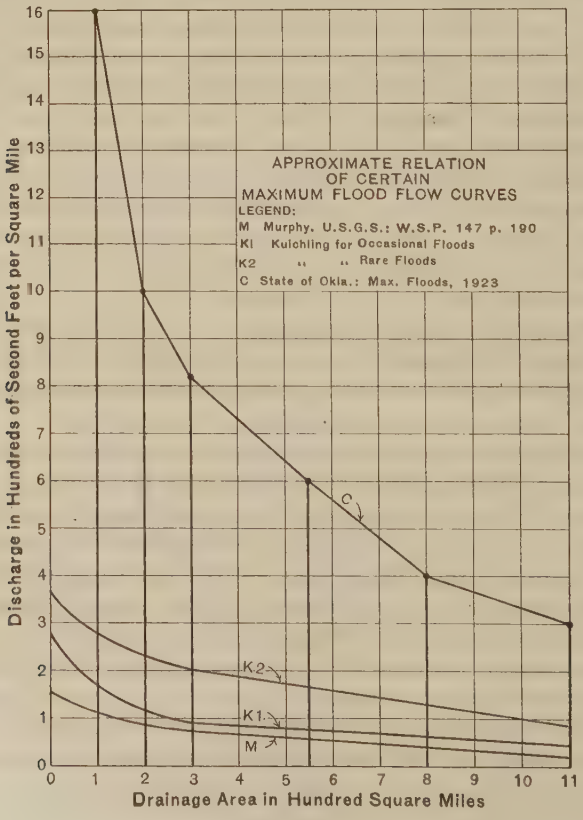

FIG. 11.

It would be interesting to know whether the author finds that any of the drainage basins named in Plate IX are found to have definite values or percentages of the constant, $C = 10\,000$; for example, whether the flood values for any one drainage district are within the limits of the 10% class and have maximum values less than $Q = 1\,000\,\sqrt{M}$.

HARDY CROSS,* M. AM. SOC. C. E. (by letter).—By listing "certain data and considerations that are often left unrelated", the author has prepared a most interesting paper. The whole subject is in a chaotic state, and discussion of it necessarily depends much on individual opinion. Any effort to clarify, systematize, or in any way make definite the problems involved, is a professional and public service. The next fifty years will see much development along the line of placing river hydraulics on a scientific basis.

The special problem of provision for flood flow at river crossings is commonly one of erosion phenomena and only occasionally or secondarily one of back-flow and consequent damages. It seems important to emphasize a distinction between streams with very mobile beds, in which, owing to bed erosion, the flood velocity is constant, and streams in which the bed is so stable that increased flood velocities encourage lateral erosion. The former undercut bridge piers and cause them to overturn, due partly to the unbalanced pressure of silt not eroded; or they may allow the abutments to slide into the bed of the stream, often together with the foundations. Streams of the second class are more likely to back-cut their abutments. Any bridge engineer familiar with the rivers of the Middle West can cite numerous examples of both types of phenomena.

Scour and fill in any one cross-section may be due to:

(*a*) Changes of location of the thalweg in the section considered.

(*b*) Changes of location of the thalweg in up-stream sections resulting in a change of burden of water threads where they cross the given section. (Note that increased erosion in the up-stream thalweg does not necessarily mean increased burden in the thalweg of the given section, for, owing to its greater inertia, the sediment does not move exactly in the line of the water threads.)

(*c*) Changes in erosive activity due to causes other than velocity at any point in the section. (Differences in the eddy-forming power of obstructions with changes of stage and, if Kennedy's law is applicable, changes in the relations of depth to velocity at various points are here indicated.)

Of these causes, the shifting of the hydraulic axis with the stage is important at bridge crossings. Many bridges carefully located square to the thalweg of mean flow are skew to the destructive currents of the falling flood stage; but this migration of the thalweg with the change of stage is only one of the causes of increased erosion on a falling stage. Water-soaked banks are another important element. Most serious in many cases is the tendency to flank the abutment by a back-cutting eddy below the approach fill.

* Prof., Structural Eng., Univ. of Illinois, Urbana, Ill.

It is important also to distinguish between the action of protracted and that of "flashy" floods. The latter, of course, have not time to improve the hydraulic efficiency of the bridge opening and, therefore, back-water may produce considerable hydrostatic heads against the approaches.

As bearing out and supplementing certain statements of the author with reference to erosion in silt-bearing streams, some selected conclusions of the twenty general rules formulated in the case of the Indus by the Indus River Commission* are worth quoting:

"The progress of erosion at any point is usually determined by the condition of the river for some miles up stream.

"Erosion is most severe when a bank, which consists of clay or heavy soil at the top, is underlain by sandy strata which can be readily undermined."

* * * * * * * * * *

"Erosion is generally more active during a falling than during a rising stage of the river, as in the former case the unsubmerged and overhanging bank is charged with moisture which weights it and diminishes its cohesion."

* * * * * * * * * *

"An embayment is, almost invariably, formed first below this point [a resisting projection of the bank] owing to the swirl of the water produced by the construction.

"If this embayment becomes sufficiently deep, the projecting bank will be outflanked and washed away."

Although it is of quite as much economic importance as any other phase of bridge design, the problem of the design of river crossings, as distinguished from the structural design of bridges, is one on which little accurate information is available. It is encouraging to note how fully the author and his co-workers realize the intricacy of the problem. It is to be hoped that such papers as this may bring out the huge mass of experience on this subject possessed by drainage engineers of large railways. The writer believes that the subject can be put on a basis approximately as scientific as has been reached in recent years in the design of spillways.

E. W. Lane,† M. Am. Soc. C. E. (by letter).—This paper is valuable in that it brings together a large amount of data on flood flows. This information may serve as a rough guide in the design of hydraulic structures, but the writer is of the opinion that a much more reliable indication of probable floods may be obtained, particularly for those in streams for which a few years' discharge records are available, by a different method from that used by the author.

The discharge rate of any flood is the product of innumerable factors, and the combinations of these factors which cause floods on any stream give rise to discharges which have wide ranges of magnitude. One of the important factors is the area of the water-shed, and this is the only one which the author includes in the formula which he adopts. After its effect is eliminated as far as possible, the data given still show a range of discharge represented by numerical coefficients of from 50 to 10 000. When the selection

* Indus River Commission Record, Sind, P. W. D., Pt. IV, Conclusions.

† Lafayette, Ind.

of the proper coefficient is left to the judgment of the individual engineer, it is obvious that the formula itself is of comparatively little assistance.

Although many factors combine in causing floods, they may be divided into two groups: (1) Those depending on the physiography of the basin in question; and (2) those depending on the weather. In the first group, the most important factors are the area, topography, geology, shape, and permeability of the water-shed, and the availability of storage in lakes and swamps. Those of most importance in the second group are the precipitation, temperature, and the snow and ice conditions on the water-shed. Vegetable cover and the condition of storage of water in soil, lakes, and swamps are really products of factors from each of the two groups.

For a given point on a stream, the factors in the first of these groups are constant; that is, these conditions remain the same. Weather conditions are proverbially variable, but, although they cover a wide range, they follow some probability law. This is particularly true of the weather phenomena that give rise to floods.

As a rational flood formula must take into account both these classes of influences, it should be made up of two parts. One would be a factor expressing the physical characteristics of the stream; this would be a constant for a given point, but would vary somewhat at different points on the same stream, still more for the streams of a given region, and widely for the streams of a continent. The other part would express a probability law which would be practically the same over a comparatively large area, but not necessarily the same for all water-sheds.

The writer believes that any formula which does not include the effect of both these groups of influences would be only a rough approximation and of little usefulness. Most formulas have a factor for the water-shed area, some consider to a limited extent the physical characteristics of the drainage basin, and a few have some indication of the time element; but the Fuller formula* seems to be the only one that gives numerical values to the probability factor and also considers the basin characteristics. As an example of the necessity of considering the water-shed characteristics may be cited the comparison of the Deerfield River at Charlemont, Mass., with Miller's River at Erving, Mass.; these streams have nearly the same drainage area, but the former gives flood discharges five or six times as great as the latter. The Souhegan River at Merrimack, N. H., gives discharges about three times as large as the Swift River, at West Ware, Mass., although their drainage areas are nearly equal. If as great variations as these occur in as small a region as New England, where weather conditions are so nearly uniform, how much larger variations can be expected when the whole United States or the entire world is considered?

The author has objected to the time element in flood formulas as "too often the basis of error". It is true that it may sometimes be misunderstood by those who blindly apply formulas without much thought as to their mean-

* *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 567.

ing; but must formulas be made so simple that the least intelligent or informed may readily understand them, thus denying a useful tool to those who are capable of using it? Progress is not made by that method. As a matter of fact, progress in engineering science is so rapid that the products of the best minds in one decade are used by all the fairly well informed in the next, so that even if a development seems complicated at the time it is made, in a few years it will be considered relatively simple.

The writer believes that the time element in a rational flood formula is a simple thing, well within the comprehension of an ordinary mind. Unfortunately, its meaning has been needlessly obscured in the development of the Fuller formula. Suppose there was a long record (say, 1 000 years) of the flood discharges of a stream at a given point, arranged in order of their magnitudes, beginning with the largest. Suppose the one-hundredth in the list had a discharge of 5 000 sec-ft. There have been 100 floods in the 1 000 years with a discharge of 5 000 sec-ft., or more. Therefore, the average interval between floods of 5 000 sec-ft., or more, is $\frac{1\,000}{100} = 10$ years. If a spillway on this stream at this point had a capacity of 4 999 sec-ft., its capacity would be exceeded once in 10 years on the average. The probability of its capacity being exceeded in any one year would be 0.10. For convenience, call the average interval, in years, I. Then the probability of occurrence in any one year would be $\frac{1}{I}$. The interval used by Mr. Fuller, in which the chances of a flood of that magnitude occurring are equal to the chances that it will not occur, is, therefore, $\frac{I}{2}$. To use the example of the spillway again, the interval used by Mr. Fuller, which he computes from his average maximum flood or median maximum flood, is the interval for which the chance of the spillway capacity being exceeded is equal to the chance that it will not be exceeded—one chance out of two, or 0.5. Since the chance in any one year is 0.10, the period for which the chance would be 0.5 would be five years, or $\frac{I}{2}$. The writer believes that the use of the interval, I, is more easily understood than the interval used by Mr. Fuller.

This discussion may seem elementary, but it indicates how simple the element of time in a rational flood formula really is. Some doubt as to the reliability of the probability formula is apt to arise in the mind of the engineer when he considers a case where several unusually large floods come within a short interval, or where severe flood conditions occur simultaneously over a wide region, as happened in March, 1913. He should remember that the theory on which life insurance is based is not disproved because several members of the same family may die in the same year, or because an epidemic of influenza sweeps over the country, claiming the lives of thousands. These cases in the field of insurance are paralleled in the field of flood probability.

To try out the writer's ideas on the development of a logical flood formula, a study was made of the floods of New England rivers from the data compiled by C. H. Pierce, M. Am. Soc. C. E.* The probability or average interval curve was computed for each station having sufficiently complete records. The flood discharges at the station in question were arranged in order of magnitude, beginning with the largest, and numbered consecutively, the largest being No. 1. Disregarding the error due to the fact that the record covers only a short period, the average interval, I, between floods as large or larger than any one of those listed, can be found by dividing the length of the record at that station, in years, by the serial number of the flood. Thus, with a 10-year record, the value of I for the magnitude of Flood No. 4 would be $\frac{10}{4} = 2.5$ years. Average interval curves were then drawn showing the relation between the flood magnitude, in second-feet per square mile, and the average interval, I. Logarithmic, semi-logarithmic, and probability paper were used, but the best results were obtained from the semi-logarithmic paper.

In Fig. 12 are shown the resulting curves. Many of the data were in the form of peak flows, but other records consisted of one reading per day, the higher of two readings per day, and the average flow, the various kinds being indicated by different symbols. On account of the wide difference in unit flows, it was necessary to divide the data into two parts, and use different scales, in order to plot them on a diagram of reasonable size. Table 6 gives the principal data regarding the stations the records of which were used. On account of the fact that the length of record was insufficient to determine accurately the average interval for floods of greater magnitude, the values indicated by the highest points are made less prominent. It will be seen that all the curves, as indicated by the data, approach reasonably close to straight lines, and converge to approximately the same point.

Fig. 12 shows that the average interval between floods of various magnitudes for the New England rivers can be expressed by an equation of the form:

$$Q = K (\log I + B) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

in which, Q is the discharge, in second-feet per square mile, which would be equalled or exceeded on the average once in I years; K is a constant for the station in question; and B is a constant for New England streams and probably nearly constant for a much larger area.

It will be seen that this formula is made up of the two parts previously mentioned as being what one would expect in a rational flood formula, namely, a constant, K, representing the physical characteristics of the water-shed, and a probability factor, $\log I + B$, representing the weather variability.

Although the writer had available only the data for New England streams, from the results of Mr. Fuller's studies, he believes that an expression of the form of Equation (4) would apply to nearly all the rivers in the United States east of the 95th Meridian, which is roughly the western boundary of

the States immediately west of the Mississippi River. He is inclined to doubt its applicability to the "plains" rivers, but believes that it would apply to many of the mountain and Pacific Coast rivers.

TABLE 6.—RUN-OFF STUDIES OF NEW ENGLAND RIVERS.

No.	River.	Station.	Area, in square miles.	Length of record, in years.	Type of record.
1....	Connecticut	Holyoke, Mass	8 390	20	Mean for 24 hours.
2....	Connecticut	Sunderland, Mass	8 000	21	Nearly all peak flows.
3....	Merrimack	Lowell, Mass	4 097	72	Nearly all one reading per day.
4-*O*.	Connecticut	Orford, N. H	3 100	10	One reading per day.
4-*H*.	Connecticut	Orford, N. H	3 100	11	Higher of two or more readings per day.
5....	Saco	West Buxton, Me	1 500	17	Average for 24 hours.
6-*O*.	Pemigewasset	Plymouth, N. H	615	26½	One reading per day.
6-*H*.	Pemigewasset	Plymouth, N. H	615	12	Higher of two readings per day.
7....	Machias River	Whitneyville, Me	465	18	One reading per day.
8....	Ashuelot	Hinsdale, N. H	440	15	Higher of two readings per day.
9....	Miller's	Erving, Mass	372	10	Peak flow.
10-*A*.	Deerfield	Charlemont, Mass	332	10½	Mean for 24 hours.
10-*P*.	Deerfield	Charlemont, Mass	332	10½	Peak flow.
11....	Housatonic	Great Barrington, Mass	280	11	Peak flow.
12....	Lamoille	Cady's Falls, Vt	280	10	Nearly all peak flow.
13....	Ware	Gibb's Crossing, Mass	201	12	Peak flow.
14....	Swift	West Ware, Mass	186	14	Nearly all peak flow.
15....	Souhegan	Merrimack, N. H	168	10	Peak flow.
16....	Westfield	Knightville, Mass	162	15	Higher of two readings per day.
17....	Quaboag	West Bumfield, Mass	150	12	Peak flow.
18....	Middle Branch, Westfield.	Goss Heights, Mass	53	14	Peak flow.

Representing the magnitude of a flood with an average interval of one year as Q_1, which, for convenience, may be called the "one-year flood", from Equation (4):

$$Q_1 = K\,B, \quad \text{or} \quad K = \frac{Q_1}{B}$$

Substituting this in Equation (4):

$$Q = \frac{Q_1}{B}(\log I + B) = Q_1\left(1 + \frac{1}{B}\log I\right) \ldots\ldots\ldots\ldots (5)$$

This is of the same form as the Fuller formula:

$$Q = C\,A^{0.8}\,(1 + 0.8 \log T)$$

and shows that the magnitude of floods of various intervals is a logarithmic function of the "one-year flood" discharge. With the data on discharge expressed in terms of their ratios to the "one-year flood" all the "discharge-average interval" curves should fall on the same line. This permits of combining all the records, as Mr. Fuller did, into a single record, with the result shown in Fig. 13.

In determining this curve, all the different kinds of records were used, as there seems to be no great variation between the shapes of the curves from different kinds of observations. It is possible, however, that if enough records were available, a difference might be shown.

The value of $\frac{1}{B}$ was found to be 0.690, which differs somewhat from the 0.80 found by Mr. Fuller. It is possible that if only the "average for 24 hours" and "one reading a day" records were used, a better agreement with the Fuller formula would have resulted. Mr. Fuller's data were based on records supposed to represent the average for 24 hours. In a great many cases, however, the observation was made once daily, which reading was assumed to give the mean flow for the day.

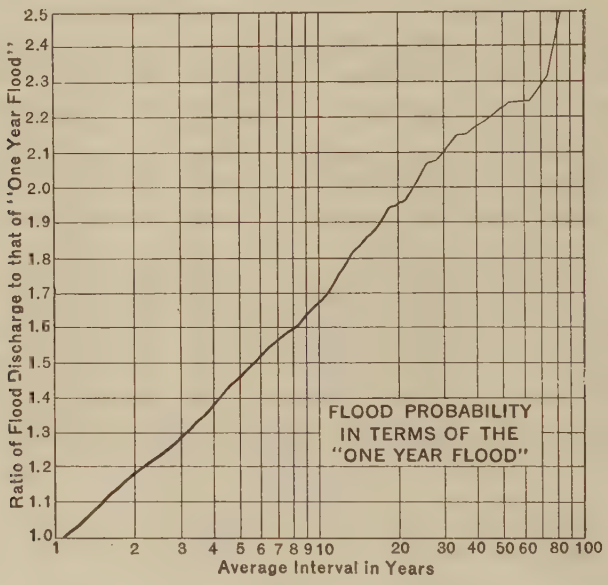

FIG. 13.

The writer does not claim originality for his method of determining flood probabilities, or for the formula, although they were independently developed to find later that some points were previously used by others. He has not hesitated to borrow from others when their methods seemed sound. He does believe, however, that the method he has outlined leads to a flood formula which combines rationality, simplicity, and accuracy to as great an extent as is possible for so complex a phenomenon as floods.

The method here given for working out probability curves and deducing the flood probability formula has certain advantages over the methods heretofore proposed. Although the form of the result is very similar to that reached by Mr. Fuller, the method is less laborious, and has the great advantage that the meaning of the result is definite and readily understandable, as compared with Mr. Fuller's "average maximum flood" and "median maximum flood", which are very difficult to understand, "if not indeed practically meaningless", to use the words of a well-known hydraulic engineer. By the writer's method, the larger floods, the average intervals of which are less reliably determined, are automatically eliminated in the determination of the

one-year flood, while in the Fuller method, a single flood considerably larger than the other members in the record exercises too much influence on the results.

The writer's method is almost identical with that outlined by R. E. Horton, M. Am. Soc. C. E., in his discussion* of Mr. Fuller's paper, but is an improvement on the Horton method in that it takes into consideration all the floods of the stream, and not merely the largest one in each calendar year. In using only the largest flood in any one year, Mr. Horton's method is subject to the criticism he makes of Mr. Fuller's method, namely, the failure to use all the available data.

If time and data were available to carry out the work for other sections of the United States as the writer has done for New England, and a study was made of the conditions which give rise to different index values, in order to determine with reasonable accuracy, from the character and location of the water-shed, what the flood index would be, a tool of great value would be in the hands of hydraulic engineers.

The work necessary for collecting these data and analyzing them is so great as to be prohibitive to a man of ordinary resources, but its value to a single piece of construction work could easily exceed the cost of the entire investigation. The logical body to make such a study is the Society's Special Committee on Flood-Protection Data, and the request of this Committee that the Society appropriate funds for an investigation of flood flows should be granted. The results would add many times the cost of the work to the wealth of the nation.

For the last ten years, the writer's work has been on flood prevention; before starting the studies outlined in this discussion, he was quite skeptical of flood flow formulas. Working entirely independently, he has arrived at the same general form of equation that was reached by Mr. Fuller, although the meaning of the terms of the two formulas, and the method of deriving them, are somewhat different. He is convinced, therefore, of the correctness of the general formula and believes that further study should be along the line of determining the constants for various streams, and the limit of applicability of the formula.

Some objection has been made to the logarithmic form because it fails to give a maximum value which can never be exceeded. The writer does not consider this a serious objection. It is based on the assumption that there is a maximum flood, but this has never been proved. With the logarithmic form discharges only a few times as great as the 10-year magnitude become so infrequent as to be almost geological periods apart, in which time the river valley may become a sea bottom. It is much better to have an empirical formula agreeing with the data within practical limits than one which is logical according to an improved theory, but may not agree so well. With equally good agreement with the flood data, the writer would prefer a simple logarithmic formula to one having a maximum limit and being thereby complicated.

* *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 665.

In this discussion it is not the writer's intention to develop a satisfactory flood discharge formula, for much study is necessary before such a result can be reached, but he desires to point out some of the basic requirements of a satisfactory formula, the lines along which study should be made, and some of the methods that he believes most likely to lead to the desired result.

One of the points requiring further study is the influence of area on discharge. Mr. Jarvis has adopted the area factor as the 0.50 power, Mr. Fuller derives the 0.80 power from nearly equally good data. Talbot used the 0.75 power, and other results have been found by other investigators. It is doubtful whether any single figure will cover all cases, and where an attempt is made to predict flood discharges at one point on a river from the data at another point having a considerably different drainage area, or different water-shed conditions, an exercise of judgment would be necessary.

For example, at Dayton, Ohio, two rivers of roughly the same drainage area as the Miami River join it at nearly the same point. As all the areas are small enough to be covered in many cases by the same storms, the flood discharges of the Miami below the junction, per unit of area drained, is only slightly less than that of the individual tributaries, although the area drained is about three times as large. As an example of another condition, the case of the Arkansas River might be cited. Its source is in the mountains, but the lower portion flows through the plains. The flood characteristics of the mountainous parts of the drainage area are entirely different from those below. It is evident that any area factor would have to be applied with judgment, but the writer believes that when flood probabilities are worked out for many stations on the same rivers, it will be possible to make quite close estimates of the area factor for ordinary cases.

The most important feature of a flood is usually the peak flow, but the published records are generally in the form of the average flow for the day, and give peak flows only when they are very large. For this reason, in computing flood probabilities, it is usually necessary to work out probabilities of average daily flows, and from this to determine the probability of peak discharges. A great deal of further study is necessary before this relation can be satisfactorily established. Mr. Fuller has derived an expression for the relation between average daily flow and peak flow, but this expression is one of the greatest objections to the Fuller formula. With great care he finds the probability of average daily flows for all parts of the United States, and to obtain the result nearly always desired—the peak flow—he multiplies this by a factor based on only thirty-three observations, many of which differ 100% from the values computed from the formula adopted. Data on the ratio of peak to average daily flow are scarce, and probably Mr. Fuller used all that were available.

His assumption that this ratio is only a function of the drainage area leaves out an important consideration and probably accounts for much of the variation between his formula and the actual results. For instance, the Hudson River, at Mechanicsville, N. Y., and the Oswego River, at Battle Island,

N. Y., have nearly the same drainage area, but a glance at their hydrographs* will show that the ratio of the peak flow to the average 24-hour flow for these rivers would differ widely. For the region east of the 95th Meridian, the writer believes that an expression combining the drainage area and the value of Q_1, which is really an index of the variability of the flow, would give much more satisfactory results.

As an example of the error resulting in some cases from the Fuller formula might be cited the Arkansas River at Pueblo, Colo., with a drainage area of 4 600 sq. miles. The average ratio for twenty-two peaks was 2.5, which agrees well with that cited by the author for the great flood of 1921, while the ratio of the Fuller formula for a stream having this area would be 1.159. In one case the discharge rose to 12 500 sec-ft., dropped to 2 100 sec-ft., and rose to 10 800 sec-ft. in a single day. All these floods were due to cloudbursts on a small part of the drainage area, while there may have been no evidence of a storm at other points.

If a great many records were available, by plotting a curve like that on Fig. 13, using peak-flow data only, and another using the averages for the 24-hour data only, some clue could be obtained regarding the ratio, but much more data like those shown on Fig. 12 for the Deerfield River, giving both the peak flow and the average daily flow for a long period of record, will be necessary before a satisfactory result will be obtained.

Although the application of the rational type of formula is not as easy a matter as that of the type suggested by the author, it is really a rather simple process. In general, there are three conditions under which predictions of future floods are desired. The point may be (1) on a stream near a station having a long discharge record; (2) on a stream near a station having a short-period record; or, (3) on a stream remote from a discharge station or having no measuring station.

The most accurate predictions can be made from the conditions in Class (1), but even here the general formula is of material assistance. For example, an attempt was made to develop a flood probability curve for the Miami River, at Dayton, from a long-period record there. It was found that the data on the larger floods were so limited that formulas giving widely different probabilities for large floods fitted the data equally well. By means of the general formula, a much more accurate flood probability could have been determined.

The number of flood records is rapidly increasing and will continue to increase. This is not only beneficial to a determination of an accurate formula, but also to the application of it. At present, some form of discharge records exist at one or more points on most of the large and medium sized streams of the United States, and reasonably reliable predictions will be possible for them when a thorough study has been made to determine the best prediction methods. Most of these fall in Class (2). The flood probability for the point in question can be determined by examination and comparison of the probabilities as determined for adjacent measuring stations.

* "The Economics of Hydro-Electric Development," by Daniel W. Mead, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 168 (Fig. 3).

This can best be done by drawing the probability curves as was done for Fig. 12, and determining the "one-year flood" from the straight line most closely fitting the points, but an approximate method may be used without recourse to plotting. In this approximate method, the floods are arranged in order of magnitude, beginning with the largest, and numbered. The one having the number equal to the length of the record may be considered as the "one-year flood". Substituting this in the formula,

$$Q = Q_1 \left(1 + \frac{1}{B} \log I\right)$$

gives the probability of floods of other magnitudes and intervals.

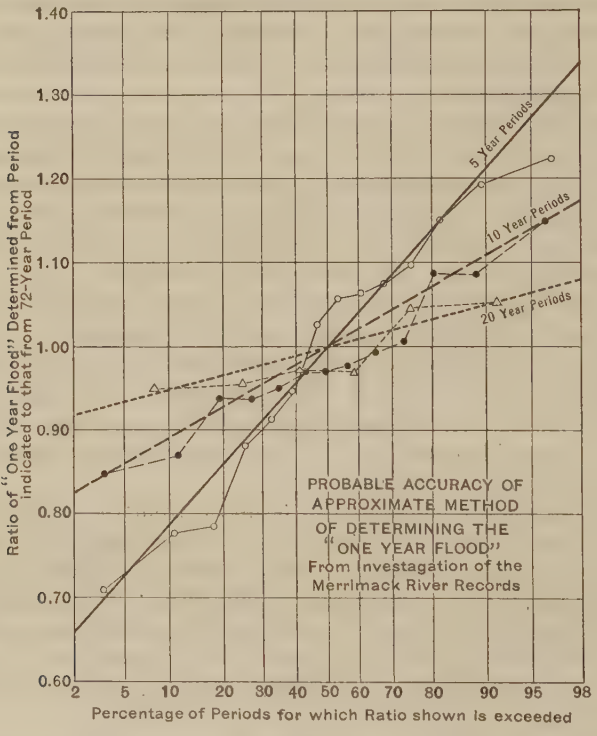

FIG. 14.

To investigate the extent of the error which might occur in the probability curves thus determined, a study was made by dividing the 72-year record of the Merrimack River, at Lawrence, Mass., into periods of various lengths, and comparing the "one-year floods" determined from these periods with that determined from the 72-year period. The result, as shown in Fig. 14, is highly satisfactory. For example, from 5-year periods, more than 75% of the determinations were within 20% of the proper value, and with 10-year periods about 98% were within 20% and about 75% were within 10%, while with 20-year periods about 98% were within 10 per cent.

Fig. 15 was prepared to show how closely the probability curves, as determined from different parts of the record, agreed with each other. For this purpose, the 72-year record of the Merrimack was divided into two 36-year periods and four 18-year periods and the curves for all the periods plotted together. The result shows a very satisfactory agreement.

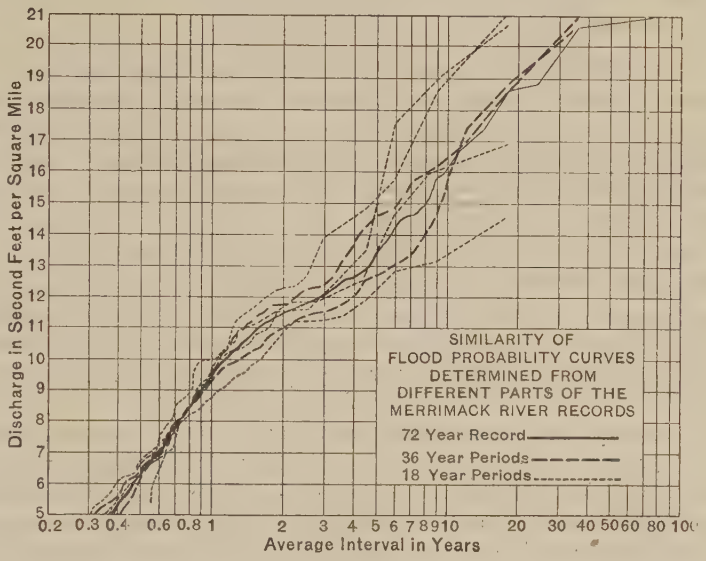

FIG. 15.

Class (3), the determination of the flood probability of a stream which has no flow records or only records at remote points, is the case most frequently met by bridge and highway engineers. As there are comparatively few records for small streams, most of them come in this class. In this field, formulas of the type adopted by the author have their greatest usefulness. Nevertheless, the writer believes that, with the exercise of care and a reasonable amount of judgment, better results can be obtained by the method outlined by him than from formulas of the other type.

To determine flood probabilities from cases in this class, it is necessary to compare the water-shed characteristics with those of adjacent water-sheds for which records are available. The results thus determined are not so reliable as those for which records at closer points are available, as streams with apparently the same water-shed conditions give different results. The Mad and Stillwater Rivers, tributaries of the Miami River in Ohio, have basins which in outward appearances are as nearly similar as could be found. The Stillwater River gives considerably higher flood flows than the Mad River, which is entirely contrary to what one would expect from their names and from the opinions generally held by local residents.

Summarizing the writer's ideas on flood formulas, it is his belief that a satisfactory flood formula must take into consideration both the basin characteristics and the time factor, and that, although considerable progress

already has been made in the development of such a formula by Mr. Fuller, great improvements are still possible, but, as these require time and expense beyond the resources of a single man, this study should be carried on by the Special Committee on Flood-Protection Data. The writer heartily agrees with the author as to the need for this type of study and believes that the Society should provide the Committee with the necessary funds to make an adequate investigation possible.

GERARD H. MATTHES,* M. AM. SOC. C. E.—This noteworthy paper clearly represents the fruits of considerable labor on the part of the author in compiling data for use in proportioning waterway areas for bridges and culverts. The treatment of the subject appears to be principally from that angle, which accounts for the fact that the author is concerned mainly with maximum discharge rates, as shown in Table 2.

Of practical interest is the following specification of the U. S. Bureau of Public Roads mentioned by the author on page 999:

"The waterway shall be adequate for the passage of ordinary flood water * * * and be adequate for the passage of extreme flood water unless other provisions are made for same. By ordinary flood water is meant the stage that is likely to occur once in ten years."

This appears to be a sensible basis for designing such structures, and should operate to provide bridges and culverts adapted to local conditions. Thus, in a region like Colorado where cloudbursts are common, the 10-year criterion would provide structures capable of passing extreme flood flows except where they could be by-passed, while in a State like Maine where cloudbursts are of rare occurrence, much smaller waterways will suffice. It would be interesting to know what considerations led to the adoption by the Bureau of the 10-year flood as the criterion for ordinary flood flow, as this might be of value also in the design of other structures built to resist flood waters.

Mr. Jarvis could have made Table 2 of more direct value if in Column (5) he had given figures representing the "ordinary flood water" as here defined.

Two aspects relating to flood studies have suggested themselves to the speaker in reading this paper: First, the imperative need for better means of interpreting the enormous dissimilarity in the flood characteristics of streams; and, second, the desirability of establishing uniform methods of compiling flood data for publication.

As regards the first, Plate IX which is the most complete tabulation of its kind that the speaker has seen, brings out strikingly the wide variation that exists in the maximum flood rates of North American streams, and, by inference, the magnitude of the task that confronts any engineer, not a specialist in flood data, who is called upon to decide what rate of flood run-off to assume in the design of a structure on a given stream. Whether he uses a formula or a diagram, he must exercise a certain amount of judgment in order that the rates of discharge selected shall be commensurate with the character of the stream and the requirements of the particular problem in hand. Methods or devices that make possible the efficient exercise of such judgment is what

* Cons. Engr., New York, N. Y.

the Engineering Profession has been seeking for a long time, and this want is, even to-day, far from being filled. The speaker's experience indicates that formulas can be used with safety only by experts who are familiar with the basic data from which they have been derived. This would seem especially true of the modified Myers formula in which the coefficient ranges all the way from 100 to 10 000. This formula fits the data in Plate IX admirably, but it is not clear how a set of coefficients might be prepared for practical use. Possibly, the author has undertaken such a task, and, if so, it would add materially to the value of his paper if he would supply this information in workable form.

Suitably prepared diagrams are, on the whole, more intelligible than formulas when judgment must be exercised, because they enable the expert and the non-expert alike to visualize many things which a formula will not disclose. For example, a glance will tell what part of a curve is supported by actual observations, and what part has been produced beyond the limits of such data. Again, in dealing with a drainage area for which few or no recorded data are available, the use of a diagram is superior to that of a formula because it permits of more intelligent exercise of judgment. Furthermore, diagrams of the right kind may be kept up to date by entering on them new data as they become available; this cannot be done conveniently in the case of formulas.

The advantages of the diagrammatic method are well illustrated by reference to curves showing the probable frequency of flood discharges of various magnitudes for 173 California streams.* A separate curve is drawn for each gauging station, or section of river, showing the observed data on which it is based, the entire range of floods that may be expected, and the probable frequencies of floods of any given magnitude. For streams on which few or no observations have been made curves are prepared based on other comparable drainage areas for which observed data are available. With such diagrams it is practicable to solve problems relating to the maximum discharge that is likely to occur at a given point in a stated period of years, and direct comparison may be effected between different streams or points on the same stream, while new data may be readily added from time to time or the curves altered in the light of later information. Such diagrams make available basic information the substance of which is open to inspection, and the derivation of each curve is readily seen. Other commendable features are the compactness of the material thus presented, and the uniformity of scale of the diagrams, which permits of showing with reasonable clearness four diagrams on a 6 by 9-in. page.

In giving consideration to the use of formulas and diagrams for publishing flood data the Society's Special Committee on Flood-Protection Data has expressed unanimous preference for diagrams of the general type used in the California report previously mentioned.

The author has well said that "there exists an endless variety of conditions that affect flood run-off". Many of these conditions have been made the subject

* *Bulletin No. 5*, Report on California Water Resources Investigations.

of study, but in the case of large streams two factors do not appear to have gained the recognition that is due them, one being the effect of the geographic arrangement of the tributaries on the building up of the flood wave in the parent stream, and the other the general direction of flow with respect to the movement of great storms. With regard to the first factor, high peak discharges in large rivers are usually traceable to synchronism in the arrival of flood waves from certain major tributaries. Other streams, exposed to storms in all respects similar, may lack this synchronism because of the different configuration of their basins, and their flood crests will be less in height but the duration of flood flow will be correspondingly prolonged.

An interesting illustration of the importance of these factors is afforded by Table 7, showing the greatest flood discharge in a century or more from each of three drainage areas of nearly equal extent. The river stage records, in each case, are of approximately the same length, and the relations between stage and discharge have been so well established as to be subject only to minor corrections.

TABLE 7.—Flood Data for Three Comparable American Rivers.

Stream.	Locality.	Drainage area, in square miles.	Date of maximum flood.	Maximum Rate of Flood Flow:		Coefficient in modified Myers formula.
				Second-feet.	Second-feet per square mile.	
Susquehanna..	Harrisburg, Pa.....	24 100	June 2, 1889...	700 000	29.1	4 520
Ohio.....	Wheeling, W. Va.....	23 800	Feb. 7, 1884...	494 000	20.8	3 210
Tennessee.....	Chattanooga, Tenn...	21 400	Mar. 11, 1867...	393 000	18.4	2 700

It will be noted that the Susquehanna River at Harrisburg discharges per square mile of drainage area, 58%, and the Ohio River at Wheeling, 13%, more than the Tennessee River at Chattanooga, although the latter drains a basin noted for its heavy storms and having a mean annual discharge greater than those of the others. All three streams are situated in the Eastern United States, two of them, the Susquehanna and Ohio, having their head-waters partly adjacent to each other; all of them drain country in many respects comparable, with mountains at the head-waters partly covered with heavy timber stands; and the climatic conditions do not differ materially except that the Tennessee River Basin lacks the cold winter seasons. Ordinarily, there would be reason to look for a fair degree of similarity in the flood behavior of these three streams. Radical differences exist, however, in the geography of their drainage basins. In the case of the Susquehanna River, two large tributaries, the Juniata and the West Branch, are responsible for the great floods in the main stream. Their basins adjoin and are usually covered by the same storms; their courses are from west to east in the same direction as the movement of storms, and their flood waves crest at about the same time, the flood peak of one joining that of the other in the channel of the Susquehanna.

On the Ohio River, the conditions are nearly reversed, there being no marked synchronism in the arrival of the main flood crests of the Allegheny and Monongahela Rivers at Pittsburgh, Pa., owing to the peculiar geographical arrangement of their basins and tributaries. In consequence, the maximum flood rates at Pittsburgh and Wheeling are not very high from the standpoint of flood run-off. The flood crests in the Ohio are caused mainly by synchronism in the flood waves of the Kiskiminetas and Youghiogheny Rivers, the water-sheds of which are contiguous and often subject to the same storms. Both streams drain from east to west, contrary to the storm movement, and, before their waters can join, one of them must first empty into the Allegheny and the other into the Monongahela. With an arrangement of this sort maximum flood rates such as occur on the Susquehanna River are physically impossible on the Ohio.

As for the Tennessee, this river and all its main upper tributaries flow in directions opposite to that of storm travel. In addition, there is little synchronism in the discharge of the larger tributaries. Thus, the flood crest of the Hiwassee River passes out first, and that of the French Broad River last.

Obviously, in the case of large streams the synchronism, or the lack of it, is an important factor. On smaller streams, the time of collection and concentration of storm run-off is usually so brief that the geographic arrangement of the tributaries cannot sensibly affect the net result. Thus, in a small basin like that of the Miami River (4 000 sq. miles), the maximum rates of flood discharge caused by the three-day flood of March, 1913, would have been no different if the tributaries, instead of converging in the existing crow-foot arrangement, could have been made to empty into the Miami many miles apart.

To what extent the coefficient of a formula can be made to take account of such divergent geographic conditions is not at all clear. It will be seen from Table 7 that the coefficient in the modified Myers formula is 4 500 for the Susquehanna, 3 200 for the Ohio, and 2 700 for the Tennessee. In the last analysis the coefficient in a flood formula is nothing more than a classification index intended to make possible a comparison between things not strictly comparable. In contrast, the California diagrams treat each stream as a law unto itself and comparisons are avoided. This, to the speaker, appears to be the rational method of dealing with flood phenomena.

The speaker feels that this is an opportune time for emphasizing the desirability of establishing uniform methods of compiling flood data. It is an undeniable fact that, of the existing mass of valuable flood statistics collected to date, only a comparatively small portion is in form for general use. Much of it has appeared in printed form, and some of it remains inaccessible to the profession at large, lying as it does in private files. No uniform system of collating any of it appears to have been advocated.

The demand of the Engineering Profession to-day is for more intensive and extensive compilations than have been made heretofore—more intensive, in the sense that data should receive closer scrutiny and be made to include

something more than mere dates and maximum flood rates; more extensive, in the sense that more streams should be studied and existing records be extended back to include information pertaining to early floods. Reviewing the long lists of flood data that have been published from time to time by the Society one is impressed with the wealth of information of this kind that may well serve as a foundation on which to build. The same may be said of the stream flow records of the U. S. Geological Survey. Its early publications give little information regarding floods, but the later ones are quite complete in that respect. Good work is being done also by State bureaus, and here and there much valuable material is available in private offices.

Flood data, to be of maximum serviceable value, must be in such form as to lend themselves to any of the many uses that engineers may wish to make of them. Engineers having dams to build and spillways to design are interested not only in maximum rates, but in the duration of floods and the total volumes of water discharged day by day. The same considerations affect the proportioning of reservoirs for storing flood waters and of detention basins. On the other hand, to the designers of bridges, culverts, flood channels, and levees, maximum rates are of chief interest and knowledge of flood duration or volumes of discharge is not essential. In all these operations, however, one factor stands out in importance above all others, controlling as it does the major aspects of any design, and that is, the probability of the recurrence of floods of various magnitudes. This may well be called the economic factor in any flood problem.

For some time the Society's Special Committee on Flood Protection Data has been at work devising a simple but comprehensive system to meet these various requirements. This has been referred to in the discussion by Mr. Grover, Chairman of that Committee. Attention is here invited to some of the features introduced, in the belief that they go far toward solving the problem of a uniform system for compiling flood data. To facilitate matters and insure uniformity, special blank forms on sheets 8½ by 11 in., have been printed by the Society, which may be had on application. The headings for these forms are shown on Fig. 16. The complete forms have space for 80 records in Form No. 1; 100 additional records in Form No. 2; 26 records (*a* to *z*) in Form No. 3, Table 2; 11 records in Form No. 3, Table 3; and 100 records in Form No. 4. Each form has space at the foot for the reporter's name and the date.

Forms Nos. 1 and 2 show in chronological order all floods that have occurred on a stream during the period covered by continuous records. By "all floods" is meant every rise of which there is record down to and including the least maximum annual flood. The latter, commonly referred to as the "one-year flood", serves as a starting point in the scale of floods, and its adoption places the flood records of widely differing streams on a comparative basis. Special pains are taken to indicate by means of a symbol whether the figures refer to peak flow or average 24-hour conditions (Form No. 1, Table 1, Column 1) (Fig. 16). For convenience of reference the three greatest known floods are entered at the top of Form No. 1 (Fig. 16), irrespective of whether or not they

occurred within the period covered by daily observations. The data so listed are fundamental for many studies. In order that its degree of reliability may be quickly judged, each record is graded with a number, the scale of which runs from 5 for data of the best character to 0 for information of questionable accuracy.

Form No. 3, Table 2 (Fig. 16) is designed for listing floods not included in the periods covered by daily records, but concerning which definite facts are known. It is not amiss to state here that early flood data of considerable value have been obtained from a variety of sources, and have proved of much value in determining the frequencies of recurrence of great floods. On Form No. 3, Table 3 (Fig. 16) may be tabulated in greater detail several of the floods listed in Table 2.

Finally, on Form No. 4, Table 4 (Fig. 16), may be entered data for platting flood hydrographs, consisting of both gauge heights and discharges. This form was adopted by the Committee in preference to graphic representations, because no one form of hydrograph could be devised that would answer the many different requirements of engineers, and it was deemed best to leave the plotting to individual tastes. All the forms were designed to be capable of indefinite addition and expansion as future data are obtained.

These forms and the data to be entered on them represent the first step in the program of the Committee, the next step being the condensation of them into diagrammatic or other form for general use and reference. To date (1925), 139 streams have been compiled on the forms, thanks to the co-operation received from various sources. Engineers possessing flood data will confer a favor on the Society and on the profession as a whole if they will co-operate with the Special Committee on Flood-Protection Data in this important work.

Ford Kurtz,* M. Am. Soc. C. E.—Flood problems can be divided into two major groups, namely, those requiring for their solution knowledge of flood heights under existing physical conditions and those requiring the estimation or prediction of flood heights under other than existing conditions. The solution of all problems coming under the latter classification depends on the rate as well as the height of flood discharge.

Nearly all flood investigations required in highway and railroad design belong to the first group, since, in general, only slight channel encroachments are involved. Information as to the maximum stage of streams is often obtainable when data on the rate of discharge are completely lacking, so that highway and railroad engineers can usually secure the records they need, whereas the designer confronted with problems in the second group finds in many cases only very meager data to aid in their solution. Thus it happens that irrigation, public water supply, and hydro-electric engineers, who nearly always deal with design problems of the second group, are much more deeply involved in the study of stream flow characteristics than either the highway or the railroad engineer. However, the final difference in the difficulties encountered by the two groups of engineers in their flood-control problems is not quite so great as indicated, by reason of the fact that highways and rail-

* Care, J. G. White Eng. Corporation, New York, N. Y.

roads involve many streams in a single project and often pass through regions where irrigation, public water supply, and hydro-electric developments could not be financed, since bankers are loath to sponsor projects of which water supply is the basic factor unless stream flow records are available for a period of years, or the discharge can safely be estimated from records on adjacent streams. Thus, some observations of flood discharge as well as of flood heights are usually available for solving problems of the second group.

This paper presents in both tabular and graphic form a great amount of data on maximum recorded flood discharges and in a general way interprets them and indicates their application to specific problems. The latter feature is the chief measure of the value of the paper, since it determines the practical use. Plate IX, which summarizes the data graphically, shows such great variations in the maximum recorded flood discharges for a given area of drainage basin as to create at once the impression that the author has consolidated data too diverse (both geographically and in the period of observation) to permit of drawing conclusions of value. Furthermore, the method adopted in preparing Plate IX takes no account of the frequency of floods of different magnitudes, which is often an important factor in design.

Geographical diversity, as representative of different hydrological conditions, can be taken care of by preparing more diagrams from a given number of observations, but the correction for difference in length of period of observation, which is at least equally important, is not so simple. For this latter purpose, the speaker proposes the analysis of flood flows by the probability method. He considers the practical application of the mathematical theory of probabilities to the problem of frequency and magnitude of floods the most noteworthy single contribution of the last twenty-five years to the science of hydrology. Its uses are many, and it is the best method for correlating flood records having different lengths and made during different periods of years, as well as for determining probable frequencies of various sizes of floods, where such data are needed for purposes of design.

If the records presented by the author were first segregated into at least as many geographical divisions as are listed on Plate IX and if certain representative streams of each division, beginning with those having the longest records, were then studied intensively by the probability method, the plotting of the resulting values for the probable 100-year or 1 000-year flood would undoubtedly show a tremendous decrease in the width of the "belt" of points as compared with Plate IX. This method of studying an individual stream often results in the discovery and rejection of erroneous or doubtful data, which might otherwise go unnoticed, and will always smooth out in a consistent manner the irregularities of records on the stream. Thus, it may happen that the maximum flood observed in a 10-year period may actually be one which occurs only once in every 100 years on the average. It is truly remarkable how the probability method will show such a flood to be "out of line". By that it is not meant that the flood could not have occurred, but rather that it will appear quite plainly as a 100-year flood which chanced to occur in the 10-year period of observation. No other method will bring out

these features so clearly. The speaker, therefore, believes that intensive and careful study of a fewer number of streams in the manner just described would be much more valuable than the compilation of a mass of data on maximum recorded flood flows so great as to preclude detailed study of them.

There still remains for evaluation the important factor of shape of drainage basin, which causes wide variation in the rate of flood flow from basins having the same area and subject to the same hydrological conditions. This is a matter of individual examination for each stream. Obviously, the effect of this factor can be studied much better if geographical diversity and difference in period of observation have already been eliminated in the manner suggested.

The speaker by no means wishes to disparage the use of general curves based on the records of a number of streams, but he does feel that such curves must be used with great care. In general, if as many as ten years of flow records for any stream are available, intensive study of the higher recorded flows of the stream itself is often more valuable in predicting flood frequencies than curves based on longer records of adjacent streams. Some engineers might feel that a 10-year period of observations is too brief to serve as a basis of probability studies. However, examination of the hydrograph of any stream will show a great many peaks projecting above the general level, rather than one only. In the speaker's opinion these should all be classified and studied as floods, the problem being to fix the "basic stage" for a flood, that is, the line between those flows governed by a few well-defined factors and those governed by the laws of probability and chance. If this opinion is correct, ten years of records may yield, not ten, but twenty, thirty, or even forty, values for probability determination. These values will give a very good idea of the trend of floods—not the true trend, to be sure, but an indication of it that represents a great advance over the results of any other method thus far presented for the study of flood problems.

In order to fix this dividing line, or "basic stage", for floods on any given stream, it is only necessary to select various values, assume every peak above that value to be a flood, and from the points thus obtained derive a probability curve. That value of basic stage the points of which lie nearest to a straight line on probability paper is chosen as the correct value, and the resultant straight line as the flood probability curve.

As already mentioned, many design problems require a solution based on the frequency of floods of different magnitudes, because it is not always necessary or even desirable to design structures in such a manner that there will be no damage caused by a large, infrequent flood. One of the great advantages of the probability method is that, more than any other, it presents a quite definite idea of frequencies as a guide in the two major features of flood-control design, that is, the economic and the social. The economic feature is embodied in the question, "Will it pay from the standpoint of probable property loss over a long period of years to protect against certain floods?" Here the frequency studies are of utmost value. The social feature involves

the safeguarding of human life and the frequency studies point the way to the determination of the flood having such a small percentage of probability of occurrence that there is practical assurance it will never happen.

The speaker, therefore, wishes to urge the general adoption of the probability method as the best presented thus far for the study of compiled flood data, such as those submitted by the author, and for the study of the individual flood problems confronting all hydraulic engineers.

CHARLES W. COMSTOCK,* M. AM. SOC. C. E.—The author has rendered a valuable service in collecting and arranging the records of about 1 000 flood discharges from drainage areas of all sizes in different parts of the world.

The speaker believes, however, that it is a mistake to relate the rate of run-off to the area of the drainage basin. This is, to use a crude analogy, as if one sought an empirical formula for stress in a beam in terms of the length as the only argument, leaving the load, the cross-sectional dimensions, and the method of support to be covered by an all-inclusive coefficient to be guessed at subsequently.

The author enumerates a considerable list of variables, both meteorological and topographic, which influence flood discharges, and then selects one (probably not the most important), "as the logical basis for a general formula", ignoring the others except as they may be included in a coefficient the values of which range from 100 to 10 000. Such procedure is certainly not scientific, nor is it likely to throw any light into the dark corners of this complicated subject.

It may well be doubted whether a formula is worth while in view of the large number of variables, most of which it is impracticable, if not impossible, to evaluate for any given drainage area. Careful study of Table 2 will give quite as much information and a far better understanding than can be had from any formula that attempts to summarize the data. Moreover, the very existence of a formula is likely to lull engineers into a comfortable, but unjustified, belief in the precision of results, instead of stimulating that healthy skepticism and critical examination of every step which so often keep them from serious blunders.

As already noted, the speaker believes that the area of the drainage basin is probably not the most important factor in determining flood run-off. The author states that he considers it the "logical" variable to which run-off may be related. May he not have been drawn to it, perhaps subconsciously, because it is the only factor which can ordinarily be ascertained?

The area covered by a violent storm is relatively small. A limited drainage basin may get the full effect of such a storm over its entire area at one time. A large basin may be crossed by the storm over a short line or a long line. In the latter case the total precipitation on the basin may be large, but it does not fall on all parts simultaneously. If the path of the storm is down stream the cumulative effect may build up an enormous flood from a moderate rate of precipitation. If the path is up stream a violent storm may produce

* Engr., Dwight P. Robinson & Co., Inc., New York, N. Y.

only ordinary high water. Again, a persistent and prolonged rain covering the entire basin at one time may cause a greater flood than either of the storms mentioned, although the total volume of water falling may be no greater. In these three assumed cases, all of which are not only possible but of frequent occurrence, the area and all other features of the water-shed are identical, and the total precipitation in a given time may be the same, yet the discharges at the gauging station will differ greatly.

An element of great importance (perhaps more than the area itself) is the permeability of the underlying rocks. The author mentions this only casually. This point was first emphasized by Belgrand in his studies on the basin of the Seine. He pointed out that 75% of this basin is underlaid by permeable rocks, the annual discharge of the river being only 28% of the precipitation; for the Garonne, of which about one-half the basin is impermeable, the run-off is 52%; and for the Po, the basin of which is almost wholly impermeable, the run-off is 64 per cent. These basins are of nearly equal size, that of the Seine being 30 000 sq. miles; that of the Garonne, 33 000; and that of the Po, 27 000.

A peculiar feature of the Po floods is that the discharge is nearly the same at all points along the lower 150 miles of the river. This seems to be due in part to the lack of synchronism of flood discharges on the numerous tributaries, and in part to the enormous storage capacity of the endiked channel.

The upper part of the Arkansas River in Colorado lies between the Continental Divide on the west and the Mosquito Range to the east. At the time of the spring run-off and consequent flood stage of the Arkansas, almost the entire supply comes from the tributaries which drain the granite massif of the main range, while the limestones, sandstones, and other permeable rocks of the Mosquito Range contribute only a trifle to the gulches which feed the river from the east.

It seems impossible that the various elements here mentioned, as well as many others, should receive suitable quantitative designation and be incorporated in any formula for general use. The engineer will necessarily be driven back on his judgment of the significance and importance of each factor in a given case, and he might better apply that judgment directly to the tabulated data.

It is easy to be critical. As Byron said:

> "One must serve his time to every trade
> "Save censure. Critics all are ready made."

It is another and far more difficult thing to contribute a new fact or a new principle. It is important, however, that in the desire to render knowledge more useful by classifying and formulating it engineers should not jump to hasty generalizations which may mislead.

As the author points out, the gauge height at flood stage is more important than the volume of discharge. It matters little whether the quantity of water flowing is large or small, as long as the surface does not rise high enough to

endanger lives or destroy property. It is well known that on the front of a flood wave the maximum velocity, maximum discharge, and maximum gauge height occur in succession in the order named. Thus, two flood waves of equal maximum discharge may have quite different gauge heights, depending on the steepness of the wave front.

There is a tendency to think that floods become increasingly destructive as time goes on. This is not so much because floods are greater in volume now than formerly as it is that there is more to destroy. For instance, the Seine flood of 1910 had a maximum gauge 0.39 m. less than that of 1658, but did incomparably more damage for an obvious reason.

The author's warning against the misuse of calculated flood frequencies is worthy of careful attention, especially in view of the prevalent, and in the speaker's opinion improper, tendency to base probability calculations on small numbers of observations.

In 1873, Belgrand published his monograph on "The Seine", one of the most elaborate and exhaustive treatises ever devoted to the study of a single river. In discussing the flood of 1658, he wrote:

"The meteorological phenomena which produced the flood of 1658 have manifested themselves again in our day. They have been renewed three times between 1732 and 1872 (140 years) in the floods of 1784, 1836, and 1866, or once every 47 years, and they were separated by intervals averaging 35 years. But, in order that there should result a flood similar to that of 1658, it is necessary that they should occur not more than five or six days apart. The probability of such an approximation is very small, and, by calculations which I think it useless to reproduce here, I have demonstrated that the recurrence of the flood of 1658, under the same conditions, *i. e.*, by floods in only two of the affluents, would require thousands of years."

Thirty-seven years later, in 1910, it happened.

A probability, however logically derived, is not a forecast. It is certain that what has occurred may recur, and even worse conditions may present themselves. There comes a point beyond which it is not financially practicable to go in providing protection against possible but improbable floods. At this point the engineer, like all good gamblers, must be willing to risk his money on a "long shot".

Thaddeus Merriman,* M. Am. Soc. C. E.—The speaker has been interested in floods for many years. He was fortunate in getting on to the ground in the Ohio Valley very shortly after the flood of 1913 and has kept up a lively interest in all matters pertaining to floods ever since. This problem is one that will always be with us because every time a new flood occurs it becomes necessary to revise a large part of our so-called fundamental data.

The speaker is heartily in accord with the point of view presented by Mr. Comstock. This matter of floods is not one which can be fairly treated by any method of probabilities. Maximum flood discharges are related to the duration of the storm and its intensity, to the direction of its path, to the characteristics of the topography and of the geology of the water-shed, far more than to any simple function of the area of the drainage basin.

* Chf. Engr., Board of Water Supply, City of New York, New York, N. Y.

On account of the ease with which these problems can be discussed with pencil and paper there is a tendency to neglect one source of information respecting flood heights that is worth more than all the direct observations which have been accumulated to date. This information is to be found in the records which the floods themselves have left on the walls of the valleys they traversed. This does not refer to the drifts of wood and leaves or other similar perishable substances, but to the sand and gravel bars which lie above the stream bed. They are to be found in every river valley and are better indices of past flood heights than any so-called records as to observed maxima. No analysis of possible flood heights can be considered complete, which does not include the records which the great floods of the past have engraved on the topography.

If, on the Catskill drainage area, there had been used any method of 10-year periods and had a probability curve been developed from them, the results would have been shattered beyond recognition by the flood of October, 1924; and that flood, moreover, was far from being a maximum.

There is a fundamental reason for the anomalous position in which we find ourselves with respect to this problem of floods. There are existent very few dependable records prior to 1900. Many floods occurred before that year and many have since occurred and passed without being recorded. Most of what are called flood records are not worthy of the name. Table 2 as presented is not a record of floods; it is merely a tabulation of observed stream flows. This is a fact which must be held clearly in mind, else we shall continue the vain task of studying and analyzing a mass of data that bears no known relation to real floods as such.

Weston E. Fuller,* M. Am. Soc. C. E. (by letter).—The paper calls attention again to the importance of the flood problem and sounds another warning of the inherent danger which lies in the encroachment of the channels that streams have used in the past for the purpose of carrying the great floods which come only at rare intervals. The great disasters that have come to many communities in the United States show this danger clearly. That similar disasters will occur at many other places can scarcely be doubted. The mere fact that for many years streams have not experienced floods that have caused any damage is, in itself, no assurance as to the future. The unusual conditions that produce great floods may occur on any stream, just as, in the past, they have come on other streams, and floods greatly in excess of the usual ones are possible at any time.

The author has discussed a number of characteristics of floods in a very helpful manner. He proposes a formula which, he concludes, represents the effect of the size of the drainage area on the maximum flood. Many investigations have been made for the purpose of determining this effect. As a result of these studies, a number of formulas have expressed the relation as an exponential function, in most of which the relation was found to be quite different from that now proposed by the author.

* Prof., Civ. Eng., Swarthmore Coll.; Cons. Engr., Swarthmore, Pa.

Grouping all the other factors affecting floods into a coefficient designated C in each case, the formulas resulting from these investigations may be expressed, as follows:

Talbot	$Q = C M^{0.75}$	
Fanning	$Q = C M^{0.83}$	
Burkli-Ziegler	$Q = C M^{0.75}$	
Dickens	$Q = C M^{0.75}$	
Cooley	$Q = C M^{0.67}$	
Ryves	$Q = C M^{0.67}$	
Dredge	$Q = C M^{0.67}$	
Metcalf and Eddy	$Q = C M^{0.73}$	
Fuller	$Q = C M^{0.67}$	for small streams, increasing to
	$Q = C M^{0.8}$	for very large rivers.
Cramer	$Q = C M^{0.7}$	to
	$Q = C M^{0.8}$	

The author's proposed formula is $Q = C M^{0.5}$, which is quite different from the previous formulas and which calls for an analysis of his data and methods in order to ascertain his reasons. He derives his formula by plotting the maximum rate of flow of many different streams, and draws a curve to envelop the highest of these maximum flows. The writer believes that this method of treating flood data has a fundamental error which leads to an erroneous conclusion. This opinion the writer has previously expressed in discussing other formulas derived in a more or less similar manner. In the closing discussion of his paper on "Flood Flows,* the writer made the following statement:

"* * * other formulas, derived by plotting the maximum floods which have occurred on streams of different sizes, give the greatest flood which has occurred on any of the large number of streams in the varied intervals covered by the several records.

"As there are many more small streams than large ones, it is obvious that there are more chances of obtaining an extraordinary flood on some one of the many small streams than there are of obtaining a similar flood on one of the few large ones."

This criticism was offered respecting data selected for streams which had similar characteristics so far as slope, rainfall conditions, and other elements affecting floods are concerned, and was simply directed toward the greater probability of securing relatively great floods on the large number of small streams than of securing a similar result from a few large rivers. In his paper, however, the author has not confined himself to a consideration of streams of a similar nature as to other characteristics affecting floods, but has plotted on his diagram (Plate IX), the extraordinary floods which have occurred on a few of the many small streams that are, in the main at least, mountain streams, and has compared these floods with those on the few large rivers on which no similar conditions exist.

In this case, therefore, the data are unbalanced in two different respects, and it is no wonder that the effect of the size of the catchment area is greatly exaggerated. An examination of Plate IX will show that the enveloping curve is controlled at the upper end by a few points, all of which are extraor-

* *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 681.

dinary floods which have occurred on a few streams having unusually favorable conditions for great floods so far as their drainage areas are concerned, and that these floods represent most extraordinary occurrences among thousands of similar streams. The other end of the curve is controlled by the floods which have occurred on the few large rivers in the United States. It will be noted that these rivers do not have similar characteristics so far as slope and other conditions are concerned. The author's formula, therefore, covers the extreme conditions for small streams, but only ordinary conditions for the large rivers, and does not properly indicate the effect of size of drainage area.

This is well illustrated by considering the two extreme points on Plate IX. Beacon Creek, the smallest stream plotted, has a catchment area on the side of a steep mountain, most of which is impervious; from it the run-off is very large. At the other end of the diagram is the Mississippi River, on which the conditions are nearly opposite. That the difference in run-off per square mile between these two extreme cases is largely effected by the character rather than the size of the water-shed, cannot be doubted.

Bearing in mind that the author has plotted on Plate IX floods which have occurred on nearly all the large rivers in the United States, it would be well to consider what the diagram would look like if he had followed the same course with small streams. In such a case he would have had a mass of points plotted on the left side of the diagram, representing the largest floods on the enormous number of small streams that have never had a flood as great as those plotted. A curve through the center of these points representing average conditions on small streams, and through the center of the points for the larger rivers, would indicate the effect of the drainage area.

Methods of treating data similar to that used by the author are quite common. For this reason the writer believes that it is well worth while to discuss the matter in considerable detail in order to show the reason why erroneous conclusions may be drawn. It may clarify the subject somewhat to indicate what would have resulted if a similar method had been followed in deriving other well-known formulas.

For instance, consider the formula to which the author likens his own, that is, the Chezy formula for the flow of water in conduits. Suppose that, in deriving the Chezy formula, data had been used which represented the maximum flows obtained in any conduits, irrespective of their slope or surface conditions, and that the formula had been based on the maximum points obtained by plotting these results. The result would have been a curve controlled at one end by the flow in small conduits with smooth surfaces, and, at the other, by the flow in large rivers, for which much less slope would have been found, and for which the surfaces would have been rough. It is needless to say that the formula thus obtained would have given the relation between the velocity and the hydraulic radius very different from that which was obtained by comparing conduits of similar slopes and similar surface conditions. Such a formula would have been misleading indeed if applied to similar conduits of different sizes. The author has used a similar method

in obtaining his formula. It is essential, in using data of this kind for the purpose of ascertaining the effect of any element, that the effect of all other elements be made at least similar, otherwise the results do not show the true relation.

The author tabulates the maximum floods for a large number of streams, the information having been collected from many different sources. These data are useful, and Mr. Jarvis has performed a real service in bringing them into a single table (Table 2). Any one who has traced data of this type to their sources, must have been impressed with the likelihood of errors, as the items are transferred from table to table. Flood data are particularly unreliable in this respect.

In the first place, the records of these floods are of varying degrees of accuracy. Some of them are undoubtedly close approximations to the actual peak flows of the floods in question; others are probably far from the actual run-off. This must be true for many of the floods, particularly for those which have caused great destruction. In the great majority of such cases the discharge has been estimated by the use of the Kutter formula. The data for determining this flow have been obtained subsequently by observation of the water marks of the maximum height attained by the flood at any time during the flood period. Whether or not the slope thus obtained represents the slope of the water flowing in the channel cannot be ascertained with any degree of accuracy where the channel has been materially changed by the floods. Moreover, the value of the coefficient, n, in the Kutter formula at the time the maximum height was attained at the point under consideration, is doubtful. It is impossible to say how much the flow in the channel is being retarded at that particular time by the mass of débris flowing down the stream. It is impossible to know whether or not the height which the flood reached at that point was caused by water flowing in a free channel or whether it was backed up by submerged obstructions. Little is known of the effect on the flow of great masses of soil, trees, brush, rocks, and other material which are being carried down the stream by these floods.

Mr. Winsor, in his discussion, vividly sets forth the condition that exists in some extreme cases where the water is practically pushing the large mass of matter ahead of it. Is it not true that for most destructive floods similar conditions, to a lesser degree, occurred at some time during the flood, thus establishing high-water marks which are afterward taken as the slope of the water which is assumed to have been flowing freely in the channel as left after the flood recedes? It must not be overlooked that, in estimating the discharge for many of the floods, values of n in the Kutter formula as low as 0.030 have been used, and seldom, so far as the writer can ascertain, have values of more than 0.040 been taken.

The writer is inclined to think that for most destructive floods the discharge has been over-estimated. In tables such as Mr. Jarvis has presented, as well as in many similar tables, there is no indication of the accuracy of the data, yet from the original source of the information, it is found—in many

cases at least—that the engineer who estimated the flood had a clear conception that his estimate may have been far from the actual flow.

As an instance of this, consider the floods on Cane Creek, in North Carolina, and on Elkhorn Creek, in West Virginia, two of the largest, relative to the drainage area, of which there are records. The quantity of water flowing during the peak of these floods was estimated by Mr. E. W. Myers, who described* the difficulties of ascertaining the discharge during these floods, and frankly stated that his estimates might have been far from the truth. It appears from his description that in estimating the flow he used the slope of the channel as it existed after the flood had receded.

To illustrate the nature of these data it may be well to quote a little of what Mr. Myers has said in regard to his measurements. As to Cane Creek, he says:

"For these reasons the writer has used all the means in his power to obtain such information and it is presented below, though with diffidence, for the possibility of considerable error is great, but the results are the best that can be obtained under the existing circumstances.

"* * * . Unfortunately, no gaugings of this stream at anything approaching flood heights has ever been made, so that a rating table giving the relation between height and discharge cannot be constructed in the usual manner. Failing in this, therefore, there are two approximate methods which can be used for obtaining this information, one based on the consideration of the amount of the rainfall during the period, its distribution, the condition of the earth as to saturation, etc., together with the shape of the basin, its average slope and the general topography; the second based on the cross-section of the channel at some point, its condition as to roughness and the slope for some distance above and below the point where the cross-section is taken.

"* * * . This method is open to objection on the ground that there is great difficulty in selecting the proper value of n, and also from the fact that the slope at flood stages is probably not the same as at low water, except at the crest of the flood, when the water is neither rising nor falling."

As to Elkhorn Creek, he says:

"As stated before, in this way no estimate of the maximum flood volume is possible and we are compelled to resort to estimates based on the slope and cross-section of the channel. Such estimates in this case present even greater difficulties than in the case of Cane Creek, since the waters of Elkhorn Creek were much more obstructed and the cross-section at different points is much more variable, making the coefficient of roughness greater than before, and introducing more uncertainty as to its proper value. As the method used was precisely the same as that used on Cane Creek, the calculations will not be given here in detail as on that stream."

Other floods, which rank high among the extraordinary recorded floods, are those which occurred in the vicinity of Philadelphia, Pa., in 1843. The record for the discharge during these floods is found by a recent re-computation based on data obtained at the time of the flood. The writer is not criticizing either the accuracy of the data taken at that time, or the method of computation, but simply noting that there is a large chance of error, and that too much dependence cannot be placed on such data. For many of these extraordinary floods, therefore, there is merely an estimate based on doubtful

* *Engineering News*, Vol. XLVIII, August 7, 1902, p. 102.

data, with no assurance that these estimates in different cases are properly comparable.

It appears further, in comparing the various tables of maximum flood flows, that there are considerable differences as to the magnitude of these floods in the different tables. In some cases these differences are accounted for by revisions of the original estimate; in others they probably are due to typographical errors and similar causes. Each time a new table is presented, some of these errors creep in. Evidently, such data are in much confusion, and there is real need of a careful study of the original records of all these great floods in order that their relative reliabilities may be determined.

The author's proposed method of determining the maximum flood on a stream is evidently based on consideration of the single flood on that river. For many of the rivers there is no method of telling whether or not this single flood is an extraordinary event. It is true that, for many streams, the author has listed what he indicates as frequent and rare peaks. So far as the writer can ascertain, these frequent and rare peaks are taken from two or three different sources. Most of them represent the data taken from the writer's paper on "Flood Flows"; others are taken from the study of floods in California, and a few others from observations and estimates by the author. So far as those taken from the writer's paper are concerned, the frequent peaks represent the yearly floods as obtained by averaging the largest flood for each year, over a period which was then available. The end of this period was about twelve years ago, and more reliable data must now be available for many of these streams. The rare peak merely represents the largest 24-hour average flow during that period.

The basing of any estimate on the single maximum flood, without consideration of any other floods which have occurred on the stream, leaves the time element entirely out of consideration.

Mr. Lane's excellent statement of the meaning of flood frequency and its importance, will serve to clarify this subject. His study, which is confined to New England streams, indicates a frequency relation for flood flow expressed by $Q = Q_1 (1 + 0.69 \log T)$. The writer, basing his study on all the streams of the Eastern Coast, which included, of course, Southern as well as Northern rivers, found a relation as to frequency for those rivers in accordance with the formula, Q maximum $= Q$ average $(1 + 0.75 \log T)$; for other parts of the United States, he found a larger variation in respect to T and adopted as a general average, $1 + 0.8 \log T$, believing that the data then available did not justify any attempt to use a different relation for different localities.

In making his study, Mr. Lane has used a method which gives the flood to be equalled or exceeded, corresponding closely to that described by the writer.* Using Mr. Lane's illustration of a series of 1 000 floods on a stream, he is correct of course when he states that the one-hundredth of the series is that which will be equalled or exceeded on an average of once in a 10-year period. But what about the largest flood? It is not the flood which will be equalled or exceeded in 1 000 years. It is the flood which will probably

* *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 580.

occur. It is the flood for which there is an equal chance that it will occur in another thousand years. This is what the writer's formula gives, and, in his opinion, it is what is desired. With Mr. Lane's method, this largest flood cannot properly be included in his series unless he includes it for a period of 2 000 years. From the method outlined in his discussion, it would appear that he has not done this, but has taken the largest flood as the one which is equalled or exceeded for the full period. If so, he is slightly in error for about one-half his records.

If it were desired to find the flood for which to design, so as to be quite sure that the structure would fail within a given period, then the flood that is equalled or exceeded in the period would be the proper one to use. The writer's view of the matter, however, is that for the design of the structure, it is desired to ascertain the flood for which there is an even chance that it will not fail during the period, and for that reason he used the average flood. It really matters little which method is used, if the computer understands what he is doing. Substantially the same results would be obtained if the value of T in the Lane method is made twice as great as in the writer's method. The relation between these methods has been discussed previously* at some length by the writer.

Mr. Lane apparently obtains his yearly flood by plotting the data rather than by averaging the floods. There is much to be said in favor of this method and something to be said against it. As he states, it eliminates any consideration of the larger floods and, in cases where these floods are unusual, this result would be better. It is not certain, however, that these larger floods are unusual. Is it not equally possible that, for the period in question, the stream has had an unusual number of smaller floods? The writer considered this question at the time he prepared his paper. He was much inclined to adopt a method similar to that proposed by Mr. Lane, but concluded that, while in some cases the average was unduly affected by including the larger floods, the error in neglecting them, while less apparent, was, in other cases, quite as great. In his own work, however, he takes into consideration both the actual average yearly flood and the yearly flood as indicated by plotting. For long records either method will produce satisfactory results, while for short records there is, of course, bound to be some error.

Mr. Lane has computed the probable error in obtaining the one-year flood by means of records of different lengths, based on the Merrimack record. His results seem to agree quite closely with those found by the writer from a study of many different rivers to ascertain the probable error in finding the average yearly flood.† In so far as the probable error is concerned, there seems little to indicate which method is the better.

A study of the floods on streams where large ground storage exists, or where there are considerable storage reservoirs which are partly emptied at times when floods occur, has convinced the writer that in some cases a method almost the opposite of that suggested by Mr. Lane is necessary. For such streams the floods are divided into two series, one representing the floods that come

* *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 564.

† *Loc. cit.*, Fig. 19, p. 685.

when storage is to be had in the ground or in the reservoir, and the other including the floods when no storage is available. The plotting then may become two parallel lines, one distinctly higher than the other. This is because the storage, when it is available, affects the total run-off from large and small storms by about the same amount, thus being a much greater proportion of the small storms than it is of the larger ones. In such conditions the flood to be used in the place of the yearly flood in the formula, should be determined largely by consideration of those floods which occur when little or no storage is available. It can be approximated by considering only the upper points representing the larger floods, drawing through these points a line representing the frequency relation and considering the "yearly flood" as that given by the intersection of this line with the one-year line. This, of course, may be higher than the average and much higher than that obtained by the Lane method. While such cases are not common in most sections of the United States, yet in a study of Southern California streams several were found, and the influence is undoubtedly felt for other rivers, although it is less marked. Here the method proposed by Mr. Lane would lead to a much larger error than the use of the average flood.

In arid regions these conditions are exaggerated, so that no floods of any moment occur during many years, yet large floods sometimes come. In his paper on "Flood Flows," the writer stated:*

"* * * in arid and semi-arid regions * * * conditions are such that no floods worthy of the name occur in some years, though occasionally there is a large one. For such cases the average yearly flood becomes low and the percentage of the maximum flood becomes unduly high. These conditions are quite different from those generally found, and it seems best to exclude such cases. It follows, of course, that the frequency relation here proposed does not hold for such rivers."

Mr. Lane suggests that the relation between the average 24-hour flood and the maximum rate of flood, as included in the writer's formula, is the weakest part of the formula. The writer agrees. At the time the study was made little data were available on the maximum rate of flow, only occasional records could be found for most streams, and there were few continuous records. What data were to be had consisted, in the main, of records based on the 24-hour average, so that it was necessary to make the study on that basis. The writer appreciated the fact that the peak flow for small streams would be a larger proportion of the 24-hour average flow than for large streams, and established the relation as best he could with the data at hand.

At present, there is a large amount of additional data available, and a far better relation can undoubtedly be established. This the writer hopes to do at an early date. Mr. Lane suggests that, instead of using this relation, his Q_1 may be used. With this conclusion the writer is agreed, providing that it is possible to obtain directly the flow at the peaks of the floods. At the time the writer proposed his formula, it was quite impossible to obtain these peak flows for any considerable number of rivers. Even to-day the bulk of the data is still expressed in terms of a 24-hour average, so that the relation between

* *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), pp. 581–582.

the peak and the 24-hour average is a necessary part of the formula. Where, however, the peak flows are available, the writer certainly would agree that they should be used in preference to any formula which could possibly be devised. In other words, where facts are available, they should always be used in preference to any indirect figures obtained by means of formulas.

There is one point in regard to this relation between maximum rate and 24-hour average rate to be made clear. Mr. Lane criticizes the relation because it does not agree with some individual cases. The relation as expressed is intended to be that between the maximum flow at the peak, during a period of years, and the maximum 24-hour average, during that same period. This relation cannot be expected to hold for individual floods, as the two maximums do not necessarily come during the same flood.

A few years ago the writer made a partial check on the frequency relation in his formula by again plotting the data for selected streams with long records, including therein the floods for five or six additional years. For most of these streams the indications were that the individual plottings approached more closely to the general relation than previously. With the large amount of additional data now available, it may be that frequency relations for different sections of the country are justified. It is the writer's intention to make a re-study of this phase of the problem.

The investigations which have been made have only scratched the surface of the flood problem. The maximum peak flow, although an important element in many problems, is in others less important than the maximum total flow during flood periods. In fact, the hourly flow for small streams, representing as it does the bulk of the run-off, is perhaps properly comparable to daily flows of larger streams, weekly flows of still greater rivers, and flows of several weeks for the Mississippi River in its lower stretches. Each represents the run-off for somewhat similar conditions. A study along such lines might tend to clarify some points not yet understood. There have been many studies of the effect of such elements as the average slope of the drainage area, the relation of the length to the width of drainage area, the average rainfall over the area, and some other elements. The effect of the percentage of the water area of lakes and ponds is another factor which could well be studied. Information as to the effect of these elements, as well as to the effect of the size of the drainage area and of the frequency relation, would place in the hands of the engineer tools with which to work in solving the problem for individual streams; but they can never eliminate the necessity for the careful study of the stream itself or the exercise of judgment.

Formulas which confuse the effect of any element are, however, not useful tools, as they tend to confuse the judgment. In the writer's opinion, the author's formula, purporting to show the effect of drainage area, while in fact including thereunder the effect of many other elements, comes in this class.

H. de B. Parsons,* M. Am. Soc. C. E. (by letter).—This paper calls attention to a most important subject, and the data of maximum observed flood discharge rates given in tabular form will be useful to those studying flood problems.

* Cons. Engr.; Prof. Emeritus, Rensselaer Polytechnic Inst., New York, N. Y.

The maximum run-off in any district must be strongly influenced by the characteristics of the district, such as the geological formation, surface contours, number and size of tributaries of the main stream, forestation, etc. When the area of a drainage basin is large, the physical characteristics of part of the area may (and often do) differ widely from those of other parts.

If the flood discharges given in Table 2 were segregated into groups according to physical characteristics and to geographical location, the variation in the value of constant, C, between upper and lower limits, as shown in Plate IX, would be greatly reduced for each group. This would make the practical application of the formula less liable to error.

It would seem that a formula to express the discharge in second-feet as a maximum to be expected, based on known flood records, should be of the form,

$$Q = C M^{\frac{n-1}{n}} K$$

This is the author's Equation (2), with the addition of K, a variable to cover the physical and geographical characteristics of the drainage area. It might be possible to determine values for K by classifying the data in Table 2, and platting the points in a manner similar to that used for Plate IX. Then, K would be constant for each classified group, and C would be constant for all groups, but sufficiently large to cover the maximum expected floods.

The writer suggests that this matter be referred to the Society's Special Committee on Flood-Protection Data and to the author, who deserves great credit for the work he has done. Perhaps a detailed study of classified drainage basins would develop the fact that values might be determined for K which would be characteristic for certain physical and geographical conditions and which would bear some simple relation to the discharge corresponding to known precipitation. This idea, expressed mathematically, might take the form of:

$$K = \text{Function of } \frac{\text{Discharge}}{\text{Corresponding precipitation}} = f\left(\frac{D}{P}\right).$$

Robert E. Horton,* M. Am. Soc. C. E. (by letter).—The author adopts tentatively the Myers formula in which flood discharge varies as the square root of the area. In most such formulas, larger exponents of A have been used, generally $\frac{3}{4}$, $\frac{4}{5}$ or $\frac{5}{6}$. The author does not give reasons for the use of so small an exponent of A; presumably he believes it better adapted to Western streams.

The average slope of the line of relation between Q and A could be determined by taking group means of all the data plotted on Plate IX within the limits of selected increments of A and plotting the mean values of Q in terms of A. This the author has not done. The data on Plate IX seem to show some justification for the reduction of the exponent of A below its customary value. A line through the center of gravity of the points having a slope corresponding, say, to $A^{0.8}$ would clearly fall below the majority of the points to the left and above a majority of those to the right of the central point. It is to be noted, however, that in nearly all cases where the exponent

* Cons. Hydr. Engr., Albany, N. Y.

of Q is taken in terms of the $\frac{3}{4}$ to $\frac{5}{6}$ power of A, slope is also included as a factor in the formula. Large areas are generally flatter than small ones. The steeper the slope the greater the flood discharge, other things being equal. The flood discharges recorded on Plate IX for small areas are, therefore, greater than they would be if the slope of these small areas was the same as that of the larger areas; hence, to fit the plotted points the line must be steeper or, in other words, a smaller exponent of A must be used, than if the slope of the drainage basins was considered separately. However, it seems certain that the data given by the author would serve to evaluate the law of slope in relation to flood discharge quite as readily as the law of area. If this was done, one less factor would be left to the uncertainties of human judgment. The author's formula apparently does not relate to basins of any particular slope, but is based, tacitly at least, on the presumption that each basin has the average slope of all basins of the same area, this average slope differing for each size of area and being steeper for small than for large areas. This assumption is hardly a safe guide in computing flood discharge in specific cases. Two basins of equal size in the same region may differ widely in slope. Drainage basins on the Great Plains are generally much flatter than basins of equal area either in the East, or in the Western mountain regions.

The author compares the Myers flood formula with the Kutter-Chezy formula for flow in channels and pipes. In the Kutter-Chezy formula two important variables, R and S, are directly included and only the effect of roughness is covered by the judgment coefficient, n. In the Myers formula only one of the two main variables is directly provided for, namely, area. Rainfall and all the factors which affect the rate of run-off from a given area are thrown into a judgment coefficient.

The writer believes it is better in general to reduce the factors depending on judgment to a minimum. That this can be done in some degree, at least, in flood discharge calculation, is evidenced by the general success attending the application of the so-called "rational method" to storm-sewer design. At present, the laws connecting surface slope, permeability of soil, and other factors with flood run-off rates are only imperfectly known. Methods by which data may be obtained for the correlation of some of these factors with flood discharge have been developed by the writer and are presented herewith, some of them for the first time.

In addition to area, the principal physiographic factors which are correlated with the flood discharge of a drainage basin are:

(1) Length of basin, measured along the main stream channel.
(2) Drainage density or length of streams per square mile of area.
(3) Average slope of the stream channels.
(4) Average slope of the ground surface.
(5) Slope ratio or ratio of stream channel slope to land surface slope.
(6) Average length of overland flow.

Quantitative values of these factors can be determined without great difficulty if suitable topographic maps are available.

Let,

A = area, in square miles.
Σl = total length of streams in the drainage basin, in miles.
h = contour interval used, in feet, measured vertically.
Σc = total length of contours of vertical interval, h, on a given area.
S_c = average slope of stream channel.
S_g = average slope of land surface.
d = drainage density $= \frac{\Sigma l}{A}$.
$\frac{S_c}{S_g}$ = slope ratio.
w = average distance between contributory streams.
z = average horizontal angle between the direction of stream flow and the direction of overland flow.
l_g = average length of overland flow.

The obvious method of determining drainage density is to measure with an opisometer the total length of the streams shown on a topographic map and divide this result by the area. For large areas this is laborious, and a sufficiently accurate value can generally be obtained by the "sample area method", which consists in determining the drainage density on a few selected representative rectangular areas and taking the average.

The slope of streams can be determined by noting the elevation of the source and mouth of each contributory and measuring its length. If ΣE_1 is the sum of the elevation of stream sources and ΣE_2 is the sum of the elevation of their mouths, then the mean slope of the streams, in feet per mile, is:

$$S_c = \frac{\Sigma E_1 - \Sigma E_2}{\Sigma l}$$

This determination can also be made by counting the number of contours intersecting all streams. Calling this number Σc:

$$S_c = \frac{h \Sigma c}{\Sigma l}.$$

The latter method has an advantage in that the small streams, which largely determine the average slope, are not so likely to be omitted. This determination should generally be made for the whole basin, although the "sample area method" can be applied after selecting representative sub-basins for measurement.

If the total length, Σc, of the contours of the vertical interval, h, in feet, crossing the basin is measured by an opisometer, then $\frac{A}{\Sigma c}$ is the average distance between contours measured horizontally, and the average slope of the land surface is:

$$S_g = \frac{h \Sigma c}{A}.$$

To determine by opisometer the length of contours on a large area, even at 100-ft. intervals, is very laborious. Although the "sample area method"

may be applied, it is better to use what may be called the "intersection method", which gives a fair determination of the slope for all parts of the area with moderate labor. To apply the "intersection method" the portions of topographic maps covering the area are divided by pencil base lines into, say, 4-in. squares. Choosing a suitable contour interval, the number of times, N, that the base lines are crossed by contours is counted and the total length, L, of base lines within the area is determined. If the contours crossed the base lines at right angles, the average slope would be $\frac{h\,N}{L}$. The contours, however, cross at varying angles from zero to 90 degrees. If x is the distance between the points where two adjacent contours cross a base line, and a is the angle between a normal to the contours and the base line, then the distance between contours, measured normally or at right angles to the contours, is $x \cos a$. Hence, the average normal distance between the contours is:

$$m = \frac{N \cos a}{L}.$$

The average slope of the ground surface is:

$$S_g = \frac{h}{m} = \frac{h\,L}{N \cos a} = \frac{h\,L}{N} \sec a$$

The average secant of angles from zero to 90° is 1.57; hence:

$$S_g = 1.57\,\frac{h\,L}{N}$$

The slope ratio, $\frac{S_c}{S_g}$, may now be determined. This is never greater than unity. In other words, the slope of the ground surface of a drainage basin is always greater than that of the streams. The average length of overland flow or the distance which the water must travel on the ground surface before reaching a definite stream channel is an important factor in relation to flood discharge, especially for flat, poorly drained areas. The larger the distance the greater is the time of rainfall concentration at any given point on the stream. If α_g and α_c are the slope angles for the ground surface and stream channels, respectively, then:

$$\tan \alpha_c = \frac{S_c}{5\ 280}$$

$$\tan \alpha_g = \frac{S_g}{5\ 280}$$

Given these values, the average direction of overland flow or the average angle, z, between the direction of overland flow and the channel direction, can be determined by the formula, readily derived by geometrical construction:

$$\cos z = \frac{\tan \alpha_c}{\tan \alpha_g} = \frac{S_c}{S_g}$$

In other words, the slope ratio is the same as the cosine of the angle between the direction of overland flow and the stream direction.

The reciprocal of the drainage density, or $\frac{l}{d}$, is the average distance between streams. As there is a divide between every two adjacent streams the average distance from the divide to a stream is one-half this, or:

$$\frac{w}{2} = \frac{l}{2\,d}$$

The average distance which water must travel overland from a point on any divide between streams or the average length of overland flow can be derived from the relation:

$$\frac{w}{2\,l_g} = \sin z$$

from which,

$$l_g = \frac{w}{2 \sin z}$$

The writer has applied these and certain additional methods to various drainage basins for the purpose of providing data for the study of the relation of run-off to slope and other physiographic factors. It has been deemed worth while to present the methods in some detail here in order to lay a foundation for attacking the problem of the laws of flood discharge for different areas on a quantitative basis.

When a sufficient body of flood discharge data has been accumulated, accompanied by physiographic and soil or infiltration data, a beginning can be made toward the derivation either of a "rational" flood discharge formula, or perhaps better, the use of the existing rational method can be extended to large natural areas. To accumulate such a mass of data may require a long time, but the Engineering Profession worked for fifty years with the Kutter and similar formulas before reaching the point where the data for their application could be considered reasonably complete.

Flood discharge data unaccompanied by adequate data for the correlation of physiographic and other factors with the discharge coefficients are little more useful than a heterogeneous table of values of Kutter's n unaccompanied by data on the kind and character of surface for which the given values of n were determined.

Viewing the subject of maximum flood discharges from another angle, the writer believes that there is for each drainage basin a certain finite rate of flood discharge which Nature is incapable of transcending, that is, the true maximum discharge. Reasons for this belief are founded on: (1) Experience; and (2) meteorological considerations. The Hudson River cannot produce a Mississippi River flood for very much the same reasons that an ordinary barnyard fowl cannot lay an egg a yard in diameter—the hen is not large enough.

Rain can only be produced as fast as moist ascending air currents can be brought over the area on which the rain falls. The larger the area covered by a storm the smaller in general are the barometric gradients around the storm center. With less wind velocity and less rate of ascent of moist air the

average rainfall rates over large areas must necessarily be less than may prevail over small areas.

On the other hand, in purely convective storms where the air ascends vertically, the moisture supply must in general be local. There is thus a natural inhibition of rain intensities exceeding certain limits, the limit depending on the size of the area. In view of these considerations a flood discharge formula such, for example, as the Fuller formula which implies that a flood of infinite magnitude may occur on any area, however small, if one only waits long enough, is, to say the least, irrational in form.

The question naturally arises: Is it possible to determine, even with approximate certainty, the true maximum or limiting flood discharge for any area? The writer believes it is possible provided a good record of flood discharges is available.

Flood discharge data when plotted in terms of frequency take the form of a skew frequency curve to which the ordinary or Gaussian law of error does not apply. Skew frequency curves, however, can be represented accurately by other forms of expression. For floods the frequency equation should be of such form that the flood magnitude approaches a finite limit as the "exceedance" interval approaches infinity.

The following expression was developed by the writer to meet this requirement and has been applied to a variety of phenomena dependent on rainfall, including floods:

$$R = R_g \left[1 - e^{-kt^n}\right]$$

in which,

R = ratio of the magnitude of the event to its average magnitude.
t = average "exceedance" interval of an event of magnitude, R.
e = base of Naperian logarithms.
R_g = true maximum or limiting value of the magnitude of the flood or other phenomenon.
k, n = constants.

Values of k, n, and R_g can all be determined from the lower definitely located portion of the "exceedance" interval curve.

Data of flood records for 70 years for the Connecticut River at Hartford, Conn. (1843-1917), give the equation:

$$R = 1.82 \left[1 - e^{-0.255\, t^{0.54}}\right]$$

The highest recorded value of R is 1.70, but there have been nine floods with R exceeding 1.40. In other words, floods having magnitudes of more than 75% of the limiting flood magnitude occur at fairly short intervals, in this case about once in eight years.*

MERRILL M. BERNARD,† ASSOC. M. AM. SOC. C. E. (by letter).—A review of the many contributions to engineering literature on flood flow and related subjects, impresses one with the fact that eventually there will develop, out of

* Application of this form of frequency equation to the determination of maximum and minimum annual rainfall in New England will be found in the *Journal*, New England Water Works Assoc., Vol. 38, March, 1924.

† Civ. Engr., Crowley, La.

the maze of meager data and unsupported theory, a definite and clean-cut working knowledge of the relation between rainfall and the resulting run-off.

The engineer, having to do with drainage works, flood control, and the design of hydraulic structures and bridges, grasps eagerly at current articles pertaining to the subject, only to find, in many cases, that they fail to clear up many of the doubtful points.

The author has made available, in most satisfactory form, an exhaustive list of flood discharges, and has made some valuable suggestions. He presents a basic run-off formula, which should be followed up and utilized by those advocating this means of estimating flood flow.

In Table 8 are listed eighteen of the more important factors entering into an analysis of flood flow on any particular water-shed, many of them influencing run-off as much as the catchment area. Six of these eighteen factors

TABLE 8.

Constant factors.	Variable factors.
(1) Area of shed.	(1) Degree of efficiency desired.
(2) Shape of shed.	(2) Intensity of rainfall producing maximum flood to be considered.
(3) Arrangement of lateral drains.	(3) Frequency of rainfall producing maximum flood to be considered.
(4) Average slope of shed.	(4) Time of concentration.
(5) Average slope of drains.	(5) Effect of vegetable cover.
(6) Geographical location.	(6) Degree of improvement of lateral drains.
	(7) Losses : Evaporation, transpiration, and seepage.
	(8) Relation of storm center to water-shed.
	(9) Travel direction of storms.
	(10) Season in which storm occurs.
	(11) Relation of storm to storm period.
	(12) Available storage.

are constant and can be given definite values. The remaining twelve are variable, but in the study of a particular water-shed can be assigned maximum or average maximum values tending to give results that are on the side of safety.

The rational expression of the relation of rainfall to run-off, $q = C\,i$, in which, q is the run-off, in cubic feet per second, from a unit of catchment area, resulting from a rainfall of intensity, i, and C is a coefficient reflecting the physical characteristics of the water-shed, is becoming popular in the field of storm sewer design. It is based on a theory that maximum flow will result from a rain the duration of which is equal to the time of concentration.

The diagram, Fig. 17, illustrates the relation of the listed factors to the formula. In application, the value of C will range from 0.11 to 0.15, where the acre is the unit of area. The time of flow can be analyzed from head-water to outlet, which, in a co-ordinated system of drains, will take care of peculiarities in the shape of the area, the arrangement of lateral drains, etc. The writer recalls a water-shed made up in part of cut-over pine hills, having an average slope of about 12 ft. per mile, changing abruptly at the stream itself to a dense palmetto swamp, with a slope of about 0.4 ft. per mile. The outfall stream ran for 30 miles without adding 1% of area to the water-shed,

due to the fact that the adjacent lands sloped away from the stream. In this case, it would be manifestly impossible to arrive at an intelligent result by considering the flood discharge as a function of the area alone.

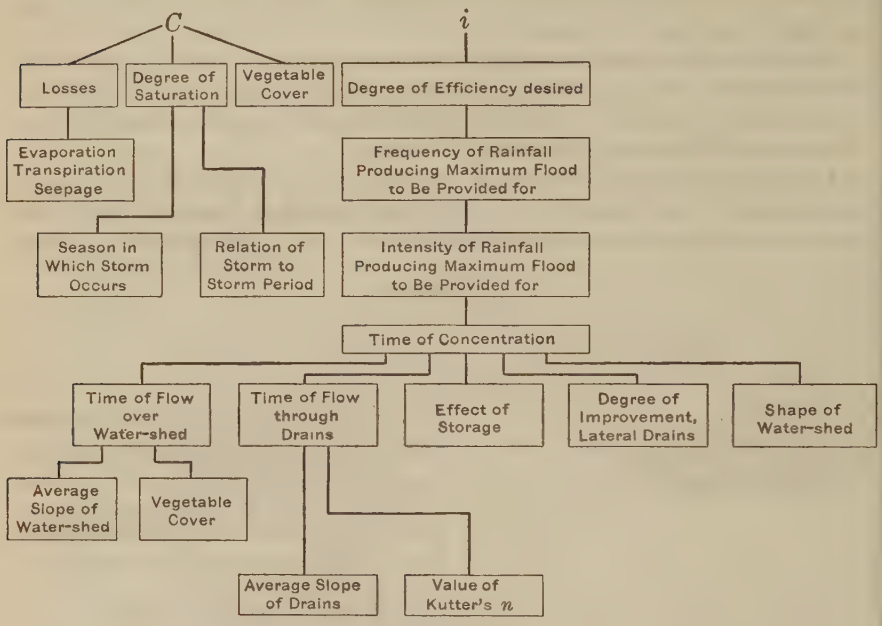

FIG. 17.—RELATION OF RUN-OFF FACTORS.

Assumptions must be made. If assumed values are applied to all factors, errors of judgment become compensative, and the designer has the satisfaction of knowing that he has dealt with all phases of his problem, even if he is in error as to some of them.

CONSTANT FACTORS

Area of Water-Shed.—The area can be actually measured or estimated.

Shape of Water-Shed.—The shape of the water-shed is reflected in the analysis of the time of flow. A long narrow water-shed will produce a shorter concentration time than a broad, fan-shaped one.

Arrangement of Lateral Drains.—The topography usually decides this arrangement, but should future improvement demand a re-arrangement of lateral drains the fact should be considered.

Average Slope of Water-Shed.—This factor is subject to measurement and is necessary in determining the time of flow over the ground surface. It also aids in selecting what must be considered as the most remote part of the water-shed.

Average Slope of Drains.—This factor, too, is measurable, and is necessary in arriving at the time in transit through the drains.

Geographical Location.—The geographical location will place the water-shed under consideration in the proper weather characteristic group, and will permit the selection of a satisfactory rainfall intensity curve.

Degree of Efficiency Desired.—An economic study of the problem will determine a value for this factor. The flood selected as the maximum to be provided for carries with it the selection of a rainfall intensity curve which will be reached or exceeded with a given estimated frequency.

Intensity of Rainfall Producing Maximum Flood to Be Provided For.—Having determined the time of concentration at any point under consideration, the intensity of rainfall producing the maximum flood can be taken directly from the rainfall intensity curve.

Frequency of Rainfall Producing Maximum Flood to Be Provided For.—Where no other data are available, such works as "Elements of Hydrology", by Meyer, will provide a source from which can be selected an intensity curve of known frequency for a given geographical location.

Time of Concentration.—Although considerable error may enter into the estimate of the time of flow over the surface, it can be rather closely estimated after the run-off has reached the lateral and main drains. Where a knowledge of the flood flow is necessary in sizing the drains themselves, the increased flow, due to the decreased time of concentration, becomes apparent.

Effect of Vegetable Cover.—An inspection and study of the water-shed will determine that part which will be improved and cleared as a result of drainage or flood protection and that part which will remain for an indefinite period as woodland. Lateral water-sheds subject to such change should be dealt with, keeping the improved condition in mind.

Degree of Improvement: Lateral Drains.—Where lateral drains are subject, within reasonable time, to extension or improvement, they should be so considered in estimating the time of flow through them.

Losses: Evaporation, Transpiration, and Seepage.—Evaporation, transpiration, and seepage are considered in giving a value to *C*, vegetable cover, type of soil, and ground slopes being the controlling factors.

Relation of Storm Center to Water-Shed.—The available rainfall record is the basis for the selection of the rainfall intensity curve. The record of a heavy downpour may or may not represent the maximum intensity of the storm, depending on the relative location of the gauging station to the storm center. The record, therefore, must be assumed to represent the average intensity to be expected. This factor, like rainfall intensity, is governed by the law of probability, and can be grouped with it.

Direction of Travel of Storm.—Where the design of structures such as dams, spillways, and bridges, is involved, the path of travel of the maximum storm should be assumed to take the direction of flow, unless long-time records disclose the fact that such a condition is not probable.

Season of Year in Which Storm Occurs.—In localities subject to freezing weather and snowfall, the combination of conditions resulting in maximum run-off should be considered.

Relation of Storm to Storm Period.—The maximum storm should be assumed to occur during or at the end of the storm period when saturation is complete.

Available Storage.—What may be a storage basin to-day may be reclaimed for other purposes on the completion of a contemplated improvement. No storage should be depended on, which will not be available for a reasonable period.

The writer feels justified, therefore, in attempting to analyze and give values to the many factors involved in the problem of run-off and flood flow. Surely the results will justify the added effort.

C. D. PURDON,* M. Am. Soc. C. E. (by letter).—Reference has been made by the author to a table of waterway areas devised by the late James Dun, M. Am. Soc. C. E., who was much interested in finding an approximate formula for the size of openings required for different drainage areas.

When Chief Engineer of the St. Louis and San Francisco Railway, he had brought this formula to the point of giving the drainage area that would be accommodated by a certain pipe, box culvert, etc. Generally, a rainfall of 2 in. per hour was assumed, but for small pipes, 4 in. was used; thus, an 18-in. pipe drained 3 acres, and a 24-in. pipe, 5.5 acres; a 3 by 4-ft. box culvert served 25 acres; and a 6-ft. arch with walls 4 ft. high, 100 acres. Open bridges or trestles were rated according to their span and depth of water—as a 12-ft. span and water 2 ft. deep for 65 acres, and 30 ft. span and 4 ft. of water for 700 acres.

Later, when Mr. Dun became Chief Engineer of the Atchison, Topeka and Santa Fé Railway, the work was continued, he being assisted by the writer. The table was intended to apply to the country adjacent to the Santa Fé, and at that time the Santa Fé Pacific (Lines West of the Rio Grande) was not included. Adjoining railways were asked for data on such openings as had proved to be about the right size, during a long term of years. Where data were not given, an assistant was sent to measure the opening and its drainage area and give a general description.

Those data were plotted on cross-section paper and a curve to envelop them was applied. This curve for areas of more than 16 sq. miles was then reduced to the formula:

$$W = \sqrt{A}\,(240 - 12\,\sqrt[6]{A})$$

in which, W is the area of the waterway, in square feet, and A the drainage area, in square miles. For small areas an arbitrary addition was made to allow for drift, etc.

Various adjustments were made from time to time, Missouri and Kansas being taken as a base. Illinois, Indian Territory (now Oklahoma), Texas, and New Mexico required a certain percentage to be applied. This was not intended as an absolute rule, but to be used with judgment, for instance, an absorbent soil would require a smaller opening than a rocky soil.†

* Cons. Engr., St. L. S. W. Ry., St. Louis, Mo.

† A lengthy discussion on waterways was held by the Western Society of Engineers, in which the Dun table appears. This will be found in its *Journal*, Vol. XI, No. 2, April, 1906. There also was a discussion in *The Area*, Vol. 12, Pt. 3, p. 481, and in the same volume a compilation of formulas (p. 490) and on p. 505 an application of the Dun formulas, converted into run-off by multiplying the waterway by 10 (his formulas assuming a speed of 10 ft. per sec. in a culvert or bridge), to all the streams in the United States of which run-off data were obtainable.

C. S. Jarvis,* M. Am. Soc. C. E. (by letter).—The generous response in discussions from members of the profession reflects the widespread interest in floods and their control. As aptly stated in a recent editorial:†

"In many respects the serious study of the subject may be taken as dating from the memorable Central States floods of March-April, 1913. Long before that time many individual flood problems had been investigated, and in addition engineers specially concerned with stream problems had recognized and given attention to the more general questions of floods. Nevertheless, the common tendency was to look upon floods of disastrous size as catastrophic happenings, like earthquakes or lightning strokes, and the attitude of engineers was greatly influenced thereby. Each community not yet visited by a large flood was inclined to believe itself immune. Only after 1913 did it come to be generally understood that flood danger exists along every water-course and that there is enough system in the attendant circumstances to warrant abandoning the fatalistic attitude of waiting for a flood to come, and substituting therefor scientific study."

Such a view is quite opposed to the theory that "every river is a law unto itself, and unrelated to other streams even within the same area."

Just as C. E. Grunsky, Past-President, Am. Soc. C. E., has defined‡ a simple relation between inches of rainfall and the percentage that will appear as run-off, it seems reasonable similarly to seek the relation between drainage areas and their discharges under assumed or known rainfall intensities and surface conditions within the water-sheds. Variable coefficients have long been used to account for those functions, as illustrated by Talbot's formula; and in Kuichling's and Fuller's formulas the time element is included.

Run-Off Expressed as Percentage on the Myers Scale.—From the fundamental equation of the paper:

$$Q = a\,V = 10\ 000\ \sqrt{M}$$

or,

$$q\,M = 10\ 000\ p\ \sqrt{M}$$

Dividing by 100 $\sqrt{M}$ there results,

$$100\ p = \frac{q}{100}\ \sqrt{M}$$

which gives the numerical value of the percentage; that is, the product of the run-off, in second feet per square mile, times the square root of the drainage area, in square miles, divided by 100, is the desired number. A single setting of the slide-rule affords a solution.

The ease with which such ratings may be ascertained is one point in their favor. For example, the Miami River, at Miami, Ohio, during the flood of March, 1913, had $q = 98$, and $M = 3\,957$. Then,

$$100\ p = \frac{q}{100}\ \sqrt{3\ 957} = 61.7\%$$

as the rating for the discharge of that stream in terms of the modified Myers formula (the "fundamental equation" just noted).

---

* Care, U. S. Bureau of Public Roads, Washington, D. C.

† *Engineering News-Record*, June 4, 1925, p. 919.

‡ *Transactions*, Am. Soc. C. E., Vol. LXI (1908), p. 514, and Vol. LXXIX (1915), p. 1165.

At one stage of the writer's investigations the desired equation appeared to have the form, $x\ y = C\ k$, in which, C is a variable coefficient and k is a constant; but this equation was found to have only limited or local application. In small drainage areas of the Western States, affected by intense rainfall, it seems to have been demonstrated that up to certain limits the maximum flood is a constant irrespective of area. This may be explained by considering the usual storm, with its vortex traversing a path only a few miles in width at most. If from 30 sq. miles the run-off amounts to a depth of nearly 1 in. per hour, the maximum flood wave will register 18 000 sec-ft. Investigators in Wyoming have concluded that such a maximum seems to prevail for areas from 1 000 to 4 000 sq. miles. Reduced to the Myers scale these floods would rate 5.7% and 2.8% at the lower and upper limits, respectively. These values occur quite frequently throughout the Rocky Mountain District for both large and small areas.

The same tendency toward a constant maximum for varying areas may be observed by reference to Items Nos. 41 and 58 in Table 2. The flood in question resulted from a precipitation estimated at 2 in. in 3 hours, over an area of 15 sq. miles which included only minor parts of the Honey Creek watershed, yet yielded a run-off at a greater rate than that which obtained during March, 1913. The maximum intensity when reduced to the Myers scale is seen to be 57.2%, as compared with 61.7% at Miami during 1913. If properly interpreted, the observations during 1918 might be an index of possible floods in this region. The extensive investigations carried on by the Miami Conservancy District resulted in a design based on a run-off 40% greater than that recorded for 1913. This would rate at various critical points in the valley from 50 to 86% on the Myers scale.

As a practical application, the same intensity should be expected for the White River floods at Indianapolis, Ind., with such modifications as the dissimilar topographic, surface texture, and climatological factors may warrant. After diligent research the designers of the protective works at Indianapolis adopted as a basis a flood stage about 4 in. higher than that of 1913. The Pueblo, Colo., flood of June, 1921, rated 15.2% for the total drainage area, or 28.5% for the part affected by the intense storm; the basis of design for the new channel is 60% in excess of these values, even though they might be regarded as indicating a 100-year, or even a 1 000-year, flood on well-known formulas.

Design of Drainage Structures for Highways.—Due to the ability of highway structures to withstand occasional overflows for brief periods without serious damage, more latitude is usually accorded in designing them than in railroad or municipal practice; thus, the 10-year maximum is often prescribed as the basis of reckoning in highway work. The trend seems to be toward using the rare flood as the datum, not necessarily in providing full capacity under the main structure, but rather using by-pass spillways corresponding with flood channels. This method precludes the possibility of a high embankment failing suddenly and without warning, as at Monterey, Mexico (see Item No. 493, Table 2). In that instance, it was reported that the loss of

human life exceeded 5 000, or double the casualties in the Johnstown flood. The sudden failure of the high embankment forming the bridge approach and impounding dam literally engulfed the peon districts of the city. Rare flood heights should be traced out so that they would be known well in advance and warnings issued accordingly.

The present situation in practice is well illustrated by the highway bridge specifications of the State of Ohio, approved June 10, 1925, in which Talbot's formula is used for small areas, and Fanning's and Kuichling's for larger drainage basins. These formulas are shown in Fig. 18 by the broken curves. The modified Myers curves of 5, 10, and 50% are also platted, together with the observed maximum flood data from Table 2 and Item No. 107 for Ohio; also representative maxima from California, Colorado, New York, and North Carolina. This demonstrates that the modified Myers formula may be substituted for a group of unrelated formulas, or may serve as a common denominator and a scale of comparison for them. Also, it applies equally well to any district if the coefficient is properly chosen.

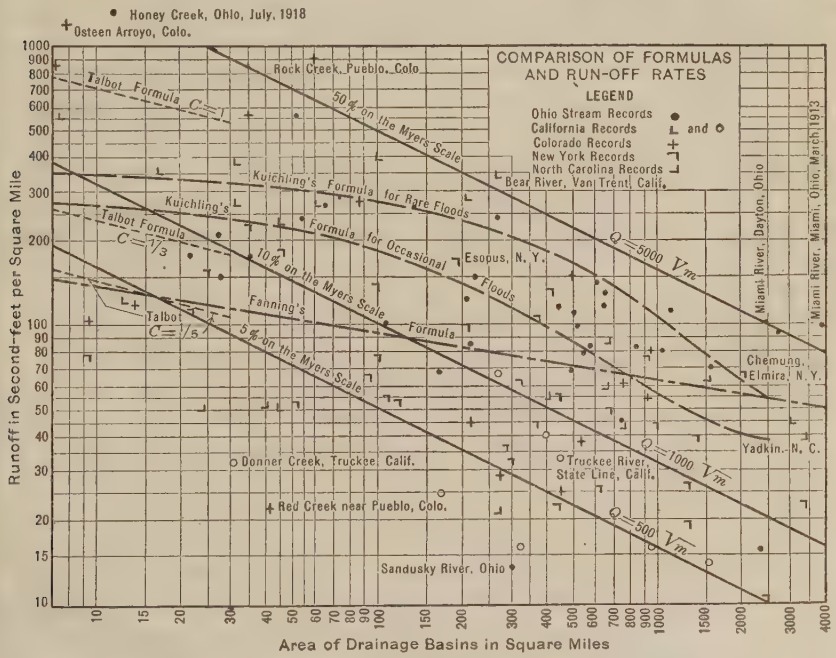

FIG. 18.—RELATION BETWEEN RUN-OFF RECORDS AND VARIOUS FORMULAS.

The North Carolina State Highway Department has used the same method for Talbot's formula,* with C ranging from 0.2 on the coastal plains to 1.0 in the mountains. Reduced to the Myers scale, these ratings would be from 10% to 35%, as shown on Fig. 19.

Need for a General Formula.—The need for a general formula was evidently recognized by the American Railway Engineering Association, for its

* *American Highways*, July, 1925, p. 8.

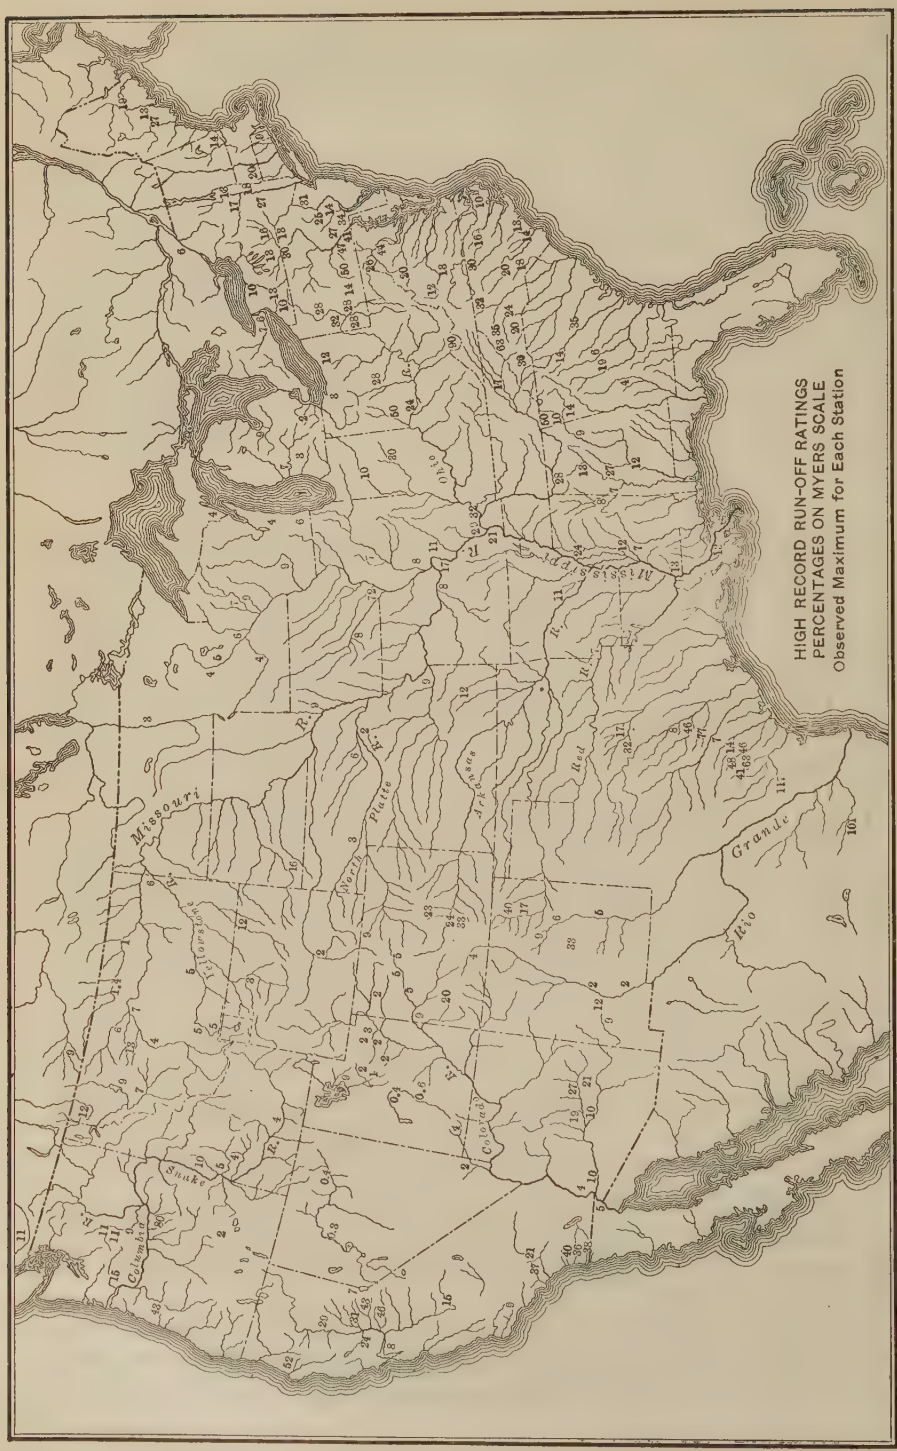

FIG. 19.—MAXIMUM OBSERVED RUN-OFFS (Q), IN TERMS OF PERCENTAGES OF MYERS' FORMULA ($10\,000\sqrt{M}$).

Special Committee seeking such an expression made progress reports in both 1909 and 1911.* Its final conclusion was that no existing formula could be recommended for general application, but that Dun's tables best represented the relation between drainage area and run-off. It is significant that the average values of these tables rate 20% on the Myers scale. Specifically, they are 12% at 1 sq. mile, 21% at 7 sq. miles, and 19% at the upper limit, 6 500 sq. miles.

Applying a General Formula.—As Chief Engineer of the Santa Fé Railroad System, the late James Dun, M. Am. Soc. C. E., found it necessary to increase or reduce his tabular values before applying them to certain districts through which he operated, so that they rate for practical purposes from 5 to 50% on the Myers scale.

Other curves in Fig. 6 which show close parallelism in their upper ranges are those of Kuichling and Murphy, while that of Metcalf and Eddy will rate 10% at 10 sq. miles and 13% at 1 000 sq. miles, and gradually increase to 14% at 10 000 sq. miles. In effect, therefore, all these formulas involve the square root of the drainage area as an important factor, although this function may not be explicitly stated. Those with greater or less slope may be excellent for a limited range, but have to be discarded when they digress from the trend of the populated area as shown on Plate IX, and others must be utilized to cover the remaining territory, as shown in Fig. 18.

Simple tests are afforded by the river diagrams in Figs. 20 and 21. If the slope of the Myers curve is correct, it should parallel the graphs of typical streams. Then the determination of the rating at any section would provide an index for all other points along its course. Thus, the Monongahela and the Ohio are fairly consistent in ratings from 25 to 35%, likewise the Sacramento and Columbia (Fig. 21). The abrupt changes of slope for the Sweetwater and the Pequannock (Fig. 20) herald the influence of the humid coastal regions in the one case, and of channel storage and flood-plains in the other. The Willamette River increases very definitely as it invades the moist valley near Portland, Ore., and the Truckee has paid toll to the desert (Fig. 21).

Discussions.—Mr. Hartwell deplores the apparent neglect of the time element. This factor is involved with others, additive or subtractive, in the value of the coefficient to be adopted in any given instance.

Mr. La Rue rendered valuable service both before and after the paper was written, drawing from his wide experience, subjecting the formula to practical tests, and lending untold encouragement to continue the tedious quest. He points out that the maximum flood of the Colorado River at the Laguna Dam is only 80% of that registered at Lees Ferry from only 58% of the drainage area. This is only natural, for the greater channel storage and percolation losses, together with the reduced slopes and desert conditions below the Grand Canyon, would smooth out the flood peak. These factors warrant the change in the coefficient, C, from 760 to 460, or the rating on the Myers scale, from 7.6 to 4.6 per cent.

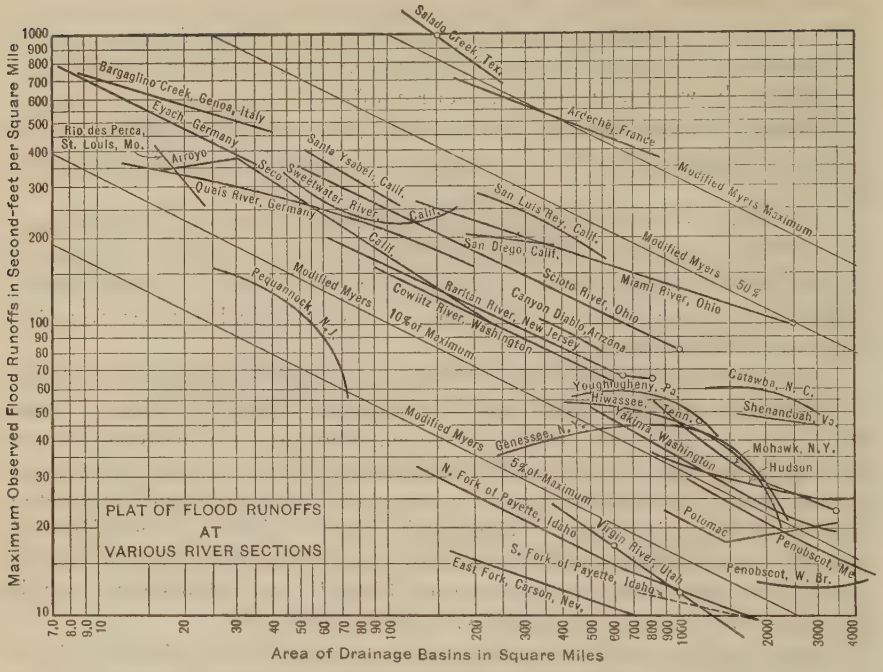

FIG. 20.—COMPARISON OF RIVER DISCHARGES.

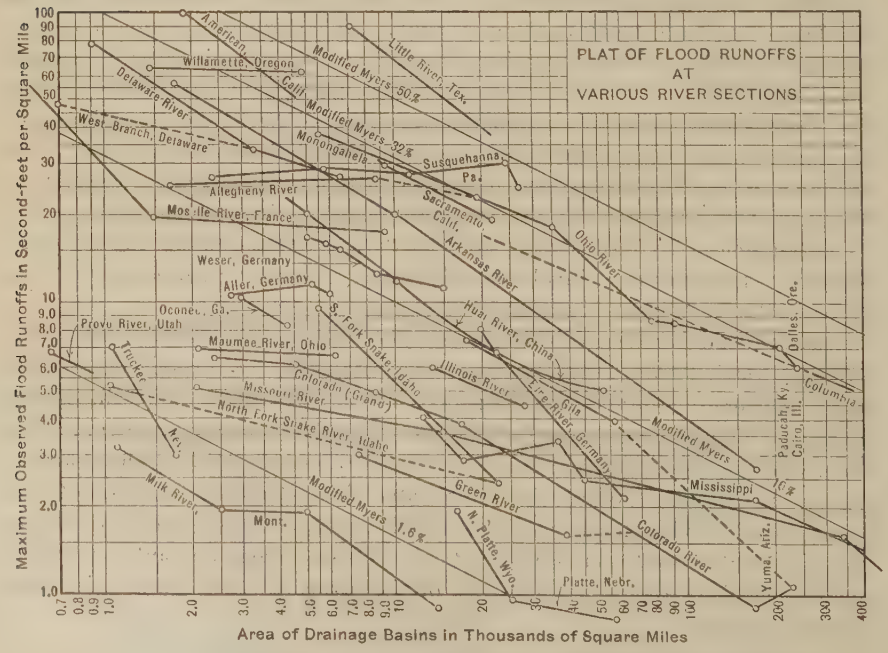

FIG. 21.—COMPARISON OF RIVER DISCHARGES.

Mr. Grover has pointed out the limitations that must be observed in the use of any general or special formula dealing with natural phenomena. In the course of his official duties he secured through the District offices a careful checking of all the flood data in the paper derived from the U. S. Geological Survey, and completed all records to date as incorporated in Table 2. Under his guidance the Society's Special Committee on Flood-Protection Data should evolve some systematized data from the chaotic mass that now exists. The writer's efforts have been co-ordinated wherever practicable with the plans of this Committee; he realizes that the task of digesting the available records must be accomplished, if at all, by some such agency.

Mr. Okazaki calls attention to the inevitable results of diking and channel rectification without due regard to by-pass functions and lateral storage. There are meadows and other lands that would derive positive benefit from inundation by a turbid crest, yet they are enclosed by great levees which insure the maximum severity of flood stage for the lower valleys.

Mr. Sherman gives valuable suggestions regarding the elements of flood frequency and rainfall intensity. The highway bridge specifications of the State of Ohio, approved June 10, 1925, have included such basic data as the following:

"Thirty-three weather bureau stations in Ohio selected at random, covering a period of observation averaging 24 years, show that a rainfall exceeding 2½ in. in 24 hours and 3 in. in 48 hours occurs more frequently than once in 5 years, also, that a 3½-in. rainfall in 24 hours and a 4-in. rainfall in 48 hours occurs more frequently than once in 20 years.

"Also six stations at which hourly rainfalls have been observed for an average period of 40 years show that a 1-in. rainfall occurs more frequently than once every 2 years, and a 2-in. rainfall (per hour) more frequently than once each 16 years."

The importance of such data as a basis for analysis and scientific design is being recognized as never before.

Mr. Winsor has doubts as to the applicability of any formula to the mud slides and rolling débris which occasionally precede a flashy flood. His careful study of this subject and his direct observations during the storm of August, 1923, along the Wasatch Range, Utah, lend additional weight to his opinions, yet, somehow, a bridge engineer must design a structure that may span such a grinding torrent. The photographs of flood effects from that storm (Figs. 3, 4, and 5), were kindly contributed by Mr. Winsor for publication with the paper.

As illustrating how a formula may apply to certain phases of desert runoff as well as to the wooded areas, consider the floods in the Rio Grande at El Paso, Tex., during the early part of August, 1925. On July 30 and 31, the U. S. Weather Bureau observed the basic data on which Fig. 22 is based. Precipitation as great as 6.3 in. occurred over a great area, centering at Hermosa, N. Mex., 30 miles west of the Elephant Butte Dam, and averaging a depth of 3 in. over 1 000 sq. miles, or more. Part of the drainage was toward desert sinks, and nearly one-half of that in the Rio Grande Valley discharged above the dam; yet about 10 800 acres were flooded when the smoothed-out

crest reached El Paso, with an estimated damage of $100 000, despite all efforts at control.

Table 9 is based on data* supplied by L. M. Lawson, M. Am. Soc. C. E., Project Superintendent, U. S. Reclamation Service, El Paso, and shows not only the desilting and flood protection produced by ample storage, but also the sixfold increase of minimum dependable yearly flow. The last three columns have been added by the writer.

The dangers outlined in the paper under the sub-title, "The Wooded Channel" (page 999), were exemplified in the havoc wrought near El Paso from a flood crest of 8 400 sec-ft., or nearly one-half the previous record.

Is it merely a coincidence that the maximum ratings on the Myers scale for San Marcial and El Paso are so nearly comparable, when the active drainage areas are considered? If this method of comparison means anything, the plane of a 20 000-sec-ft. stage should be traced out below El Paso, so that the limits of the danger zone may be known well in advance in case the recent storm intensity should be repeated, with the center at Hillsboro, N. Mex., instead of Hermosa, or else a storage reservoir should be established for the joint purpose of flood control and power development below Elephant Butte.

On July 24, 1924, the intensity of a local storm near Hondo, N. Mex., about 100 miles east of Elephant Butte, equalled or exceeded the one recorded in Fig. 22. The writer had occasion to observe the effect on a newly constructed Federal Aid road project, and reported in part as follows:

"The drainage structures on 70% of the 16-mile length were overtaxed by 10%, and on the remaining mileage they were not required to perform full duty. As the crest which caused overtopping of the road grade evidently lasted only a few moments, the damage was insignificant."

The culverts were proportioned by tables comparable with Talbot's $C = 0.2$, or from 2 to 6% on the Myers scale for the areas considered, with due regard to special local conditions. Spillways or dips in the grade proved very effective in safeguarding the major structures. At one of these locations traffic was halted for a few hours; but even desert habits of run-off have proved amenable to rational design.

Mr. Hinckley and the writer have evidently traversed parallel paths of investigation and their conclusions are in close agreement. The fundamental equation of the paper may be written as:

$$Q = \frac{10\,000\,M}{\sqrt{M}}$$

This shows that the run-off from each square mile which rates 100% on the Myers scale is 10 000 cu. ft. per sec. for 1 sq. mile; 3 162 cu. ft. per sec. for 10 sq. miles; 1 000 cu. ft. per sec. for 100 sq. miles; and 316.2 cu. ft. per sec. for 1 000 sq. miles of drainage area. Where $M < 1$, the modified Myers formula becomes $Q = 10\,000\,M$ for the upper limit, or 100%; and for any rating, $Q = 10\,000\,p\,M$, as illustrated by the first five items in Table 2.

The Musi River, India, is reported to have discharged at the rate of 493 sec-ft. from each of the 862 sq. miles above Hyderabad.† The corresponding

TABLE 9.—DISCHARGES AND SEDIMENT CONTENT OF RIO GRANDE AT SAN MARCIAL, N. MEX. (ABOVE RESERVOIR) AND AT EL PASO, TEX.

(Storage in Elephant Butte Reservoir began in 1915.)

Place and period.	Annual Run-Off, in Acre-Feet.			Maximum discharge, in second-feet.	Mean annual silt content, in acre-feet.	Run-off, in second feet per square mile (*q*).	Drainage area, in square miles (*M*).	Maximum rating on the Myers scale percentage.
	Maximum.	Minimum.	Mean annual.					
San Marcial, 1895-1924.....	2 422 008	201 000	1 225 727	33 000 (Oct. 11, 1904)	19 000	1.10	30 000	1.90
El Paso, 1889-1914.	2 010 000	50 700	925 400	17 000 (Oct. 15, 1904)	15 300 (1906–09)	0.45	38 000	0.89
El Paso, 1916-1925.	870 418	348 951	685 232	8 400 (Aug. 2, 1925)	480	1.05	8 000 (Below reservoir)	0.94

position on the Myers scale is 144 per cent. The four items thus far discovered that exceed the 100% limit adopted for convenience of reckoning ought not to detract from its applicability.

The discharge of 10 000 sec-ft. from 1 sq. mile is equivalent to 1 in. of rainfall run-off every 4 min., and requires special extreme conditions or coincidences, such as a deluge on melting snow, or exact synchronism of violent flood waves.

By far the majority of ratings fall below 50%; the 10% line is the axis of gravity, apparently, on Plate IX; and many streams stay consistently below 5% throughout their courses, as illustrated on Figs. 20 and 21.

Table 5 illustrates the fallacy resulting from the application of a "rule-of-thumb" method outside its proper bounds. It seems absurd to multiply the outstanding maximum flood rates by any factor such as 3.4 as there used, simply because the period of observation was unknown or indefinite in each case. The fact that each of the items listed in Table 5 has a rating so nearly approaching 100% on the Myers scale, and far exceeds any other observation in the same district, should indicate that these are maximum floods of a century or more. The recommendation in Mr. Fuller's paper evidently sought to achieve such a maximum rating by multiplying the frequent flood by a suitable factor, and did not contemplate increasing such run-offs as those listed in Table 5.

Mr. Lane has furnished an instructive elementary analysis of many factors which the writer recognized and enumerated, but could not develop without obscuring the central idea. The results derived from due consideration of the time, climatic, and physical elements will surely be expressed numerically; and if so, they will take a definite rating on the Myers scale. As an example, the rare floods at Pueblo, Colo., may rate 15% or even 25%, according to recent design data for protective works built under Mr. Lane's direction; but the frequent floods will probably rate less than 5 per cent. Between these values lies a wide range for refinements such as analytic or rational methods will produce. The Myers scale affords a direct method of first and, perhaps, second approximations, but does not take the place of the later extended research and the exercise of mature judgment. It is essentially a common denominator for diverse expressions.

Mr. Matthes has made an attractive presentation of governing principles for this subject and has furnished one of the best practical tests that could be devised for the Myers scale. The Susquehanna, Ohio, and Tennessee Rivers are shown in Table 7 to have ratings of 45.2, 32.1, and 27%, respectively, for comparable drainage areas with a century of record or observation on which to depend. It would be interesting to extend the comparison to some of the typical tributaries of these and other rivers.

As regards Mr. Matthes' suggestion for providing run-off coefficients, Fig. 19 and Column (9) of Table 2 express percentage ratings on the Myers scale. If these are multiplied by the factor, 10 000, in the fundamental equation (see page 994) there results a set of coefficients in workable form for practical use, if, indeed, the percentage ratings have not already filled this need pointed out by Mr. Matthes.

Whether statistical data are portrayed by graphs, numbers, or diagrams, the final step in comparing the similar or contrasting the divergent results will generally involve the reduction to a percentage basis. Whether the St. Lawrence River at Ogdensburg is rated at 5.8%, or has a coefficient of 580 in the modified Myers formula, in which the factor, 10 000, represents 100%, the modes of approach are identical.

Mention of the St. Lawrence flood rating of 5.8% as compared with the Mississippi's 21.2% at Cairo should call forth as definite a mental picture as could be conveyed by the charted lines of proportionate lengths on a diagram of flood intensities. Moreover, this ratio holds among their average or typical tributaries, irrespective of the area drained. Any great divergence from these ratings may be ascribed to variations in the precipitation, concentration, or detention factors peculiar to the given water-sheds, some of which are readily ascertained in advance of the actual test.

The flood problem resolves itself into a scientific and practical study of relative capabilities for discharging or detaining surface water, and also for estimating the precipitation that may occur.

The scope of the work and the arrangement of the data outlined by Mr. Matthes, as Secretary of the Society's Special Committee on Flood-Protection Data, lend assurance that its efforts are well directed. Although this promises to be one of the most fruitful fields for engineering endeavor the activities have been halted by lack of funds. From the standpoint of insurance the expenditure of one-millionth of the values at stake would be repaid many-fold during the next year of violent storms.

Mr. Kurtz has displayed the same conception of the best form for presenting the data as first appealed to the writer. This had to be deferred because of time limitations, and because the Society and the Government possess the proper agencies to evolve the elaborate analyses and comparisons. From a tangled mass of unrelated data the transformation must proceed step by step. The imperfect, incomplete, somewhat fragmentary assemblage which Table 2 represents may be most useful in showing that most of the work still remains to be done. The methods of interpolation and exterpolation used by Mr. Kurtz have proved basically sound in many cases observed by the writer.

Mr. Comstock opposes the practice, almost universally adopted, of relating the rate of run-off to the area of the drainage basin. Some standard or well-known formulas use few, and some involve many, factors of influence; but where is there an expression that omits consideration of the drainage area? This factor may be measured, and it remains nearly constant; but most of the others depend on probabilities and estimates at best.

Mr. Merriman develops the idea that Table 2 is not so much a record of floods as of maximum observed discharge. This thought was clearly impressed on the writer during the tedious process of tabulation, for many streams would rate on existing records far below the probable high flood intensity, and portrayal on the Myers scale gave a basis of comparison not otherwise furnished. The river diagrams shown in Figs. 20 and 21 result from merely connecting the points representing run-off intensities on the Myers scale for various sec-

tions. The Mohawk River is there shown to yield only about one-third of the Miami discharge from an equal area.

The Pueblo flood of 1921 taught engineers more about Arkansas River run-off capacities than did the data from previous decades, and multiplied the run-off given by previous records by the factor, 9. Likewise, the maximum observed on the Santa Ana River, in California (Item No. 301, Table 2) has increased more than fivefold during the past ten years and the San Gabriel (Item No. 331, Table 2) has quadrupled its rating. Others have doubled since the paper was first written. On the other hand, the great mass of records, probably 90%, has undergone only minor changes, if any, in twenty years.

If Esopus Creek might be used as an index to the Catskill water-shed the record run-off of September, 1924, ought not to be regarded as a radical upsetting of data. It rated only 23.9% on the Myers scale (Item No. 305, Table 2), as compared with 27.0% for the same stream at Saugerties, N. Y. (Item No. 437, Table 2). The Chemung, at Elmira, N. Y., reached 30.4% in 1889 (Item No. 700, Table 2), and the Mohawk rated 16.8% at Cohoes, N. Y., while the Hudson was 17.9% at Mechanicsville, N. Y., during 1913.

The Schoharie adjoining the Esopus water-shed reached only 18.9% at Prattsville, N. Y.; but with a similar storm centering differently there seems to be no insurance against its rating 25% or more. The same might apply to the Catskill Creek Basin or the Rondout as described and illustrated in the discussion by Mr. Honness.

After scanning the percentages recorded on the map in Fig. 19, the basic data in Table 2, and the information on Fig. 18, a generalization might be ventured regarding the St. Lawrence drainage from Wisconsin to New York: It seems to range below 15% on the Myers scale, averaging nearly 6%, the same as the Niagara River. This may be accepted as a first approximation, and further research may show that capacities of one-half or even one-tenth would suffice on several streams in this area. Furthermore, it may be deduced by the same process that the Mississippi drainage in the same States would rate double or, in some cases, five times those determined for the St. Lawrence water-shed. The disparity is evidently not in rainfall but is due in part to the presence of lakes among glacial débris in the one area, and the increased slopes in the other.

The writer must differ with Mr. Merriman's views regarding the reliability of flood flow data prior to 1900, believing that there is much to be gained from even the crude approximations which necessarily served on the frontier. No doubt, present methods will be regarded as inadequate by later investigators. However, there is thorough agreement as to the value of Nature's historical monuments along each water-course. The rings denoting annual growth of timber may by their varying widths indicate the trend of climatic changes and the extremely dry or humid years of past ages. The record afforded by the gravel bars, detrital cones, and laminated sediment should be interpreted by expert geologists. Otherwise, many signs may be misinterpreted; for example, the back-water effects from a temporary impounding dam at a junc-

tion, or a landslide such as occurred on the Gros Ventre River, Wyoming,* June 23, 1925, or the successive stages occupied during the process of erosion.

Mr. Fuller rendered his first service to this paper when he published his notable work on "Flood Flows"† in 1914. Mr. Hazen's discussion of that paper included a map‡ of the United States with Fuller's coefficients recorded on various streams; and when the writer observed that Central Texas was rated at less than one-tenth of what prevailed in the Pacific Northwest, he began his definite quest for a basic formula capable of more satisfactory comparison. The paper is without doubt a composite of the experience, observations, and analyses of many in the field of research; and among the prominent influences are the works of Messrs. Fuller, Hazen, Metcalf and Eddy, and the late Emil Kuichling, M. Am. Soc. C. E. Acknowledgments have been made wherever practicable, but there are numerous factors which cannot be defined.

The only reply that will be ventured to the objections outlined by Mr. Fuller regarding the slope of the Myers formula is the suggestion that his own curves be platted on Plate IX for any small-area floods worthy of the name, and that he observe how far above the large-area floods these lines will fall.

Mr. Parsons evidently has understood the writer's purpose more clearly than most readers, for his suggestion as to an additional factor, K, to represent the influence of physical and other characteristics of drainage areas coincides with the original conception of a percentage scale on which all streams may be rated. It would give a product, $CK = C'$; or in other words, a coefficient in which are combined and reflected all the factors and influences that claim consideration.

Mr. Purdon rightfully speaks with authority regarding the development of Dun's waterway table, because of his participation in that achievement. His statements confirm accounts hitherto published. The resulting tabulation, based on field observations along the Santa Fé Railroad System from Illinois to New Mexico, almost coincides with an element rating 20% on the Myers scale derived from a study of flood flow from all continents.

The application of the Dun formula referred to by Mr. Purdon indicates the hypothetical velocity which would have prevailed in each case if the maximum observed run-off had occupied the entire waterway prescribed by the table. The computed velocities range from 0.02 for Item No. 330§ to 26 ft. per sec. for Item No. 156, instead of the assumed rate of 10 ft. per sec. In view of the wide departure from the assumed rate of flow displayed by that test, it appears that the subtractive term in the original Dun formula may be neglected because of its slight influence; computations show that for drainage areas between 8 and 6 500 sq. miles, this effect is less than 3% on the modified Myers formula, 20% rating. This proves that the Myers and Dun expressions are fundamentally similar, and that they differ mainly in scope.

The discussions may be the source of the greatest benefit derived from this paper. The writer gratefully acknowledges the contributions of Messrs. Follansbee, Honness, Cross, Horton, and Bernard. Although these discussions do not call for special comment, the data contained therein have added greatly to the value of the paper. Thanks are also due to the many engineers—in the U. S. Geological Survey and elsewhere—who have so kindly checked and corrected the statistics regrading flood flow. Table 2 has been corrected accordingly and as here published represents the data in their most complete and up-to-date form.

The task of segregating and digesting the available data should be carried on, not by individuals who will duplicate each other's efforts, but by a well-equipped organization such as the Society's Special Committee on Flood-Protection Data, working hand in hand with the U. S. Geological Survey.

THE RELATION OF THE OHIO RIVER AND ITS TRIBUTARIES TO TRANSPORTATION IN THE UNITED STATES

By C. W. Kutz,* M. Am. Soc. C. E.

The Ohio River extends from the confluence of the Allegheny and the Monongahela Rivers at Pittsburgh, Pa., to the Mississippi River at Cairo, Ill., a distance of 968 miles. Its width varies from less than 900 ft. to nearly 6 000 ft. and its slope from 11½ in. per mile in the upper reach, to 3 in. per mile near the mouth.

The more or less uniformly changing slope has one break at the Falls of the Ohio (Louisville, Ky.), where there is a low-water drop of 26 ft. in a distance of 2 miles. The low-water discharge varies from 1 100 sec-ft. at Pittsburgh, where the water-shed is 18 970 sq. miles, to 27 500 sec-ft. at the mouth, where the water-shed is 203 900 sq. miles, and the maximum high-water discharge (estimated) varies from 440 000 sec-ft. at Pittsburgh to 1 500 000 sec-ft. at Cairo. The extreme fluctuations of stage at different points along the river due to floods, and the year in which they occurred, are indicated in Table 1.

TABLE 1.

Place.	Highest recorded stage above low water, in feet.	Year.	Place.	Highest recorded stage above low water, in feet.	Year.
Pittsburgh, Pa.....	35.5	1907	Portsmouth, Ohio....	67.9	1913
Beaver, Pa.....	47.1	1907	Cincinnati, Ohio.....	71.1	1884
Steubenville, Ohio....	48.6	1884	Louisville, Ky. (below Falls).....	70.0	1884
Wheeling, W. Va....	52.1	1884	Paducah, Ky.....	54.3	1884
Parkersburg, W. Va..	58.9	1913	Cairo, Ill.....	54.8	1913
Point Pleasant, W. Va.	68.8	1913			

In its original condition, the river, in addition to the Falls at Louisville, was obstructed by snags, rocks, and bars composed of sand and gravel. The minimum depth over bars at extreme low water was about 1 ft. in the upper, and about 2 ft. in the lower, section. In some of the intervening pools the depths were as great as 30 ft. In 1825, just 100 years ago, the Legislature of Kentucky empowered a stock company to construct a canal around the Falls of the Ohio with suitable locks, docks, and basin. It was completed in 1830. In addition to a canal 64 ft. wide, there was a flight of three locks of equal lifts at the western end, each chamber having a width of 50 ft. and a usable length of 185 ft. The Federal Government became a stockholder in this company in 1826. Tolls were charged and the project was a profitable one. In 1874, the Government acquired complete title and tolls were reduced from 50 cents to 5 cents per ton. A few years later it was made a free waterway.

* Col., Corps of Engrs., U. S. A., Cincinnati, Ohio.

Until 1879 work elsewhere on the river was limited to the removal of obstructions and the building of contracting dikes with a view to securing a low-water depth of 3 ft. In this year Congress authorized the construction of a lock and dam about 5 miles below Pittsburgh, which proved to be the beginning of a slack-water system for the entire river. As first proposed the canalization project contemplated a depth of only 6 ft. and covered a distance of only 90 miles. Even as late as 1896, it was limited to the reach above Marietta, Ohio, 174 miles in length.

As now formulated the project provides for a navigable depth of 9 ft. throughout by the construction of fifty low-lift dams, each with a lock chamber 110 ft. wide and 600 ft. long in the clear. To prevent any increase in flood height and to permit open river navigation when the natural depth is 9 ft. or more, all the dams are of the movable type except the one immediately below Pittsburgh. This is of recent construction and replaced Dams No. 1 and No. 2 as originally built.

The main part of each movable dam, through which navigation passes when the dam is lowered, is known as the navigable pass. It is from 600 to 1 000 ft. long and consists of a series of wickets or shutters, 3 ft. 9 in. wide and 16 to 20 ft. long, depending on the lift of the dam, each supported in an inclined position by a prop. The dam is lowered by means of a derrick-boat, known as a maneuver-boat, the props being released from their seats one by one and the wickets lowered so as to lie flush with the bottom of the river. In addition to the lock and navigable pass there are weirs of different types for the purpose of regulating the pools and facilitating the raising and lowering of the navigable pass.

Of the fifty dams, thirty-eight are completed and in operation, and the remaining twelve are under construction. Of these, four are nearly completed and on two work of a preliminary character only has been done. The reach from Pittsburgh to Cincinnati, Ohio, will be completed in 1925 and the last dams should be completed in the season of 1929. This relatively long construction period is due to the fact that the various parts of a lock and dam are built within coffer-dams, designed to hold out the river to a stage of 16 ft. When the river rises above this stage, work must be suspended until the water subsides. With this limitation, the working season rarely exceeds 5 months—July to November, inclusive—and sometimes is as short as 100 working days. Under normal conditions, 4 years are required for the construction of a lock and dam, and, in the lower river where the dams are longer, 5 years will be required.

Tributaries.—In Table 2 are listed the principal navigable tributaries of the Ohio with information that tends to show their relative magnitude and the nature of the improvements made to date. Navigable sections of those rivers not now connected with the Ohio are not included in Table 2. An exception to this rule is made in the case of the Cumberland River, the canalized part of which will not have a 12-months connection with the Ohio until Dam No. 52, Ohio River, is completed. On the Allegheny, Big Sandy, Cumberland,

and Tennessee Rivers, where authorized projects are incomplete, only the completed sections at the lower end are given.

The lack of uniformity in lock dimensions is partly accounted for by the fact that on five of these tributaries, the canalization projects were first undertaken by the States or by private capital and subsequently acquired or taken over by the Federal Government, but even where not thus hampered, there was an apparent failure on the part of the Government to standardize lock dimensions to the extent that now seems desirable.

TABLE 2.—PRINCIPAL NAVIGABLE TRIBUTARIES OF THE OHIO RIVER.

Mouth, in miles below Pittsburgh.	Name.	Drainage area, in square miles.	Low-water discharge, in second-feet.	Length canalized, in miles.	Number of dams.	Project depth, in feet, canalized section.	Dimension of locks, in feet.	Notes.
0	Allegheny	11 580	1 440	24	3	7	55 by 286	Locks Nos. 2 and 3 slightly larger.
0	Monongahela	7 390	160	101 30	8 6	8 7	56 by 360 56 by 182	This assumes completion of new Locks and Dams Nos. 7 and 8 now being built to replace old Nos. 7, 8, and 9. Locks Nos. 1 to 6 have double lock chambers. At Lock No. 3 one of the lock chambers is 720 ft. long.
172	Muskingum	7 797	672	91	11	5.5	36 by 160	Lock No 1 is 56 by 360 ft.
184	Little Kanawha	2 288	....	48	5	4	22.7 by 125	One lock is 26 ft. wide.
265	Kanawha	12 200	1 100	88	6 4	6 6	55 by 313 50 by 271	.....
317	Big Sandy	4 182	100	55	5	6	55 by 158	Lock No. 3 is only 52 ft. wide. Three locks on main river and one on each fork.

Table 3 shows the first cost of the existing river improvement projects in the Ohio Basin and the cost of operation and maintenance. In the case of the Ohio River, the amount given is 80% actual cost and 20% estimated. On the Monongahela River, the figure includes the estimated cost of Locks and Dams Nos. 7 and 8, now under construction, to replace old Locks and Dams Nos. 7, 8, and 9. In other cases the cost is the historical cost as shown by the Annual Reports of the Chief of Engineers, U. S. Army. The costs of operation and maintenance are compiled in a similar manner. In Column (4) of Table 3 is shown the cost per mile and, in Column (5), interest on the first cost at 4 per cent. Column (7) shows the total fixed charges and Column (8) the fixed charges per mile.

Commerce.—Table 4 shows, for the Ohio and for the tributaries listed, the commerce for certain selected years as taken from the Annual Reports of the

Chief of Engineers, U. S. Army. The year 1900 was selected as marking the peak of water-borne commerce on the Ohio, and the year 1913 as typical of conditions just prior to the World War. Present conditions are shown by the tonnage reported for the calendar year 1924, and by the average for the period 1919-24, inclusive. The approximate ton-mileage in 1924, the fixed charges per ton-mile, and the cost of maintenance and operation per ton-mile are also shown.

TABLE 3.—OHIO RIVER AND THE CANALIZED PARTS OF ITS PRINCIPAL TRIBUTARIES.

*Not available.

Strictly speaking this commerce is not all applicable to the sections of the rivers listed in Table 4, as, in some cases where separation was impossible, it includes all the commerce reported for the entire river, but the error thus introduced is not large. The tonnage reported for recent years is exclusive of floated timber and timber products. For earlier years such tonnage was not

separately reported. The tonnage listed includes sand and gravel much of which is transported for very short distances. To show the nature of the traffic, the reported tonnage for 1924 has been divided into four groups: Coal, sand and gravel, other bulk freight, and package freight, as given in Table 5.

Percentage	65	23.68	9.70	1.62

From Table 5 it will be seen that the Ohio River System is primarily a coal carrier and in the small percentage of other freight resembles some of the principal coal-carrying railroads.

Decrease in Tonnage.—The great decrease in tonnage on the Ohio notwithstanding the improved navigation facilities is due in large measure to a change in the place of marketing the coal mined in the river mines of the Monongahela Valley. In 1901, 3 200 000 tons of coal from such mines were shipped by water to points on the Lower Ohio River. None is shipped to-day either by water or rail.

The recorded decrease is also due in part to the greater care that is exercised to prevent duplication in the collection of statistics. Some years ago it was the practice on some rivers to arrive at the total tonnage by a summation of the tonnage passing each lock. However, even with such errors eliminated, there has been on some of the rivers in this Basin an actual reduction in the amount of water-borne commerce. A marked exception to this general rule is the Monongahela River, on which the commerce has increased from 7 000 000 tons in 1900, to 12 039 175 tons in 1913, and to an average of 19 558 000 tons during the past six years. The Allegheny River also shows an increase, largely in sand and gravel which made up 75% of its traffic in 1924.

The decline in water-borne commerce has not been limited to the Ohio River Basin, but is more or less general on inland rivers. This subject was brought to the attention of the Society in 1915 in a paper by W. W. Harts, M. Am. Soc. C. E., entitled "'Rivers and Railroads in the United States."* Many reasons for the decline are set forth in that paper and in the voluminous

* *Transactions*, Am. Soc. C. E., Vol. LXXIX (1915), p. 919.

discussion thereon. Among the discussors was H. Burgess, M. Am. Soc. C. E., who stated:*

"* * * the more favorable freight rate charged by railroads on any portion of their lines for which there is a competing water route. The result of the lower rates for towns connected by a water route is that 'inland' towns must pay a portion of the rail transportation charge on freight received by river towns. These latter, therefore, receive the superior facilities offered by the rail route over carriage by water at practically what such freight would cost if carried by boat, and these superior facilities are obtained at the expense of the 'inland' towns."

In the same discussion, J. H. Bernhard, Assoc. M. Am. Soc. C. E.,† after making a series of comparisons between rail rates on lines with and without a competing water route, states:‡

"Although rebates are forbidden by State or Federal statutes, railroads grant them quite as much to-day as at any time in the past, the only distinction being that formerly they were granted to individuals surreptitiously, and now they are granted to cities and towns openly; the former became illegal, the latter is legalized. These rebates arise from the unjust practice of railroads in basing rates to river points on water competition."

To determine to what extent this practice prevails in the Ohio River Basin, existing rail rate tables have been examined and the results which are summarized in Tables 6, 7, and 8, are platted on Figs. 1, 2, and 3. On Fig. 1 is

* *Transactions*, Am. Soc. C. E., Vol. LXXIX (1915), 941.

† Mr. Bernhard resigned from the Society on April 12, 1926.

‡ *Transactions*, Am. Soc. C. E., Vol. LXXIX (1915), p. 946.

shown a series of coal rates from bituminous coal fields to points with and without river competition. A curve representing a rate of 4.5 mills per ton-mile plus $1.00 per ton, may be taken as the mean. The short hauls are comparisons between rail rates in the valley of the Monongahela which is canalized and rates in the uncanalized section of the Allegheny. These rates show

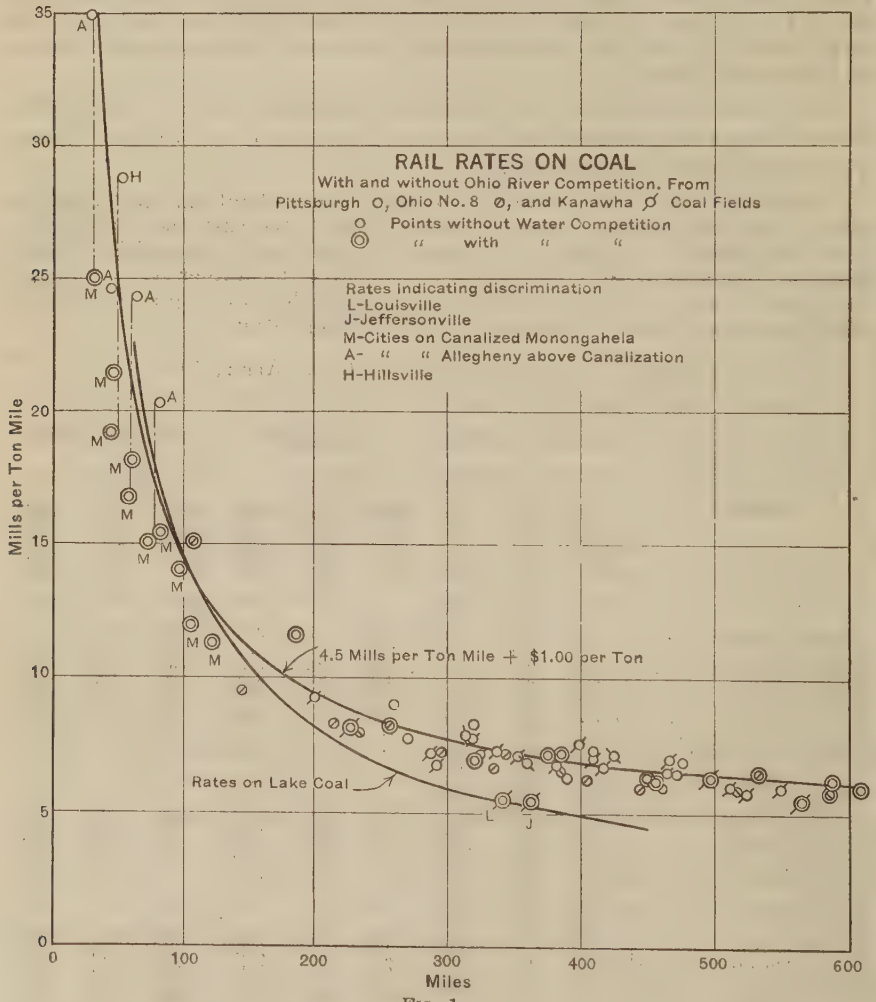

Fig. 1.

marked discrimination in favor of points with water competition, the average difference being 7 mills per ton-mile. In the longer hauls no such discrimination is apparent except on hauls from Pittsburgh to Louisville and to Jeffersonville, Ind. On the same diagram, as a matter of general interest, a line is drawn representing the rates on coal from a number of bituminous coal fields to lake ports for re-shipment on lake vessels.

On Fig. 2 a series of fifth-class rates (bulk products, carload lots) from Pittsburgh and from Cincinnati to points with and without water competition, have been platted. The results show that for points in Central Freight Association territory (that is, the territory bounded on the north by the Great Lakes, on the south by the Ohio River, on the west by the Mississippi River,

and on the east by a line drawn from Buffalo, N. Y., to Pittsburgh), the rates are based on mileage, and no difference is noted between rates to inland points and to points on the Ohio. The rates to many points south of the Ohio, however, are noticeably higher, and some distinction is made between inland points and points on the Mississippi River, such as Memphis, Tenn., Vicksburg, Miss., and New Orleans, La.

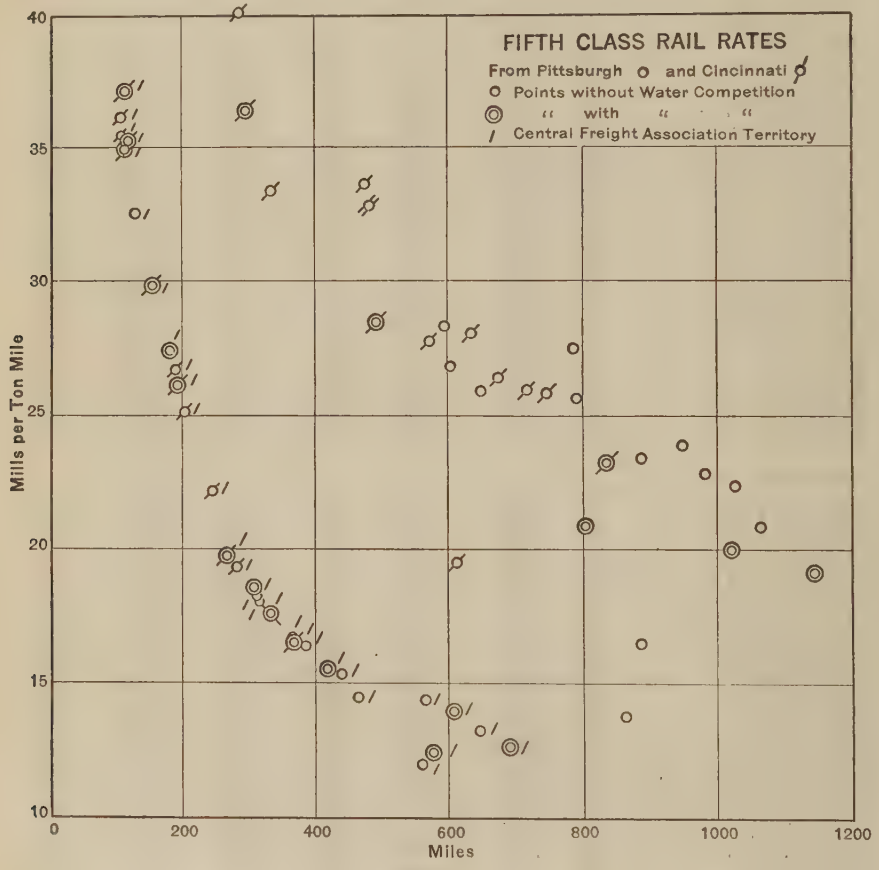

FIG. 2.

On Fig. 3 are platted a series of rail rates on finished steel products from Pittsburgh. In Central Freight Association territory such products move at fifth-class rates. In territory south of the Ohio, they move under a commodity rate which is not only much less than fifth-class rates in that territory, but is practically uniform with fifth-class rates in Central Freight Association territory. The rates indicated on Fig. 3 show no distinction between inland points and points having water competition.

There is a considerable movement of coal from the West Virginia coal fields through Cincinnati to points in Indiana. Some of this coal comes in by rail and is turned over to another railroad for delivery to destination.

Another part comes in by river, is transferred to cars, and delivered to the same railroad for delivery to the same destination, but the rates charged on the coal coming in by rail are lower than the rates charged on the coal coming in by river, other conditions being identical. This differential in favor of the all-rail movement to Indianapolis, Ind., is now 18½ cents per ton and several years ago was considerably higher.

With the exceptions noted, the results of the investigation seem to justify the general statement that in the movement of coal and structural steel in the Ohio River Basin, the existing rail-rate structure does not discriminate between points having water competition and points that are without water competition.

Cost of Transportation by Water, Ohio River System.—In determining the economic advisability of creating an inland waterway or in measuring its usefulness as a part of the country's general transportation system, one of the most important factors and one concerning which available information is limited is the cost of water haulage, that is, the cost of transportation by water exclusive of fixed charges. This cost is subject to the combined influence of many factors, among which may be listed:

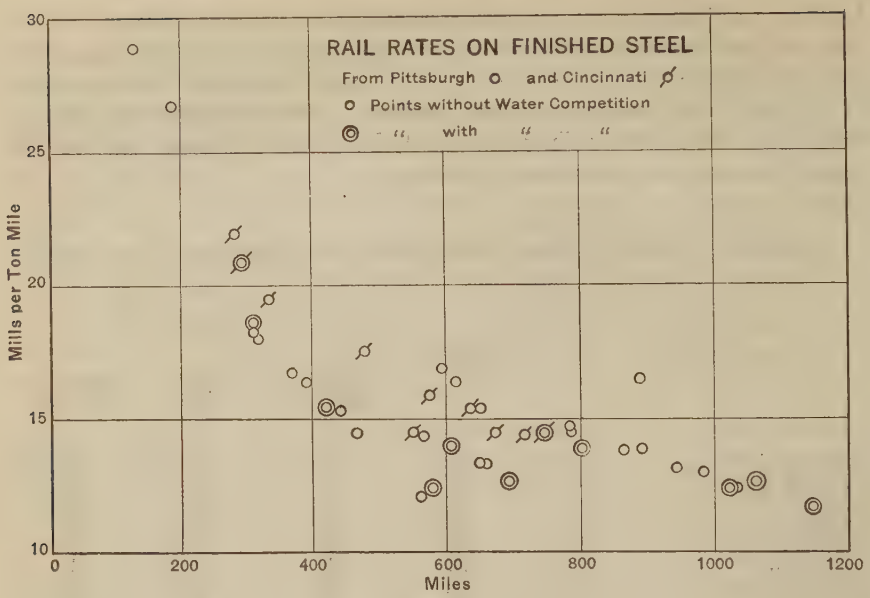

FIG. 3.

(*a*) The physical characteristics of the waterway, of which in canalized rivers the more important are the size of the locks and the depth and width of the intervening pools.

(*b*) Types of transportation service, which may be grouped as private industrial, contract industrial, and common carrier.

(*c*) The kind of freight: In the comparisons to follow only bulk freight will be considered and in some cases only coal.

(*d*) Type of floating plant: As more than 98% of the tonnage on the Ohio and its tributaries is carried on barges, open or decked, no consideration will be given to a movement of freight on packet-boats or other self-propelled carriers.

(*e*) Annual volume of tonnage: The volume of tonnage handled annually by a given operating agency affects the number of barges required per towboat, and the plant performance. On the Monongahela River, with its large volume of tonnage, a standard tow consists of six barges, each approximately 175 ft. long and 26 ft. wide, with a maximum capacity of 1 000 tons. These barges are lashed together, two wide, and pushed by a stern-wheel steamer, the overall dimensions of which are somewhat less than a standard barge. For passage through a standard Monongahela River lock such a tow must be broken into two parts. On the Ohio a fleet of eight such barges with towboat can pass through the locks. Tows with twelve to fourteen barges are not infrequent on the Ohio between the mouth of the Kanawha River and Cincinnati, and formerly even larger tows were not uncommon.

(*f*) Back haul: Very little freight is available as back haul that can be carried on barges used for the transportation of coal, sand, and gravel. Where

back-haul traffic is available, the costs of transportation are from 60 to 65% of those without back haul.

(*g*) Length of haul: This factor influences the investment per ton-mile and the plant performance.

(*h*) Co-ordination of terminal and transportation services: This factor gives private industrial operation an advantage over contract industrial or common carrier and results in lower costs.

In a discussion of the paper presented by William M. Black, M. Am. Soc. C. E., entitled "Waterways and Railway Equivalents",* C. I. Grimm, Assoc. M. Am. Soc. C. E., analyzed† waterway haulage costs on rivers similar to the Ohio, and reached the conclusion that 2.5 mills per ton-mile was a fair measure of the cost under the following conditions: 250-mile haul, no back haul, 6 000-ton cargoes in 1 000-ton barges, wide river, large tonnage, and steady movement.

The principal users of the Monongahela River have kept comprehensive cost records for a number of years. These records were furnished in confidence to the office of which the speaker is in charge and, together with the analysis made by Mr. Grimm, have been made the basis of the water haulage costs shown on Fig. 4. These costs are based primarily on tonnage moving with the current. Other conditions are shown on the diagram itself.

Rail vs. Water Rates.—Fig. 4 also shows existing rail rates on coal on roads coming into direct competition with the Ohio River or its coal-carrying tributaries. Ton-mile rates by rail and water are, however, not directly comparable, one important variation being the difference in the length of the haul.

Fig. 5 shows water and rail distances from Pittsburgh to points on the Ohio and the Mississippi Rivers. For a rail haul of 230 miles the water distance is approximately 50% greater than the rail distance and, for convenience in comparison with rail distance, a line representing this ratio has also been shown. On the Monongahela River the competing railroads parallel the river, and differences in lengths of haul are insignificant.

Another point that must be taken into consideration in any economic comparison is the difference in terminal costs. Experience on the Monongahela River indicates that it is somewhat cheaper to load into cars than into barges. On the Ohio the difference is greater, due to the greater range between normal and high-water stages. Coal cars can be unloaded from a trestle or elevated and tipped bodily, while coal barges must be unloaded by a grab-bucket. With modern unloading plants of large capacity this difference amounts to less than 5 cents per ton.

Every transfer of bituminous coal, whether loading or unloading, involves some loss due to breakage and, as this breakage is generally proportional to the drop, loading into barges has been considered as involving greater loss than loading into cars. To minimize this loss, three modern plants in Huntington, W. Va., for transferring coal from rail to barge are in the form of inclined belt conveyors. For joint hauls involving two railroads, cars can

* *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 538.

† *Loc. cit.*, p. 568.

be switched from one to the other at small cost, whereas in joint hauls—part river and part rail—both a transfer charge of about 10 cents per ton and a breakage loss must be absorbed.

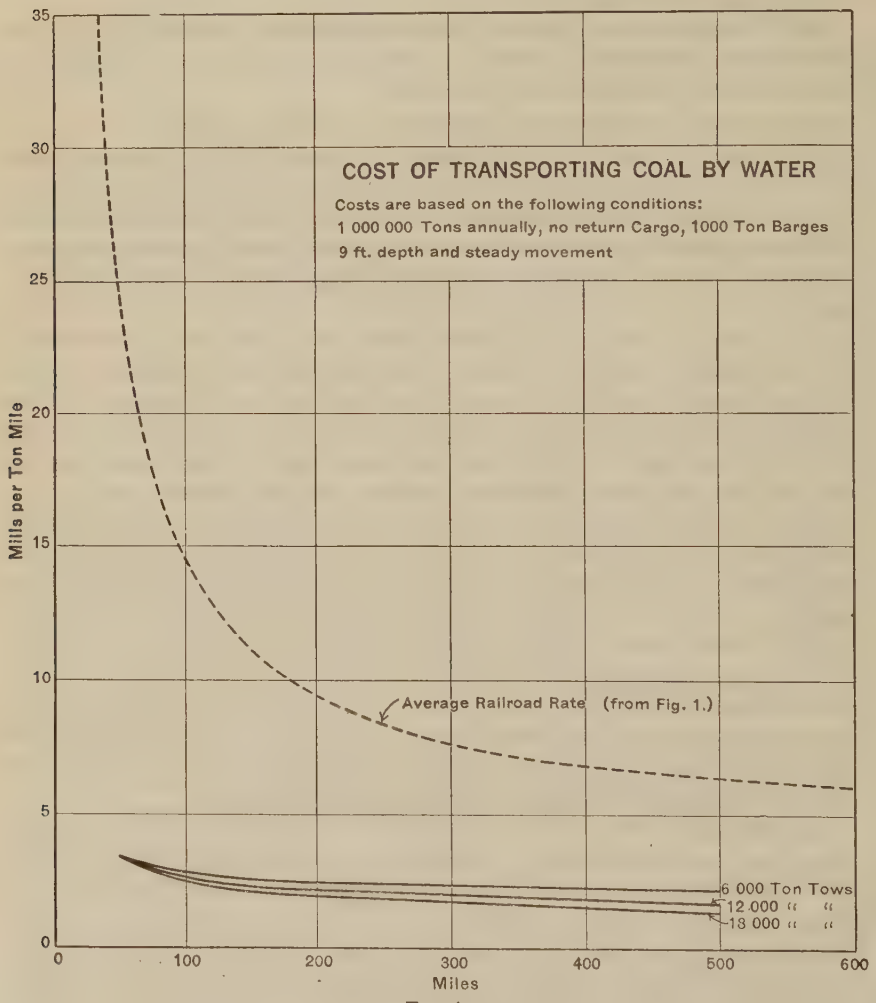

FIG. 4.

Economic Comparisons.—If the points of origin and destination and the ton-mileage of each commodity hauled on these rivers are known, as well as the water haulage costs, the direct benefits or savings resulting from their use can be readily ascertained by comparison with existing rail rates and their economic justification determined by comparing the savings or benefits with the fixed charges. Although neither the traffic data nor the water-haulage cost data are sufficiently comprehensive for a complete comparison, approximate results can be secured by limiting the comparison to coal and assuming

that the ton-mile savings on that commodity represent the average savings on the total ton-mileage.

The average cost of moving coal on the Monongahela River is quite well determined and is 3 mills per ton-mile and the rail rate on coal on parallel roads for the same average haul—42 miles—is 19 mills per ton-mile, the rail and water distances being practically equal in this case. This difference applied to the total ton-mileage—919 000 000—reported for 1924, shows a gross annual saving of $14 700 000, or allowing for difference in terminal costs, a net annual saving of $12 700 000, in comparison with fixed charges of $1 729 980.

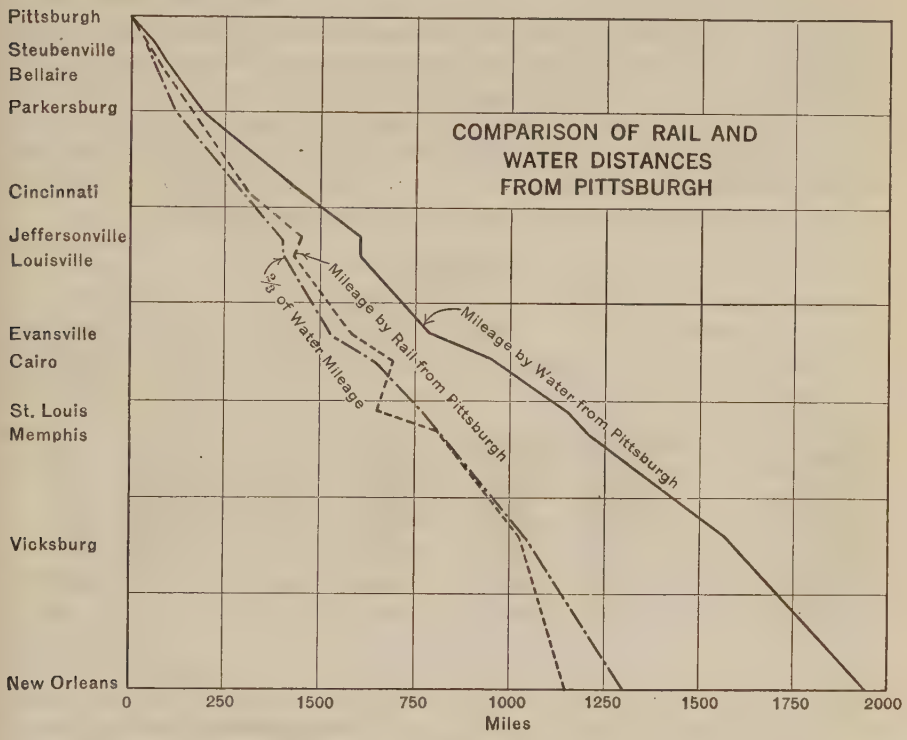

Fig. 5.

A similar comparison on the Ohio is limited to the reach between Pittsburgh and Cincinnati, 483 miles in length. There are only three uncompleted dams above Cincinnati and as they will be completed in 1925, the cost of that part of the project and the cost of operation and maintenance can be closely approximated. With a first cost of $54 500 000, interest at 4%, and operation and maintenance cost of $1 500 000, the fixed charges will be $3 680 000.

The coal moving on the Upper Ohio may be divided into three groups:

(*a*) That coming out of the Monongahela River and moving to points in the industrial district between Pittsburgh and Wheeling;

(*b*) That coming out of the Kanawha; and

(*c*) That coming into Huntington, W. Va., by rail and being transferred to barge.

Part of Movements (*b*) and (*c*) goes to the industrial district at Ashland and Ironton, Ohio, but the major part goes to Cincinnati. Some of the latter coal is re-shipped by rail, involving a rail-river-rail movement, the coal being hauled from Guyan Valley by rail, 70 miles, transferred to river barges, hauled by water to Cincinnati, 162 miles, and re-shipped by rail to points in Indiana.

The computation of direct benefits on the Upper Ohio is not as simple as on the Monongahela, but a study of the major movements and a comparison with rail rates and distances indicate a weighted average saving of 4.0 mills per ton-mile. If this is applied to the total ton-mileage—800 000 000—reported for this part of the Ohio in 1924, the gross savings amount to $3 200 000 or, allowing for difference in terminal costs, an estimated net saving of $2 200 000. This is approximately 60% of the fixed charges. As this part of the project is not yet completed, a characteristic of every large transportation enterprise, the showing is regarded as promising of ultimate economic success.

TABLE 9.

River.	Cost.	Tonnage.	Ton-miles.	Average haul, in miles.	Fixed charges.	Fixed charges, in mills per ton-mile.†

Investment per annual ton (not including equipment)	$3.50	$3.75
" " " ton-mile	0.016	0.0675
Fixed charges per ton-mile	0.002	0.0046

* Not including Green River.

† The fixed charge per ton-mile for the entire system is 4.6 mills, 2.3 times the fixed charge per ton-mile on the principal coal-carrying railroads in this region. If upon completion of the Ohio canalization project the commerce is doubled, as seems probable, the fixed charge per ton-mile will be quite comparable with that on coal-carrying railroads.

Similar comparisons made on other tributaries show some as yielding benefits comparable with the fixed charges, others have not yet reached the stage of economic justification, while still others have apparently passed beyond it, as did the old canals constructed 100 years ago. Certain data concerning the Ohio River System as a whole for 1924 are shown in Table 9.

On the lower half of the Ohio, the tonnage for 1924 amounted to 1 400 000, of which, 420 000 tons was a seasonal movement of coal from the West Kentucky fields to Paducah, Ky., Cairo, and points on the Mississippi River. With the completion of the canalization project this tonnage bids fair to increase greatly. There is now a seasonal movement of steel products from Pittsburgh to Memphis and Baton Rouge, La., where two of the large steel corporations have established distributing points for supplying the Southwest; 66 000 tons were shipped in 1924 and with year-round navigation the tonnage will increase.

On the Mississippi River, in 1923, there was an up-stream tonnage (Memphis to Cairo), of 400 000, consisting principally of sugar, molasses, logs, bauxite ore, and miscellaneous items. Similar traffic will develop on the Ohio when the project is completed. For some of this tonnage, covered barges will be required which, in turn, will be suitable for the shipment of manufactured products from the Ohio Valley to points on the Mississippi River, resulting in a balanced haul.

The coal movement on the Ohio and its tributaries is nearly all down stream with practically no back haul. There are many indications pointing to an increase in this movement, but very little prospect of developing back-haul traffic that can be carried in coal barges. In this respect, however, the river does not differ from the principal coal-carrying railroads. As evidence of increase in the movement of coal by river, two additional coal companies are planning to ship, to Cincinnati by water, coal brought into Huntington, W. Va., by rail. The combined capacity of the three rail-river transfer plants at Huntington will then be 4 000 000 tons annually.

A modern unloading plant at Cincinnati is equipped with a bucket having a capacity of 5 tons of coal and the speed is such as will permit a round trip from barge to hopper in 40 sec. The cost of unloading is reported as less than 10 cents per ton. The new steam power plant under construction 20 miles below Cincinnati is planning to receive its coal by river. The initial installation will require from 250 000 to 300 000 tons annually and its ultimate requirements will be nearly three times that quantity. A proposed by-product plant at Cincinnati contemplates the shipment by water of 500 000 tons of coal annually.

The steel-making industries on the Ohio are responsible for the largest part of the present coal movement, 2.6 tons of coal being required directly or indirectly in the manufacture of each ton of steel, and if these districts continue to grow or other similar districts are established, the Ohio may eventually be as essential to their success as the Monongahela River is to the steel industries in that valley.

In connection with its Parkersburg, W. Va., refinery, the Standard Oil Company has established a water delivery service for its refined products. With a fleet of six steel barges, with a capacity of 100 000 gal. each, deliveries are being made to points on the Ohio between Wheeling and Huntington and to points on the Kanawha River. Another development is the movement

of 100 000 tons annually of crude oil from points on the Kentucky River to the Ohio, thence to Louisville.

Many of those interested in the completion of the Ohio River project look forward to such reduction in transportation costs as to make Baton Rouge and New Orleans the exporting points for a great part of the Ohio Valley instead of points on the Atlantic. Others foresee the time when iron ore will be brought by sea to Baton Rouge and barged up the Mississippi and Ohio Rivers to meet the coal; but even if some of these forecasts are not realized, it seems probable that the canalization of the Ohio will eventually yield benefits in excess of the fixed charges and thus justify the investment.

By some it is held that inland waterway improvements are justified even if the benefits are less than the carrying charges, but in its report to Congress, a number of years ago, the National Waterways Commission stated that:

"The cost of facilities for carrying freight, whether borne by the Federal Government or by private capital, is a burden upon the resources of the country. The fundamental criterion should be whether a railway or a waterway, when constructed or improved, will be a profitable investment of capital."

The same view was expressed recently by General Black in his paper on "Waterway and Railway Equivalents", previously mentioned, as follows:

"New waterway lines of transportation should not be established unless an analysis of the existing railway, highway, and waterway lines and of the need for transportation shows that the proposed new line is required and that if established it will produce an annual saving in the cost of transportation greater than the interest on construction plus maintenance and operating costs."

The writer would phrase a similar thought by saying that the people of the United States are entitled to have the products of the farm, mine, and factory move from origin to destination by the cheapest means, all elements of cost considered. Every inland waterway project should be gauged on that basis. Projects that are economically sound should be prosecuted vigorously and their use encouraged by wise regulation of rates and by the establishment of joint rail and water rates so as to make them an integral part of the country's transportation system.

THE RELATION OF THE OHIO-MISSISSIPPI WATERWAYS TO PRODUCTION AND INDUSTRIAL DEVELOPMENT

By H. B. Luther,* M. Am. Soc. C. E.

The proper utilization of the Ohio-Mississippi Waterways for transportation is rapidly becoming essential to the safeguarding of National prosperity and to the proper economic and industrial development of the United States. This is considered to be a fair statement because two distinct types of studies have indicated that these waterways afford a means of solving important industrial problems. This particular paper is confined to a description of these two fundamental studies and the relation of the Ohio-Mississippi route to them. The first was a war-time study of production which is equally applicable to the general problem of production, and it stresses a serious situation which is worthy of frequent re-statement from all angles. The second study is concerned with the industrial development of the Cincinnati District.

Prosperity is linked with production. Periods of prosperity make demands on the entire capacity of the nation for production, and in time of war the country's ultimate military effort is limited by production. There are seven limiting factors of production, namely, (1) demand; (2) fluid capital; (3) transportation; (4) labor; (5) raw material; (6) equipment; and (7) power.

It is impossible to place these factors in the order of their importance, because at different periods any one of the various items may become the limiting factor. At present (1925), demand is the limiting factor in production. The country is so equipped with labor, raw materials, and sources of power in its coal supply and water-power possibilities, that the proper handling and utilization of these commodities should make them meet any demands that can be anticipated. At critical periods, however, transportation is the real limiting factor of production. The great panic of 1907 was caused fundamentally by the inadequacy of transportation facilities, and the transportation facilities again failed to meet the demand after the entrance of the United States into the World War.

That Division under the U. S. Chief of Ordnance, which handled economic problems, emergency production, and labor matters, made a survey of transportation conditions in the fall of 1917. The flow of material was primarily eastward. Congestion appeared very early. Outline maps of the United States, such as are used by the U. S. Weather Bureau, were prepared with each railroad yard represented by a red dot. The congestion in each yard was indicated by an arrow pointing backward from the yard, westward. This arrow lengthened week by week and the rate at which this length increased was the basis for the prediction of the date of complete congestion. In December, 1917, it was clear that this would occur by February 1, 1918. Addi-

* Prof. of Civ. Eng., Univ. of Cincinnati, Cincinnati, Ohio.

tional factors—in particular, severe weather conditions—hastened the tie-up and by January 17, 1918, the Coal Commission issued its orders closing down all factories for one week and for one day per week thereafter, until the congestion was cleared. It was necessary to suggest many changes in orders for war material which various Departments had placed in plants admirably adapted by equipment and personnel, but situated where material could not be shipped in or out with needed regularity.

Herman Schneider, Assoc. M. Am. Soc. C. E., who was closely concerned with those studies, gives a simple illustration of the transportation situation in one of his professional papers. The transportation facilities correspond to the aisles of a factory along which the raw materials are carried to the machines and the finished products are carried away from them. There is an efficient width of aisle which will avoid congestion and consequent tie-up of various machines. Further, the proper layout of the equipment must be considered in its relation to a proper sequence of functions and a minimum transport of material from the entrance of the plant to its issue as finished product. Individual plant layout is a matter of careful analysis. The industrial layout of the entire country should be viewed in much the same manner, treating the country as one vast factory. At present, the aisles are not wide enough nor is the machinery in all cases properly placed.

In 1904, there was $1 in railroad property for each $9 of other property; in 1912, the ratio was 1 to 12, and, in 1920, there was nearly $25 worth of other property for each $1 of railroad plant. Although the basis of valuation has changed somewhat in that period, the comparison of these ratios is an important index. In case of a war, the nation's efforts would still be limited by transportation. It is stated that during the period of congestion on the Eastern seaboard, under World War conditions, it was easier to ship goods from Pittsburgh, Pa., to New York, N. Y., *via* New Orleans, La., than from Pittsburgh to New York direct by rail. On the completion of the work on these waters, a similar tie-up into the North Atlantic ports would make exporting by way of New Orleans feasible, that is, it would be easier to ship from Cincinnati, Ohio, to New Orleans by river and then by boat to France than to ship from Cincinnati to New York and export from there. The increased utilization of these waterways is necessary for general business demands and as a measure of National security.

Again the matter may be viewed from a study of proper industrial development. Such development for any particular locality should be based on sound searching studies of all the economic principles involved and on a proper consideration of the industrial relation of that particular section to the country at large. In the past, industries have been encouraged for the purpose of building up communities, without due care in the selection of the proper type of industry. There are exceptions, of course, primarily in the location near the source of supply of those industries using bulky raw materials.

In this problem of the selection of proper industries, the Ohio-Mississippi Waterways, is an important factor for those States bordering on it. Investigations of the proper industrial developments of the Cincinnati District are

under way. The work has not yet reached the stage where direct recommendations can be made, but a discussion of the fundamental principles involved, with stress on the question of transportation, together with an illustration of the specific type of problem which arises, will indicate the importance attaching to the waterways.

The question of the proper industry for a site involves many factors. First, the natural resources of the surrounding country should be studied; the demands of the community must be analyzed; the type of power and labor available must be known; and the contacts with neighboring industrial centers considered.

For example, assume that a plant to manufacture a given commodity is to be located in Cincinnati and that a request is made for capital. In the investigation of the wisdom of such investment it is necessary, in order to determine the transportation charges, to determine the sources of supply of its raw materials and to learn the dependency to be placed on a continual flow of this supply. Then, with the cost of the finished product known, there may be determined the distance this product can be sent in competition with similar factories which may be located in Chicago, Ill., St. Louis, Mo., and Pittsburgh. The demand for this product in the territory it may economically supply must be studied and the output of existing local plants determined. Obviously, if the demand in the local marketing area is already 90% filled by existing agencies, a 25% increase in production capacity would mean failure of some of the companies or severe financial stress for all. This leads toward the question of decentralization for certain types of industries.

In order to have a basis for solving these industrial problems, two surveys have been started in Cincinnati. The first is determining the natural resources available to the Cincinnati District. The area to be studied varies with the type of material, in some instances a radius of 50 to 100 miles is taken, in others, one of 500 to 1 000 miles, depending on the bulk of the commodity and the means of transportation. This work is being carried on by the University of Cincinnati, with aid from the Commercial Club. At the same time, a study of the existing manufactures in this District, the demands in raw materials made by these plants, and the output from this District, is being carried on by the Technical Advisory Corporation. This work is supported financially by the Chamber of Commerce.

To illustrate how Ohio River transportation has entered this study, the following illustration serves excellently. Among the studies being made in connection with these investigations has been a review of the uses of salt and the sources from which it is now obtained for local purposes. At present, salt is brought chiefly from Northern Ohio and Michigan. Rock salt is mined somewhat more cheaply in New York State, but transportation charges make the Northern Ohio and Michigan sources more available. However, rock salt can be obtained in large quantities in Louisiana, a source which bids fair to become of great importance in supplying the demands of the country. It may be brought from this supply in barges on the Ohio and Mississippi Rivers and delivered to factories established on the banks of the Ohio at favorable rates

in competition with the present sources. There it can be crushed and screened and the demands for various sizes of rock salt for all local needs in the chemical industry supplied. The excess of all sizes can then be used at these new factories on the river to manufacture certain chemicals. Alkali (sodium hydroxide), suggested as the lime needed in conjunction with it, is available in great plenty in this region, and the electrolytic manufacture of sodium hydroxide could use any excess electric power if this proves feasible. Salt cake for the glass industry has also been suggested.

Also, salt cake (Na_2SO_4) demands sulfur, and this demand carried the investigation to a study of the source of this raw material. The sulfur used at present comes chiefly either from the Eastern seaboard, from places such as Perth Amboy, N. J., where it is obtained from pyrites imported in bulk, or from pyrites found in Tennessee. Sulfur may be obtained practically pure from wells in Louisiana and Texas and transported on the inland waterway. With cheap sulfur for the manufacture of sulfuric acid, an ample salt supply, and adequate power, the materials are assembled for the maintenance of a heavy chemical industry, for the manufacturing of such products as the salt cake, already mentioned, soda ash, caustic soda, and hydrochloric acid, all of which are products that find places in the industrial demands of Cincinnati.

This is the type of problem now confronting those engaged in the investigations of accessible materials and their utilization. The feasibility of this particular manufacture is still to be determined. However, recent studies seem to indicate that the Ohio-Mississippi route will place rock salt and sulfur among those raw materials so situated geographically as to fall among the natural resources which determine the proper industry for this locality.

There is a local demand for pig iron, and the question has been asked, should blast furnaces be located in the more immediate vicinity of Cincinnati? The transportation factor involved is that of barging coal from the Pittsburgh region in West Virginia—a water haul—and the rail shipment of the ore from a lake port, such as Lorain, Ohio, a haul comparable to the haul from the Great Lakes to Pittsburgh. Local factories that use by-product coke and slag cements deserve consideration in this connection, as well as the practicability of smelting at Cincinnati, a mixture of Birmingham iron, Bessemer and Lake Superior ores. The use of sulfur and salt is stressed, however, to indicate the need of an investigation of the natural resources of the Ohio-Mississippi Basin as a means to intelligent industrial expansion, along proper lines, of those industrial centers adjacent to the waterway.

COMPARISON OF RAIL AND RIVER TRANSPORTATION COSTS IN RELATION TO THE OHIO RIVER AND ITS TRIBUTARIES

By Frank H. Alfred,* M. Am. Soc. C. E.

The relation of the Ohio River and its tributaries to transportation in the United States may mean either of two things: First, how the one compares with the other as to amount, importance, expedition of service, economy, or some other characteristic; and, second, how the two are connected with or related to each other—the nature and extent of their interdependence and interaction. The first is largely a matter of statistics. The salient facts in regard to transportation on the Ohio River† are contained in Tables 10 and 11.

TABLE 10.—Freight Traffic, 1923.

Commodities.	Net tons.	Percentage of total.	Value.	Percentage of total.
Coal and coke	6 041 708	73.0	$27 466 401	25.0
Sand, gravel, and stone	1 372 404	16.6	1 542 881	1.4
Metals and metal products	389 792	4.7	36 714 894	33.4
All other commodities	476 617	5.7	44 298 077	40.2
Total	8 280 520	100.0	110 022 253	100.0

The figures given in Tables 10 and 11 include freight handled in car ferries. Since 1918 this item has been kept separately, and figures exclusive of car-ferry traffic are, as follows:

Year.	Tons.	Value.
1919	5 004 378	$88 912 336
1920	9 382 464	223 433 492
1921	7 307 880	93 274 814
1922	6 291 828	144 796 250
1923	8 280 520	110 022 253

Characteristics.—The characteristics of the Ohio River are, as follows:

Length, in miles		968.5
Drainage area, in square miles		203 900
Discharge, in cubic feet per second (estimated):		
	Low water.	High water.
At head, Pittsburgh, Pa.	1 600	440 000
At mouth, Cairo, Ill.	27 000	1 500 000

* Pres. and Gen. Mgr., Pere Marquette Ry., Detroit, Mich.

† Annual Report, Chf. of Engrs., U. S. Army, 1924.

Average fall per mile at low-water stage:

	Miles.	Inches.
Pittsburgh, Pa., to Wheeling, W. Va.	90	11½
Wheeling, to Cincinnati, Ohio.....	378½	5½
Cincinnati, to Cairo, Ill.....	500	4

Construction of Locks and Dams.—The existing project for improvement was adopted by the River and Harbor Act of June 25, 1910, and contemplated a 9-ft. channel from Pittsburgh to Cairo. It includes fifty-two dams, with a lock, 110 ft. by 600 ft., at each dam. Of these, thirty between Pittsburgh and Portsmouth, Ohio, are in operation, being all that are contemplated between those points, a distance of 358 miles. Between Portsmouth and Uniontown, Ky. (480 miles), seven dams are in operation, nine are under construction, and one is not yet begun. Between Uniontown and Cairo (130 miles), the five dams contemplated are not yet begun. This makes a total of thirty-seven in operation, nine under construction, and six not begun, on June 30, 1924.

1921	8 037 788	484 576 262
1922	7 039 188	968 327 994
1923	9 245 647	372 534 148

In 1910, prior to the adoption of the present project, $17 657 273 had been expended, with $58 974 278 since that time, making a total of $76 631 551. The estimated cost of completing the project is $34 084 625, which would make the total cost $110 716 177. The cost of maintenance and operation in the year ending June 30, 1924, was $1 420 574.

The classification of freight in 1923 by principal commodity groups and by up-stream and down-stream movement, with the ton-miles and average haul in each case, is given in Table 12.

TABLE 12.—Freight Classification, 1923.

Up Stream.

Commodities.	Tons.	Percentage of total.	Ton-miles.	Average haul, in miles.
Coal and coke	343 225	20.6	13 563 726	40
Sand, gravel and stone	972 645	58.2	10 946 066	11
Metal and metal products	167 055	10.0	22 353 055	134
All other commodities	187 361	11.2	75 233 212	401
Total	1 670 286	100.0	122 096 059	73

Down Stream

	Tons.	Percentage of total.	Ton-miles.	Average haul, in miles.
Coal and coke	5 698 483	86.2	489 752 210	86
Sand, gravel and stone	399 759	6.0	6 328 085	16

All other commodities	476 617	5.7	104 557 690	219
Total	8 280 521	100.0	749 120 486	90

No attempt to compare Ohio River traffic with all classes of transportation in the United States will be made, as that would include not only other water-borne traffic, but also that carried on the highways. The comparison will be confined to the freight traffic carried by the railways. This is shown in the following statement (Table 13) for 1923, the last year in which statistics as to river traffic are available.

In this comparison (Table 13) it should be noted that the cost of railroads includes rolling stock, which amounts to about one-third of the total cost, whereas the cost for the river does not include boats and barges, nor does it include anything to correspond to shops, fuel and water stations, freight and passenger stations, or terminal facilities in general, which form so large a part of the cost of a railroad. It is really equivalent to the cost of the roadway only, which, in the case of the Pere Marquette Railway, amounts to only about one-third of the total.

TABLE 13.

	Railroads in United States.	Ohio River.	Percentage of railroad.
Length, in miles	250 183	968.5	0.39
Tons of freight	2 333 000 000	8 280 520	0.35
Tons of freight per mile of length	9 065	8 550	94.3
Ton-miles	416 211 000 000	749 120 486	0.18
Ton-miles per mile of length	1 663 228	773 485	46.5
Cost, including equipment	$22 681 000 000	.....	.....
Cost per mile, including equipment	$ 90 658	.....	.....
Estimated cost of improvement	.....	$110 716 177	.....
Estimated cost per mile of improvement	.....	$ 114 318	.....

In 1923, the average railway revenue per ton-mile was 1.116 cents. On the Pere Marquette Railway the average revenue per ton-mile was 1.118 cents, which was disbursed, as follows:

	Cents.
Maintenance of way and structures	0.141
Maintenance of equipment	0.233
Transportation	0.390
Traffic, general and miscellaneous	0.063
Taxes	0.044
Rentals	0.071
Interest	0.053
Surplus	0.123
Total	1.118

This distribution is on the assumption that the ratio of expense to revenue is the same for freight as for all traffic.

Data are not available for arriving with accuracy at corresponding figures for Ohio River traffic. However, the uncertain factors are not important, so that a total may be reached, which is fairly comparable with that for railroads.

The improvement project will probably be completed within the next three or four years at a cost now estimated at $110 000 000, on which interest at 4% would be $4 400 000. The maintenance in 1923, with thirty-seven dams in operation, cost $1 420 574, so it may be assumed that the cost of maintenance of the completed project will average $2 000 000 per year.

Depreciation on the railroads is included in their maintenance cost, but not in the figures given for the river. In a paper on "Traffic on the Ohio River"*, Mr. Charles Whiting Baker states that: "The first dams built on the Ohio River already require reconstruction. A depreciation charge of 1½% allows at least as long a life for these works as can safely be assumed." This rate gives a yearly depreciation charge of $1 650 000.

The Government, by making this expenditure, will have withdrawn $110 000 000 from the taxable wealth of the nation, on which otherwise it would be receiving taxes. A fair comparison with railroad costs, therefore, should

* *Engineering News-Record*, January 15, 1920.

include taxes on this amount. In 1923 the railroads paid taxes of $332 000 000 on an investment of $22 681 000 000, or at the rate of 1.46%, which applied to the cost of $110 000 000 is $1 606 000.

The total annual charge against the improvement is summed up as follows:

Interest at 4%	$4 400 000
Depreciation at 1½%	1 650 000
Taxes at 1.46%	1 606 000
Maintenance	2 000 000
Total	$9 656 000

This amounts to a cost of 1.29 cents per ton-mile, based on the volume of traffic for 1923. As the volume of traffic decreases, this cost will increase.

This charge does not include the amount paid the carriers for actually moving the freight. Such figures are not available, but H. G. Moulton, M. Am. Soc. C. E., has estimated* that a rate of 0.089 cent per ton-mile would be necessary to enable a carrier to haul coal from Pittsburgh to Cairo at a profit of 5% on its investment. Although coal constitutes by far the greater bulk of the tonnage, there is enough other material handled at a much higher rate to raise the average rate level. Further, this rate assumes a through movement from Pittsburgh to Cincinnati; but the average haul on all traffic is only 90 miles, with correspondingly greater terminal delays. These two factors would result in at least doubling the rate quoted, and the increase in cost of labor, fuel, etc., since this estimate was made, would add about 60% more to adjust it to present-day costs. These adjustments would raise Mr. Moulton's estimate to approximately 0.27 cent per ton-mile, or about one-fourth the rail rate. Of course, rates on most commodities are much higher, for there is little competition by water, and rates are based largely on railroad competition.

River carriers no longer make the rates; instead, they adjust their rates to a little below the scheduled rate of the railroads, which is based on the experience of all the railroads of the United States and must stand the test of study by the Interstate Commerce Commission, a fact-finding body. This new condition has come about through the shifting of traffic from water to railroad, and the attendant specialization of traffic on the river.

The average rate is kept down by the relatively large tonnage of coal; but making all due allowance for this, it is not probable that the average cost is less than 0.27 cent per ton-mile, if interest, taxes, depreciation, and maintenance on the floating equipment, in addition to the actual cost of operation, are properly taken into account.

Adding the cost of operation, 0.27 cent, to the ton-mile charge for improvements, gives a total ton-mile cost of 1.56 cents, which is 40% greater than the rail rate. Even this figure is not comparable to the railroad cost per ton-mile, as a ton-mile by river is not the equivalent of a ton-mile by rail. All towns

* "Waterways versus Railways", 1912.

of any considerable size on the river are also accessible by rail. Table 14 shows a comparison of distances by water and the shortest rail routes.

TABLE 14.

Place.	Rail.	River.	Ratio: River to rail.
Pittsburgh to Wheeling, W. Va.	68	90	1.32
" " Cincinnati, Ohio.	326	468	1.42
" " Louisville, Ky.	455	604	1.33
" " Evansville, Ind.	509	784	1.54
" " Cairo, Ill.	670	968	1.45
Total.	2028	2914	1.44

In order to obtain a fair comparison of rail and river cost it is necessary, therefore, to multiply the river cost by 1.44, resulting in a cost of 2.24 cents per ton-mile by river, as against 1.116 cents by rail, or just twice as much. There are two other features which, if taken into account, would further modify this comparison to the advantage of the railroads. Coal, sand, and gravel constitute 90% of the river traffic, which is more than twice the proportion on the railroads. Railroad rates on these commodities are considerably lower than the average, and if such rates were used in this comparison instead of the average, it would result in a still more unfavorable showing for the river. Further, the rail rate of 1.116 cents per ton-mile covers revenue freight only. The traffic figures on the Ohio, as compiled by U. S. Engineers, may be based only on revenue freight, but it is probable that they include all freight moved on the river, as well as the fuel for steamboats and the materials used in constructing the river improvements. If this is true, a cost per ton-mile for river traffic, based only on revenue tonnage, would be appreciably higher. To sum up, it may be said conservatively that river transportation costs at least twice as much as railway transportation. In addition to costing twice as much, river traffic is subject to other disadvantages. It is a slow movement down stream, and much slower up stream. It is subject to interruption from the periodic floods and even ice at certain times.

River transportation is not comparable with railroad transportation in regard to service, inasmuch as it is limited as to point of loading and unloading. In the case of the railroads, the service is not thus restricted; and to this is due no doubt the development of the railroads in the river territory to the disadvantage of water-borne transportation.

This comparison shows that as a transportation facility, the Ohio River may be likened to a very crooked railroad of similar length with less than one-half the average traffic density; with a very badly balanced traffic, but with grades favorable to the heavier movement; with a roadbed which cost more than three times that of the average railroad; and operating at a total cost per ton-mile at least twice that of the average railroad. Fortunately for the

shipper on this route, he does not have to pay interest, taxes, depreciation, or upkeep on its roadway, for this expense is borne by the whole United States.

This brings us to the other phase of this discussion: How Ohio River transportation and railway transportation affect each other. When the writer began this brief study, his impression was that, in this sense, there was no relation between the two. Ohio River traffic seemed so self-contained, so independent of rail transportation, and so restricted to local traffic and to certain commodities which it can handle to advantage, that he failed to see much connection between it and transportation at large. The history of river and railroads since the latter invaded the Ohio Valley, however, shows that the railroads have had a very unfavorable effect on river traffic. On the other hand, the influence of river traffic on the railroads has been negligible, although it has resulted in favoring certain communities at the expense of others, as will be shown later.

The steamboat was invented nearly a generation before the locomotive, and water transportation was in full swing on the Ohio before the railroads arrived. As the railroads developed, however, the cost of transportation was reduced, although it was fifty years before they could seriously compete with water traffic. As this reduction continued, the railroads made serious inroads on river traffic. This reduction in cost of rail transportation, if measured by the purchasing power of the dollar, is still going on, and there is every reason to believe that it will continue indefinitely. On the other hand, river transportation has made little or no progress in that direction, and, from its very nature, will not be able to do so. The result may be noted in the trend of traffic on the Ohio. The peak was reached in 1900, since which time it has grown less at a fairly uniform rate, if the fluctuations due to varying business conditions are eliminated. This is shown in Table 15, which also shows the increase of railroad freight traffic for the same periods.

TABLE 15.

Year.	Tons of Freight.		Percentage.
	Ohio River.	Railroads.	
1900	14 054 322	1 081 983 301	1.30
1910	11 111 216	1 849 900 101	0.60
1920	9 869 325	2 427 622 267	0.41
1923	8 280 520	2 411 239 000	0.34

An editorial in *Engineering News* of May 4, 1916, stated that "Commerce has practically deserted most of the inland waterways. The great and controlling cause is the development of railways." This is undoubtedly true, but there are other contributing causes. The mines that can ship by river to advantage, on account of being directly on the river bank, are becoming exhausted, and the new mines that are being opened, are inland and are served by railroads.

The production of coal, per capita, is declining, not only on the Ohio River, but throughout the United States. This decrease is shown by the following information taken from the reports of the U. S. Geological Survey:

Calendar years.	Production of coal in net tons.
1913	569 961 000
1914	513 523 000
1915	511 617 000
1916	590 101 000
1917	651 399 000
1918	678 212 000
1919	546 155 000
1920	658 264 932
1921	506 395 401
1922	476 951 121
1923	657 446 000
1924	573 494 000 (estimated)

This statement shows that the production in 1924 is practically the same as in 1913. In the meantime, however, the population of the United States had increased from approximately 96 000 000 in 1913 to 112 000 000 in 1924.

The reason for this decline per capita is not difficult to find. The use of electricity has been growing by leaps and bounds, as shown by the following figures obtained from the U. S. Census Bureau:

Year.	Electricity generated, in 1 000 kw-hrs.
1907	5 862 277
1912	11 569 110
1917	25 438 303
1922	40 291 536

Part of this electricity is derived from water power, but the major part is obtained from coal. Much of the coal, however, is consumed at central locations provided with ample transportation facilities. The widening use of electricity results in less transportation of coal whether the electricity is derived from water power or from coal.

Another reason for the decline per capita in the use of coal is the rapidly increasing production of petroleum, as shown in the following figures obtained from reports of the U. S. Geological Survey:

Year.	Production of petroleum, in thousands of barrels of 42 gal.	Year.	Production of petroleum, in thousands of barrels of 42 gal.
1910	172 769	1917	335 316
1911	220 449	1918	355 928
1912	222 935	1919	378 367
1913	248 446	1920	442 929
1914	265 763	1921	472 183
1915	281 104	1922	557 531
1916	300 767	1923	725 702

The automobile is responsible for a large part of this increase, but not for all of it. The majority of the locomotives in the Southwest are now equipped for burning oil, and its use for this purpose is rapidly extending. On January 1, 1924, there were in use on the railroads of the United States 6 763 oil-burning locomotives. Still more marked is the increase in the use of fuel oil for vessels, domestic consumption, etc.

In fact, it is evident that the railroads of the United States have reached their peak of tonnage per capita. The decrease in the quantity of coal transported has been made up to a certain extent by the large quantity of materials handled for highway construction. This will probably continue for many years, but it is doubtful whether at any time it will exceed the tonnage now handled.

The relative decline in coal production will affect both river and rail traffic, but will affect river transportation more seriously, as coal constitutes about three-fourths of the Ohio River traffic, and when it goes, there is nothing to take its place. On the other hand, the railroads will have more capacity to handle higher grades of freight; they now have excess capacity, and could probably handle 25% more business than they do, without taxing their present facilities. For this reason, the declining coal traffic may cause some hardship for a time, but as the country develops, this loss will be more than made up by greater shipment of higher grade commodities.

Railroad freight rates generally are so much higher in Europe than they are in the United States that there is a wider margin for successful operation on the rivers and canals. The average revenue per ton-mile for 1913 in a number of European countries and in the United States is shown in the following tabulation, pre-war figures being chosen in order to eliminate the effect of varying conditions and exchange rates since the war:

	Cents.
Great Britain	2.23
France	1.28
Germany	1.37
Austria-Hungary	1.51
Sweden (1912)*	1.52
Belgium (1912)*	1.13
Holland	1.36
United States	0.729

Waterways have always been favored as to railroad rates for the reason that the original rate structure was based on the existing traffic and competition. This has often resulted in lower rates to towns along the rivers. In his discussion of the admirable paper† by William M. Black, M. Am. Soc. C. E., on "Waterway and Railway Equivalents", Edward Burr, M. Am. Soc. C. E., states that:‡ "The waterways, however, have justified the public's confidence and willingness to spend its money on them, although they may carry little actual

* Figures for 1913 not available.

† *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 538.

‡ *Loc. cit.*, p. 564.

commerce. To use a naval phrase they have the value of a 'fleet in being' ". This may have been true at one time, but Colonel Burr has evidently forgotten the Transportation Act of 1920. This Act establishes a fair return for the railways, and authorizes the Interstate Commerce Commission to adjust rates so that they will earn such a return. This being the case, it is evident that if any community or set of communities enjoys rates lower than they would pay in the usual run of affairs, this deficiency must be made up by other communities which pay a higher rate. Colonel Burr's "fleet in being"—in this instance, the improvement of the Ohio River—serves only to protect those who dwell along the banks of the river in an advantage secured at the expense of other communities. The shipper and consumer in Columbus and Dayton, Ohio, and Indianapolis, Ind., not only help pay for these improvements, but if the improvements fulfill their purpose and stimulate river traffic, the shipper and consumer at inland points will also pay a higher rate on account of them.

It does not seem likely, however, that the completion of the improvement project will result in any considerable increase of river traffic. Coal which formerly went from Pittsburgh to New Orleans is now obtained from Tennessee and Alabama, partly by rail and partly by water. The sand and gravel business is purely local and would have existed in about its present volume if no improvements had been made. In the light of present experience, one is forced to the conclusion that the construction of these works was an economic waste. The Ohio is the one river in the United States on which there seemed to be a fair prospect of developing a large and important traffic. These great expectations have not been realized, and the writer feels it must be admitted that the experiment is a failure.

It is not probable that such an improvement would be undertaken at the present time (1925). The attitude of the people toward the railroads has changed since 1910. The thinking part of the population now realizes that the railroads are its friends and servants, and not its enemies and would-be masters. As a people, Americans think more in economic terms than they did a few years ago. Even so, it is difficult to predict what may result from an active propaganda directed by interested parties and acclaimed by politicians who are seeking a campaign slogan.

There is a lesson to be learned from the results of the Erie Canal. In his Annual Message to the New York Legislature in 1925, Governor Smith stated:

"The Barge Canal, including construction, terminals, grain elevators, repairs, maintenance, operation, and payment of claims for damages, has cost the people since 1905 up to date, $191 626 000; between 1905, when the first canal bonds were sold, up to 1924, inclusive, we have paid in interest $39 880 387, making the total cost of the barge canal to date, $230 881 014."

In the six years following the opening of the new Barge Canal in 1919, the freight averaged 1 640 481 tons. Interest on the cost of the Canal at 5% is $11 544 000, to which should be added $4 182 696 for maintenance and operation, making a total annual charge of $15 727 000, which equals $9.59 for every ton of freight handled.

In 1911, when the agitation for a deep waterway from the Great Lakes to New Orleans was at its height, Mr. H. G. Moulton, after describing the earlier waves of popular enthusiasm for the development of waterways, stated:

"Attention should be directed to the incessant suggestion in public discussion and in the press that transportation upon our rivers and canals should be revived. The remarkable conjunction of influences should be recalled, namely, the lingering glory of our waterways, the widespread movement for the conservation of all our natural resources, the relation of waterways to the reclamation of flooded lands, to the development of water power, and to sanitation, the supposed remarkable cheapness of water transportation, the opposition to the monopolistic tendencies of the railways, the inadequacy of the railway service to meet the country's needs, the alleged benefits of waterways even to the railways, the avowed advocacy of waterway development by railroad men, and the extensive use of waterways in foreign countries. Finally, it should be noted that, in addition to this incessant and broadside suggestion, the movement has had the active support of some economists, and of many prominent business men and politicians, who have served to give the necessary sanction of authority. Under such a cumulation of causes and combination of influences, it was utterly impossible for the average individual to weigh the various arguments which were presented or to subject them to the test of reason; and it is not surprising that a large portion of the populace should have grown excited over the matter and jumped to the conclusion that the industrial growth of the country is fundamentally dependent upon the development of water transportation."

The country is in the midst of a similar agitation for the "Lakes-to-Ocean" waterway. It is to be hoped that a decision in regard to this gigantic project will only be reached after it has been most carefully considered in all its engineering and economic aspects, and that such a decision shall be made on the basis of the findings of the most expert investigators and not in response to an ill-informed and more or less hysterical popular enthusiasm, as has too frequently been the case in the past.

RIVER-RAIL TERMINAL

By Julian A. Pollak,* Esq.

What is the meaning of a river-rail terminal? First, it means that the river will help the railroads; second, it means that the railroads will help the river; and, finally, that both will help the port as well as the so-called hinterland. Every city of prominence and importance has been made in two ways—either by water, such as lakes and seaports, or by railroads. The largest cities in the United States, and those of the greatest importance, have a combination of both water and rail. New York, N. Y., Chicago, Ill., Cleveland, Ohio, Baltimore, Md., Pittsburgh, Pa., Detroit, Mich., and San Francisco, Calif., are a few examples of the wonderful combination of water and rail.

Engineers are familiar with the improvement for navigation of the Ohio River and the great plan of development of inland waterways. When this entire program is complete in the near future, the question is, what next? The answer to this question is the problem of each locality so situated that it can and will use the facilities at its disposal. For this reason the writer will confine his remarks to a definite locality—the City of Cincinnati, Ohio.

Begin with a natural highway equivalent to a 10-track trunk line from Pittsburgh to Cincinnati, built at a total cost of $103 000 000 for engineering development to make it navigable for approximately twelve months in the year, barring ice and exceptional conditions. When this waterway is completed, it will connect with other waterways such as the Mississippi River which, in turn, connects with seaport, ocean, canal, and more ocean.

Locally, this means that a single city on the banks of the Ohio River begins to think in terms of New Orleans, La., Seattle, Wash., even Hong Kong, China, to say nothing of neighboring cities such as Pittsburgh, Pa., Louisville, Ky., and St. Louis, Mo. By visualizing such commercial connections, the inland neighbors in Springfield, Columbus, and Dayton, Ohio, will see that trade opportunities await them also.

It is obvious that with a highway passing the door, with money already spent on river improvements, and with trade developing in such a startling manner, that locally the citizens of Cincinnati should think about handling it. When millions of dollars are being spent on river craft, such craft should be invited to stop at this port.

One of the difficulties in the interchange of traffic between water and rail is the transfer, the cost of which in money and time must be reduced to a minimum. It must be done in the most expeditious and cheapest manner which modern science can provide. The key to securing this minimum of time and expense in transfer is the terminal—the rail-water terminal located on the banks of the navigable river, connected by belt line with all the railroads serving the community, and provided with cranes and other modern

* Vice-Pres., Pollak Steel Co., Cincinnati, Ohio.

facilities for transferring freight between the warehouse and the boat, or the boat and the car, cheaply and expeditiously; and it follows that this key must be provided. Who shall provide it, the United States, the States, or the political sub-divisions—the municipalities?

In order to handle this approaching situation, a river-rail transfer company has been formed in Cincinnati to connect the rail and water facilities. The first idea was to form a company which eventually would become a municipal enterprise, thus opening the Port of Cincinnati to all. Owing to the lack of funds in the City Treasury, as well as the political complications that might arise, it was decided to organize this company other than municipal and strictly on a commercial basis and for profit. The advantage of such a plan is that it stimulates the individual initiative which developed the railroads and their terminals.

The group interested plans to make this enterprise quasi-civic by encouraging the large and small shipper alike to share in the company. There are no large stock subscriptions, but it is planned to have a city-wide list of stockholders. Already the subscription list includes industrials, lawyers, department stores, advertising agencies, insurance companies, and banks—some are directly interested and others are interested purely for civic reasons. The company will be free from any monopolistic tendency, and such that any one can have any commodity handled at any time. The project, in a sense, is pioneer work, for the company has neither handled costs nor guaranteed shippers, but it has faith in water transportation, and feels that if the Congress of the United States has sufficient faith in the project to make the Ohio navigable, the citizens should have enough confidence to use such facilities.

In order to design a transfer terminal to accommodate a variety of shippers, many things must be considered before proceeding with the work. First, there is the usual incorporation to cover the business aims or business franchise; next, the location of property easily accessible to the railroads and automobile trucks. This is the first problem, because, in addition to being on the water, the facilities must be above high water for protection of machinery, storage, railroads, and streets. A high abrupt river bank will overcome the flood-water obstacle, but when the bank is abrupt, the cranes must be of ample capacity and have sufficient swing to reach the barge in pool stage as well as the top of the bank where the tracks and trucks are situated.

The next problem is a natural harbor, free from ice, and situated so that drift does not injure the barges moored for unloading and loading. In this respect valuable assistance was obtained from the Government engineers who aided by surveys and reviewed the plans. When the location and plans were submitted to the Government engineers the permits and harbor-line locations were granted. From this stage, it was possible to estimate the cost of dredging, excavation, piling, fill, and tracks, and thus work back to a first unit capacity for crane, storage, and handling.

Added to all this is the usual easements, property rights of approach, and arrangements with the railroads. The writer has only attempted to describe

briefly a few of the problems involved in locating a transfer terminal with the idea that some engineers may utilize the experience of the company in so far as it has gone.

It is felt that now is the time to go ahead so that when the 9-ft. stage is completed, facilities will be ready to handle the traffic and to point out to others that there is ample room for more companies of a similar character to do likewise.

DISCUSSION

R. N. Begien,* M. Am. Soc. C. E. (by letter).—Prior to the era of railway building, the Ohio River, then a navigable stream during certain parts of the year, was the principal means of transportation and communication for a large tributary territory. As the railway lines were extended across the mountains to Ohio River points, river transportation came to be used conjointly with railway transportation in serving this territory and in reaching communities which were without a railway. As the railway system of the United States developed, competition between the river and the railways grew apace and the joint rail and river transportation was utilized less and less, but it has never been entirely superseded and is still used to good advantage in some instances.

The construction of the Chesapeake and Ohio Railway to Huntington, W. Va., on the Ohio River, was completed January 29, 1873. From that time until August, 1889, when the extension of the road to Cincinnati, Ohio, was placed in operation, the Ohio River formed the connecting link for Chesapeake and Ohio traffic between Huntington and Cincinnati. The river was thus used as an adjunct to the railway in reaching this important city.

Coal from inland mines is shipped in some volume by rail to river points and then moved by barge and towage to industries which the originating railroad does not reach, either by its own rails or by satisfactory through rates with other lines. In this manner river transportation is still being used as a supplement to railroad transportation, and to the advantage not only of industries but of individual railroads.

When the Chesapeake and Ohio Railroad was extended to Cincinnati, there immediately arose a sharp competition between the railway and the steamboats on the river. This competition still prevails to some extent, for the influence of the river has been, and still is, a factor in the determination of rates on coal. On other business, however, the effect of this competition is negligible and is virtually ignored in present practice.

At one time quite low rates on local merchandise and miscellaneous freights along the Ohio River were made to meet the competition of the irregular steamboats, but it was found that reliable service was of greater importance than the lower rates. Accordingly, rates which were thought to be fair and reasonable were established and since then, notwithstanding the operation of some river steamboats, the local business along the river handled by the railway has continued to increase and the railway has retained its share of the competitive business through superior service.

During the past fifty years a number of steamship companies of apparently ample financial strength and other resources have engaged in transportation on the Ohio River, but they have dropped out one by one and now only a few of them are operating as common carriers. The territory is restricted, the cost

* Vice-Pres., in Chg. of Operation, C. & O. Ry., Richmond, Va.

of transferring freight from cars to boats and *vice versa* is high, and comparatively few commodities can be handled advantageously. These factors combined with the hazards and seasonal character of river transportation and the competition of efficient railroad transportation at low cost have reduced river transportation to a minimum.

It is well to emphasize that in the development of American industry reliable transportation has been found of such great value as to constitute an essential. Dependability is the important thing. The transportation afforded by the railways, at somewhat higher cost perhaps, has proved to be of greater economic value than that provided by the less dependable and more restricted inland waterways.

The traffic handled on the Ohio River, excluding that moved from shore to shore by the ferries, for the period 1918 to 1923, inclusive, is as follows:

Year.	Tons.
1918	6 171 413
1919	5 004 337
1920	9 382 463
1921	7 307 880
1922	6 291 825
1923	8 280 520
Total	42 438 478
Average	7 073 080

The tonnage of 1923 was made up as shown in Table 16. It is apparent that the volume of business is subject to quite wide fluctuations, this being brought about by variations in the total volume of available traffic; by the number and extent of interruptions to navigation by low water, ice, and floods; by railroad competition; and, moreover, by railroad congestion.

Of the total tonnage for 1923, minerals (coal) constituted 90%, ore, metals, etc., 5%, and chemicals 2½%, leaving 2½%, or about 200 000 tons of other freight. Assuming 20 tons per car this would amount to 10 000 car loads. Any one of the great railroad systems which serve the Ohio River territory will load this number of cars in from 1 to 3 days.

Under favorable conditions river transportation is well adapted to handling certain tonnage which moves in large volume to consuming industries located on the river banks. The Monongahela River, for example, is used by the steel mills and other industries in the Pittsburgh District for transporting coal from the mines to the plants. This coal is dumped by the mine tipples into barges and is unloaded from them by bucket conveyors or other mechanical devices, so that transportation is afforded at low cost to the users; but even in this case there are substantially no common carriers in operation, and the river bears the same relation to the users as an industrial railroad bears to the industry which it serves.

In the Annual Report of the Chief of Engineers, U. S. Army, 1924, the following items in connection with the Ohio River improvements will be found:

Net amount expended on all projects to June 30, 1924	$76 631 552
Total appropriations to date of this report	86 406 577
Amount estimated required to be appropriated for completion of existing projects	24 309 600
Total estimated to complete projects (appropriated and to be appropriated)	110 716 177

TABLE 16.

Commodity.	Tons.	Percentage.
Minerals (non-metallic)	7 483 126	90.4
Ores, metals, etc.	389 792	4.7
Chemicals	208 069	2.5
Wood and paper	141 673	1.7
Vegetable food products	35 068	0.4
Animals and products	13 392	0.2
Machinery and vehicles	3 531	0.1
Textiles	2 041	
Miscellaneous	3 828	
Total	8 280 520	100.0

Interest on the total estimated cost of the completed projects at 4½%, amounts to $4 982 228 per annum. The cost of operation and maintenance of the Ohio River locks and dams for the fiscal year ending June 30, 1924, was $1 420 575. Assuming a proportionate increase in these costs as the project is continued, the amount per annum on completion will be $2 052 427; adding the interest to this it will be found that a total annual charge of $7 034 655 will be required by the Ohio River waterway.

It has not been practicable to make a reliable estimate of the cost of handling miscellaneous freight by river transportation because of the lack of accurate information and the quite wide variation in the methods followed by the different users of the river. Believing, however, that some comparison of the cost of river and rail transportation would be of interest, an effort has been made to determine the cost of handling coal, which amounts to 90% of the river traffic, from inland mines to a river point in the vicinity of Huntington, thence by river to another river point in the vicinity of Cincinnati, and also by river and rail to an inland point beyond, as an example of which Indianapolis, Ind., has been selected. Although admitting the probability of considerable variation in the cost of dumping, towing, and elevating coal, it is thought that the estimates given in Table 17 are sufficiently accurate and representative for the purpose.

Table 17 indicates that a probable saving by river transportation of 28 cents per ton to river points (rail delivery), and of 12 cents per ton to inland points can be made. For river-side industries the saving would be about 50 cents per ton. Any large increase in this tonnage would undoubtedly have to go principally to inland destinations. Assuming 20 cents as the average, the river traffic would have to reach a total volume of approximately 35 000 000

tons for the saving to equal the interest charges on the capital expenditure and the annual cost of operating and maintaining the river improvements. This is four times the tonnage of the peak year and about five times that of the average six-year period ending with 1923.

TABLE 17.

	To river point (Cincinnati) per ton.	To inland point (Indianapolis) per ton.
Railroad rate, mines to river	$0.50	$0.50
Dumping cost (estimated)	0.06	0.06
Towing cost "	0.55	0.55
Elevating cost "	0.25	0.25
Railroad switching rate	0.25	....
Railroad rate, river to destination	....	1.01
Total	$1.61	$2.40
Railroad rate, mines to destination	$1.89	$2.52

An effort has been made to ascertain what effect the lower cost of river transportation has on the prices of coal in the communities along the river having both rail and water transportation. No reason could be found for believing that the river has any appreciable influence. The price of coal, both retail and wholesale, seems to be fixed on the basis of the rail rates, so that any saving in the cost of transportation by river, as compared with that by rail, is not transmitted to the consumer.

The formation of ice in the Ohio River during severe winter weather renders it ineffective as a means of transportation for one to three months at a time. During such interruptions the burden of handling the tonnage normally moved by the river is thrown upon the railroads. It is during severe weather that the railroads are subjected to the greatest load, not only because the effectiveness of locomotives is from 20 to 50% less than during summer weather, due to increased resistance and the greater demands on the boiler, but also because the consumption of coal and other fuel for industrial and domestic uses is greatest during these seasons. If, therefore, the railroads are to handle the normal river traffic under such conditions, it will mean either one or two things:

1.—That they will have to provide facilities, consisting of locomotives, cars, engine-houses, shops, yards, etc., to take care of this business for a short time each year, or at intervals of two or three years, the cost of which in interest, taxes, and maintenance charges will have to be borne by the other traffic through a higher general average of rates.

2.—If such additional facilities are not provided, the normal railroad traffic increased by the tonnage from the river during severe winter seasons will so tax the railroad facilities that the entire railroad transportation system in the river territory will become congested, traffic will be seriously delayed, the cost of handling it will be unduly increased, and industry and business will suffer. At the same time the capital expenditures involved in the river

improvements and the steamboat and other shipping facilities will lie idle. This means, of course, that the rates for river transportation must be high enough to cover the fixed charges and operating costs of the river transportation companies during these periods of enforced idleness.

There is little doubt but that through the proper development of their facilities all the transportation required in the territory served by the Ohio River can be provided by the railroad alone at less cost than the same transportation can be provided jointly by the river and the railroads. It is true that by far the greater part of the capital required for river development is furnished by the United States Government, and that the comparatively few industries and individuals who make use of river transportation contribute a very small part toward the interest and carrying charges of such improvements. Nevertheless, these charges have to be borne by some one, and, in the last analysis, they constitute a burden in the form of taxes on industry in general, the railroad industry not escaping its share.

L. D. Cornish,* M. Am. Soc. C. E.—There is an important improvement that is under construction by the State of Illinois, namely, that of a 65-mile stretch of the Des Plaines and Illinois Rivers to connect the Great Lakes with the Mississippi River System. That improvement runs from Lockport, forty miles south of Chicago and the terminus of the Chicago Sanitary Canal, down to La Salle, which is the head of navigation on the Illinois River. The Illinois Waterway will have locks of the same dimensions as those on the Ohio River, consequently, the tonnage capacity will be 9 000 in one cargo; the capacity of the entire waterway per year is estimated at 60 000 000 tons.

The paper by Colonel Kutz is a valuable and timely contribution on the subject of inland waterway transportation. In the past much has been said about the engineering design or construction of waterways, but not enough about the economics of waterway transportation. Such inland waterways as this country possesses have been obtained against the persistent opposition of powerful interests that now maintain that the improvement and maintenance of waterways is unsound, that waterway tonnage is decreasing, and "that all the canals and other inland waterways planned would not make a dent in the American transportation problem", to quote from a recent statement† by Mr. Charles H. Markham.

A summary of Columns (3), (4), and (5) of Table 3 of Colonel Kutz's paper shows that the tonnage in 1924 was 31% greater than in 1913, and 10% greater than the average for the last five years. This indicates a very healthy condition in view of the fact that the main line, the Ohio River, is not only incompleted as to its total length, but has several widely separated incompleted sections which prevent the economical development of through transportation. If statistics should be gathered to show the amount of money that has been expended by private capital in the past three years, and is planned to be spent in the next five years, in the development of terminals and floating plant for the Ohio River System, the total would give a better indication of

* Asst. Chf. Engr., Div. of Waterways, State of Illinois, Chicago, Ill.

† *Chicago Daily News*, February 23, 1925.

the future of transportation on the Ohio than can be secured from tonnage statistics of the past and present.

In any question of national importance, much depends on the point of view, and this is true of waterways. Many advocates see only the waterway side; its opponents, only the railroad side, or the point of view of materialistic capitalists. The latter ask, Will it pay interest? If not, away with it. This is the view expressed by the National Waterways Commission in the paper from which extracts have been quoted by Colonel Kutz, who expresses a similar thought when he considers the right of the people to "have the products of the farm, mine, and factory move from origin to destination by the cheapest means". Note his use of that little word "move", then reflect on the periods of railroad congestion during the past twenty years when products could not be moved, or could only be moved so slowly that thirty or sixty days' credits were due before the goods were received. Also, reflect on the fact that tonnage doubles every decade, and then try to estimate what the transportation needs of this country will be thirty years hence.

Professor Luther forecasts the future national prosperity, and places transportation as the most cardinal requirement. It is the speaker's belief that thirty years hence the need will be so great that no method or artery of transportation will be considered uneconomical. If such be only partly true, then it is the duty of this generation to give proper consideration to the needs of the next, and to continue improving the principal waterways. If such standards had prevailed in the last century as prevail to-day, the United States would not be the leading nation of the world, because one-half of the present railroad mileage would probably never have been built, for fear of the railroads becoming bankrupt. In fact, about two-thirds of those railroads did become bankrupt. Yet who would dare assert now that the construction of those thousands of miles of railroads was not justified?

If such standards should govern waterway improvement, they should also govern highway construction. Fortunately, the people of the State of Illinois and its Chief Executive do not judge the needs of that State by those standards. If they did, Illinois would not be, as it is to-day, the leading State on hard road construction. The State has approximately 3 000 miles of hard roads completed and expects to build 5 000 more. Judged by economic considerations of interest, maintenance, and operating cost, it may be unsound, but judged by the need of the people of Illinois to move, not only their goods, but themselves, they feel that it is justified.

Charles S. Churchill,* M. Am. Soc. C. E.—The paper by Colonel Kutz, brings out many points of interest and value in connection with the great improvement work on the Ohio River; and the tabulated statements, tables, and diagrams contained therein have enabled Messrs. Alfred and Begien to make correct and careful comparisons between the true costs of such improved transportation and the corresponding costs of railroads. On this account, as well as many others, the paper by Colonel Kutz is to be commended. The discussions of Messrs. Alfred and Begien contain very reliable statements

* Vice-Pres., in Chg. of Purchases, Real Estate and Valuation, N. & W. Ry., Roanoke, Va.

of railroad statistics which have been compared with the statistics and statements of Colonel Kutz, and deserve the careful consideration, not only of men engaged in, and users of, river transportation, but also an equally careful consideration of men engaged in, and users of, railroad transportation.

When considered in connection with the discussions of Messrs. Begien and Alfred, the paper may become of great use to those officials of the Government who are engaged either in the improvement of waterways, or in the recommendations of further improvements, and especially to citizens who pay their individual share toward the cost of such improvements and who have a right to know that the expenditure is in all particulars a useful one.

That there were no unanswerable objections to these improvements of water transportation on the Ohio River itself seems to be proved by the near and successful completion of the work. The undertaking had a general public approval, and it was not made a political question. However, in the past, some of the improvements by the Government on the smaller rivers have been made on political solicitation and at times against the best judgment of the Government engineers. Some improvements of this kind were made on branches of the Ohio River, and are included in Tables 3 and 5 presented by Colonel Kutz. The speaker refers to some of this work as being of vital interest to the public, both as to the mistaken local or political reason for its undertaking; the consequent small present public use, and also the great relative fixed charges, plus maintenance and operation costs, and consequent loss of public funds; and the importance of preventing other such wastes of Government funds.

In the spring of 1911, the speaker had occasion to interview J. G. Warren, Lt.-Col., Corps of Engineers, U. S. A. (now Col., U. S. A. (*Retired*)), M. Am. Soc. C. E., who was then Chairman of a Board of three Army Engineers detailed to pass on the question of the improvement and enlargement of the bridge of the Norfolk and Western Railway crossing the Ohio River at Kenova, W. Va. After this business matter was finished, mention was made of the expenditure of moneys on rivers smaller than the Ohio. Colonel Warren became somewhat reminiscent and on this subject he said in substance that when he was a Lieutenant and afterward as Captain of Engineers, his recommendations against the advisability of an improvement on such a river amounted to something. Later, with his higher rank, it was often not worth a tinker's dam. In explanation, Colonel Warren stated that politics had often governed the appropriation of Government funds directly against the recommendation of the Government engineering official in charge of the District. One of these cases was the improvement of the Big Sandy River. Another case was a branch of the Ohio River in Kentucky.

Later, the writer met Colonel Warren's Assistant Engineer, at one time connected with the Norfolk and Western Railway, who stated that he had just completed the determination of the maintenance costs of the Erie Canal and had found that these costs were higher per ton-mile than the rates being actually received by the railroads of New York State for carrying the same kinds of freight. These data were regarded by him as proof of the lack of

wisdom in recommending the expenditure of large sums of money on canals, especially in territory where railroads exist.

Colonel Kutz presents Table 5 which shows that the fixed charges alone, in mills per ton-mile, on the Ohio River and tributary improvements averaged 4.6 mills. The large sections of the Ohio itself, together with the Monongahela and Allegheny, averaged 4.2 mills; the Big Sandy, however, was 211.0 mills per ton mile; the Little Kanawha River, 29.7 mills; the Cumberland River, 24.5 mills; and the Muskingum River, 16.1 mills. By making use also of the data in Table 3, which gives the cost of "operation and maintenance" in mills per ton-mile, the total of fixed charges, maintenance, and operation, for the Ohio, Allegheny, and Monongahela are found to have averaged 5.88 mills per ton-mile; whereas the Big Sandy was 288.0 mills; the Little Kanawha, 51.3 mills; the Cumberland, 31.1 mills; and the Muskingum, 24.5 mills.

As the economic value of any great engineering work or improvement can be determined only by a complete knowledge of the fixed charges and the maintenance and operation costs of the entire plant, it would have been better if Table 5 had been made complete by the inclusion of all these items.

Charles Wuest, Jr.,* Assoc. M. Am. Soc. C. E.—Having been engaged in railroad as well as river improvement work, the speaker feels that at present his is a neutral position in a discussion concerning the relative merits of railways or waterways as freight carriers. As engineer for a corporation producing about 200 000 tons of paving brick per year, he now has the viewpoint of a contributor to the shipping wants of the carriers.

Under the head of "Economic Comparisons" (page 1118) Colonel Kutz states:

"If the points of origin and destination and the ton-mileage of each commodity hauled on these rivers are known, as well as the water haulage costs, the direct benefits or savings resulting from their use can be readily ascertained by comparison with existing rail rates, and their economic justification determined by comparing the savings or benefits with the fixed charges."

The question that presents itself is, To whom are these direct benefits or savings to accrue? It is here conceded that waterways afford an easy, cheap, and most natural means of moving heavy, bulky freight, and that the development of the rivers should be encouraged to help bring about a general reduction of the prevailing high railroad freight rates. Let us see, however, how far the latter is true at present. On the basis of recent experiences, there seems to be little encouragement in the action of several operating companies on the Ohio River to produce the much hoped-for low freight rates, because of low transportation costs.

The transportation companies in quoting rates for the transportation of freight by river are not blind to opportunities afforded them by a beneficent Government in opening a way for the conduct of their business, but are totally indifferent about benefits which should rightfully, and, at least, in part, accrue to the public which provides for the way.

In April, 1925, the company which the speaker represents had a prospect of shipping 8 000 tons of paving brick from Portsmouth, Ohio, to Madison, Ind.

* Chf. Engr., The Peebles Paving Brick Co., Portsmouth, Ohio.

Having facilities for shipping by river, as well as by rail, the company requested several transportation companies operating on the Ohio River for rates by barge delivery, in expectation that a low and favorable rate by water would insure the movement. The quotations, with certain restrictions of time in loading and unloading attached, were the same in all cases. The rate quoted was $2 per ton.

Consider the fairness of such a rate in view of what has been said about the costs of transporting coal by water. As coal and paving brick differ little in the classification of bulky, heavy freight, there should be little, if any, difference in actual transportation costs.

Colonel Kutz has stated that, based on the following conditions, 250 miles haul, no back haul, 6 000-ton cargoes in 1 000-ton barges, and wide river and large tonnage, 2.5 mills per ton-mile was a fair measure of haulage cost by waterway. This is practically confirmed by Mr. Alfred, who has placed the cost at 2.7 mills per ton-mile.

By river, the distance from Portsmouth to Madison, is approximately 200 miles. To be conservative, by using the larger of the two figures, the cost of transporting heavy freight for this distance would be 54 cents per ton. The rate asked was $2. This carries with it 270% for profit and overhead. Why?

On other occasions in the past, rates were requested of the same companies for shipments under similar conditions from Portsmouth to Cincinnati, Ohio. As in the previous instance, a rate of $2 per ton was quoted, in one case, equal to, and, in another, in excess of, competing rail rates between the latter points. This distance by river is approximately 110 miles. From Colonel Kutz's Fig. 4, the cost per ton-mile for this distance is shown as approximately 3 mills, therefore, the actual cost of transporting 1 ton of heavy freight, based on Colonel Kutz's specifications, between these points would be 33 cents. The rate quoted was $2 per ton, which carries with it 506% for profit and overhead. Why?

This would seem to indicate that the river transportation companies are basing their rates to river towns on rail competition, or as near to it as they deem safe. It would indicate, too, that this is the reversal of a condition mentioned by Mr. J. H. Bernhard in referring* to the practice of rebating arising from "the unjust practice of railroads in basing rates to river points on water competition."

In conclusion, it may be said that a regulation of such conditions is in order, and that fair rates for river hauling must be established if the work of making the rivers into navigable waterways is to proceed unchallenged.

The speaker wishes to express his disapproval of the practices cited, which he believes tends to destroy the real purpose of the splendid work being done by the U. S. Corps of Engineers in the improvement of the national waterways.

C. E. Grunsky,† Past-President, Am. Soc. C. E.—This discussion indicates the attention which engineers are to-day giving to the economic aspects of their problems.

* *Transactions*, Am. Soc. C. E., Vol. LXXIX (1915), p. 946.

† Cons. Engr. (C. E. Grunsky Co.), San Francisco, Calif.

What would this section of the Middle West be like if there were no Ohio River and if this river had not fixed the transportation rates? The railroads have been compelled to take the water competition into account. In this connection a proposed canal comes to mind which was under consideration about thirty years ago but was never built. It was an easy matter to show that if this canal had been built, as proposed, for the purpose of moving grain crops out of two counties, it would have compelled a reduction in railroad freight rates which, from the standpoint of the two counties mainly involved, would have justified its construction even if it was never actually used for freight transportation. It might have been unfair to the railroads. Some one would have had to pay the cost.

It is only by a thorough study of the economic aspects of such projects that the question of undertaking them can be satisfactorily answered. The economic problems are equally as important as those of an engineering character.

Charles A. Wilson,* M. Am. Soc. C. E.—These papers and the relative discussion raise the question as to rates for transportation by water and rail and the basis on which such rates are now fixed in the United States. The Interstate Commerce Commission has always been inclined to base rates on the cost of the service and, in this, it has been abetted by Congress. It could depend perhaps on no other basis for support by the judiciary of the Government.

The complaint of Mr. Wuest against the water carrier was based on his desire to have the value of the service considered in fixing the water rate. Great efforts have been made before commissions in rate cases to have the value of the service considered. To-day, there is no rule or basis for fixing rates and, in the speaker's opinion, there is no scientific basis for fixing rates alike for all carriers. If the law of supply and demand is sound economics, then the value of the service should be considered.

The railways running along the valley of the chain of the Great Lakes are apparently successfully competing with the water carriers using the lakes. The tonnage of the carriers using the Great Lakes is tremendous, yet there is no serious competition between the lake carriers and the railways. This water transportation carries very little between producer and consumer except by additional services of the rail carrier.

Rail transportation and water transportation can never be considered as competitive. Highway and waterway transportation differ in their functions and capacities for transportation service and if any are to be governmentally regulated all should be regulated by the same agency and that service assigned which each is fitted by its nature to perform best and most economically.

The comparisons disclosed by the papers and the discussion show no cost for the use of waterways, and without such charges a comparison with the railways is not a fair one. If the railway, through the special characteristics of its type of transportation, can deliver a car at the warehouse of the shipper

* Cons. Engr., Cincinnati, Ohio.

(and that service is impossible for the waterway carrier), then before a fair comparison can be made between water and rail transportation the cost of delivering the water-borne freight from the waterway to the store door must also be added to the cost of water transportation. One of the principal functions of the Government is to deal justly between all its citizens, but to encourage some by charter to build railways from their private funds and then for the Government to build other ways, such as highways and waterways, out of public funds and give their free use to other citizens, is neither just nor fair and not to be upheld, at least by fair-minded men. The water carrier is forced to use the rail carrier in gathering and distributing the freight constituting the bulk of its tonnage.

The United States Government through its War Department is improving the rivers and seems to be fostering their use in transportation, but in this latter is ignoring the Interstate Commerce Commission. Until all commerce on these rivers comes under the same Government regulating agency, it cannot be expected that the railways will co-operate willingly with either shippers or river carriers in promoting river and rail interchange.

To place waterways, highways, and railways on a parity, the use of the waterway, the highway, and the railway should be paid for by the user, and their use and the charges therefor, placed under the same Government regulating agency. Without such regulation it is neither fair nor right to charge the railway carriers as seeking to discourage the development of waterways because the railways do not co-operate with river carriers.

HUNTER MCDONALD,* PAST-PRESIDENT, AM. SOC. C. E.—The Cumberland River Terminal, already mentioned, was completed in 1920 out of funds produced by a bond issue of the City of Nashville of $300 000. Its cost consumed practically all the bond issue. It was built on faith that transportation on the Cumberland River would greatly increase in the near future.

A study of the Cumberland River reveals the fact that above Nashville, and for some distance below it, the river flows through a deep gorge which it has eroded through limestone rock. It is bounded, therefore, on each side by rocky hills some distance apart. With the exception of the Tennessee Central Railroad for a short distance below Nashville, it is not, and never will be, paralleled by any railroad on account of the prohibitive cost of construction due largely to its crooked course. The country through which it flows would not sustain a railroad built at such cost. The coal which lies on the upper waters of the Cumberland is beyond the reach of present navigation, and it is a question whether if the river is made navigable as far up as this coal region it would move by water or over the Cincinnati-Southern Railroad, which crosses the Cumberland at Point Burnside, the present head of navigation. Such coal as might be moved out by water would necessarily be from mines adjacent to the river.

If it is incumbent on the Government to furnish transportation to people living along the Cumberland River who cannot hope for rail facilities, then the canalizing of that river for transportation purposes only might have been

* Chf. Engr., N. C. & St. L. Ry., Nashville, Tenn.

justified; but it is not the duty of the nation to furnish at public expense transportation to people living along rivers any more than it is to furnish transportation to communities living along the non-productive branches of railroads. On many such branches, the cost to the present operating companies is such as to require the expenditure of from $2 to $5 for every dollar that is earned. Nevertheless, solvent roads are required in most cases by public authority to continue the operation of these unproductive lines, the burden falling on the stockholders of the carrier as long as the carrier remains solvent. Furthermore, such solvency often depends on the profits derived from through business.

The traffic on the Cumberland River above Nashville is handled by two small steamboats. From Nashville to the mouth of the river, only one boat operates regularly and urgent appeals for support of this line have been made to the citizens of Nashville, such appeals being based upon sentiment and the desirability of controlling competitive railway rates by water competition.

The upper floor of the terminal warehouse at Nashville was rented shortly after its completion and is still rented to a wholesale grocery firm in an effort to meet a part, at least, of the interest on the bonds. It is entirely proper that Nashville should have provided a terminus to take care of the Upper Cumberland trade, but, in constructing the present facilities, the future has been largely and erroneously anticipated.

Mr. Alfred has referred to some extent to conditions in Europe with respect to water-borne freight as compared with those in the United States, but he did not go far enough into the reasons for the existing sentiment in America favorable to freight moving by water. American tourists who travel over Europe come back much impressed by the amount of water-borne commerce on the rivers and inland canals of Europe; but they are ignorant of the conditions which have brought this about.

The industries located along those inland waterways were established and in a flourishing condition many years before railroads were ever thought of. The political influence of these industries and of the people operating craft on the waterways has been so powerful as to throttle the development of the railroads in those countries and they have been prohibited from charging the rates which might have been remunerative but which would take the business away from the water carriers. The result of this policy has been to force the railroads, through foreclosure, into Government ownership, the railroads in Great Britain and a small proportion of those in France being the only privately operated railroads.

Shortly after the Federal Government took over the American railroads, instructions were issued by Walter B. Hines, Assistant Director General of Railroads, to the Regional Directors of the Western and Southern Districts, R. H. Aishton and C. H. Markham, respectively, to investigate and report on the advisability of the Government undertaking to establish and operate barge lines on the Mississippi and the Warrior Rivers. These Regional Directors appointed a committee of which the late John Howe Peyton, M. Am. Soc. C. E., at that time President of The Nashville, Chattanooga and St. Louis Railway,

was Chairman. This Committee held extensive hearings and in May, 1918, submitted its report, which was adverse to the project, such conclusion being based on data fully set out in the report. Having assisted to some extent in the collection of data, the speaker remembers that the five railroads operating between St. Louis, Mo., and Gulf ports had never been congested and were then in position to move speedily and effectively millions of tons more of freight; that they possessed ample ocean terminals; and that congestion on the Eastern seaboard could quickly be relieved if the Government would order the diversion of traffic originating in the West from the congested Eastern ports to Gulf ports and would provide the necessary shipping to take care of such traffic.

It was the conclusion of that Committee that the establishment of the proposed barge lines and their operation by the Government could not be justified under transportation conditions existing at that time.

Now, it is commonly admitted that the Eastern and Western railroad trunk lines were congested during the World War and that they were taken over by the Government largely as a result of this congestion, but, if the speaker remembers the situation correctly, the cause of that congestion was the fact that there was not sufficient shipping at the Atlantic ports to admit of prompt unloading and dispatch of the goods moved to such ports. Everybody knows that damming up the mouth of a river backs up the river. The condition on the railroads was similar. The congestion at the Atlantic terminals prevented further cars being delivered to the seaports and the traffic gradually backed up into the inland terminals, blocking them. This explains to some extent how the blocking of the terminals was progressive and how, by measuring the rate, it was possible to predict when a complete blockade would take place.

Personally, the speaker has never felt that the taking over of the railroads by the Government was a necessary step. If the Government had given the railroads a very short stay of action and if Great Britain had come to the rescue earlier and furnished enough ships to move the goods promptly from the seaports, the railroads would have worked their way out in an entirely satisfactory manner and without Government control.

Harry Taylor,* M. Am. Soc. C. E.—The speaker believes that this discussion and the interest which the Society has shown in this particular question will be of great benefit to the country in general.

There are two factions in the United States that look at river improvement from two different points of view: One thinks that if there were a little more water all their troubles would be over; the other that the rivers are no good anyway, that no matter what is done to them, they will be of no benefit.

The improvements to the Ohio will go quite a long way toward answering the question. It has been stated by Mr. Alfred that if the matter of cost were being considered at the present time, it is doubtful whether the work would be undertaken. Whether that is so, or not, the speaker does not know, but it is perfectly safe to say that if there is no increase in the present business on the river, no one would think of spending the amount of money required to

* Maj.-Gen., U. S. A.; Chf. of Engrs., U. S. A., Washington, D. C.

improve it; but those who have studied the problem do not believe that the present business represents by any means the ultimate amount that will be carried by the river. That may be shown pretty conclusively by looking at what some of the business institutions on the river are doing, such as the steel corporations at Pittsburgh, Pa. Jones and Laughlin and the Carnegie Steel Company are not firms that spend large sums of money in unprofitable business ventures as a rule; and they are spending large sums in the development of floating plants. During the season of the year when there is sufficient water in the Ohio, these companies carry large shipments down the river into the Mississippi, for delivery at St. Louis, Memphis, and New Orleans, and even for shipment abroad. The speaker has recently noted a statement in the press that one of the largest shipments of steel products that had ever left Pittsburgh was recently taken down the Ohio and delivered at Memphis in eleven days from the time of departure. That is not bad time for a railroad, so that the element of slow movement can be omitted.

In making recent allotments for the river improvements, the Ohio River has been given very liberal consideration by the Federal Government. The engineers engaged on this work would like to see the improvements finished, and, with ordinary luck, it is hoped to be able to finish them in the fall of 1929.

That there has not been a very large through movement of freight on the river to date is natural, when it is considered that during much of the year there are only 2 or 3 ft. of water at the lower end, making navigation of the river impracticable. With the improvement completed and with the 9 ft. depth throughout, that handicap will be overcome.

Something of the future of the Ohio River can be predicted from what is happening on the Mississippi. As is probably known, the Government is operating a barge line between St. Louis and New Orleans. The equipment was built during the World War, and a large part of it is not adapted to the service. The towboats are too large and heavy, with too deep draft for the river between Cairo and St. Louis; some of the barges were not exactly suited to the business, and the towboats were picked up where the management could find them; but notwithstanding these physical handicaps, that barge line is developing a large and profitable business.

In addition to the physical handicap that the line had to overcome, the lack of interchange of freight with the railroads had to be met. At present (1925), the barge line has traffic arrangements with 165 railroads, so that it covers practically the entire country. It has been of great benefit to the farms in Kansas. In a pamphlet recently published by the National Rivers and Harbors Congress for distribution among the agriculturists is quoted a statement from an address before the Twentieth Convention of the National Rivers and Harbors Congress held at Washington, D. C., on December 10, 1924, by the Hon. F. E. Frizell, of Larned, Kans., who is a farmer, a cattle raiser, and a member of the State Senate. He said:

"We have learned that the Federal Barge Line between St. Louis and the Gulf has made a substantial reduction in the freight rate on wheat shipped from Kansas for export. The rate from Kansas to New Orleans, all rail, is

30½ cents per 100 lb., while the rail-and-barge rate is 25 cents, a saving of 5½ cents per 100 lb.—something over 3 cents per bushel saved by shipping our wheat from Kansas to either St. Louis or Cairo to reach the northern terminus of the Federal Barge Line. I have it on good authority, in fact from experts, that with the Missouri River properly improved to Kansas City, Kansas, a saving of another 3 cents per bushel could be made to the farmers of Kansas.

"Since the farmer, in effect, pays the freight on all of his wheat to Liverpool (since that market fixes the price of all the wheat whether the wheat is actually exported or not), when we compute the value of Missouri River navigation to the Kansas wheat farmer, we cannot merely calculate the saving on the entire Kansas crop, because, if you raise the price of the export wheat 3 cents per bushel by reducing the cost of the freight to Liverpool by 3 cents, you automatically raise the price of all the wheat crop in Kansas.

"A reduction of 3 cents per bushel in the freight to New Orleans means a saving of $4 500 000 on the 1924 Kansas wheat crop of 150 000 000 bushels. With the Missouri River improved, a net saving of 6 cents per bushel could be made, which would mean a saving of $9 000 000 to Kansas wheat farmers for the year 1924.

"It is estimated that the State of Kansas has raised and sent to the markets of the world an average of 100 000 000 bushels of wheat each year since the plan to improve the Missouri River was first made fourteen years ago, in 1910. That would make the stupendous total of 1 400 000 000 bushels that has been shipped out by Kansas wheat farmers during the fourteen years we have been patiently waiting for Congress to furnish the money to improve this great water highway. It would have cost not to exceed $20 000 000 to improve the river to a permanent depth of 6 ft., but it has cost the wheat farmers of Kansas more than $40 000 000 not to improve the Missouri River as was recommended by the Engineers Corps."

In the fall of 1920 crops were good, the demand was urgent, and prices were high, but the railroads could not furnish cars and the crops remained unmarketed until the demand had been supplied from other sources and prices had been cut in half.

That was a case where, while the river probably could not carry all the wheat that was offered, it might have carried an appreciable portion of it. The small relative amount of commerce carried by the Ohio compared to that carried by the railroads was also referred to by Mr. Frizell. The Panama Canal carries a relatively small commerce as compared with the transcontinental railroads, but, as is well known, the Panama Canal has had a marked effect on transportation conditions in the United States.

The rivers, the speaker believes, should be made a part of a great transportation system; they must fit in as parts of the system. They cannot operate by themselves; they can only reach the cities on their banks. Operating in connection with the railroads, they can reach practically every part of the United States, as the barge line is doing. As to the barge line, it may be stated that, while it is a Government-owned transportation system at present, operated under the authority of Congress, the endeavor is to establish a successful line and then sell it to private transportation interests. The Government has not authorized that line to continue indefinitely. The speaker doubts whether any private corporation could have financed it through its struggle for existence to build up a business. It appears to be reaching a condition, however, where its success is assured, with more business offered to it than it

can possibly handle; and it has these interchange rates established throughout the country.

Reference has also been made by Mr. Alfred to a waterway connecting the Great Lakes and the ocean. The speaker does not know what particular waterway was referred to, whether it was the St. Lawrence Waterway, the one across the State of New York, or that across the State of Ohio. They have all been under consideration.

Several years ago, Congress authorized an investigation of the practicability and advisability of building a barge canal to connect the Ohio River and the Great Lakes. This subject is still under investigation. Congress has also authorized the investigation of the question of the construction of a ship canal across the State of New York. Little progress has been made on this investigation to date, but it may be said that before the existing Barge Canal across the State of New York was constructed the State authorities went into the question as to whether the canal to be constructed should be a barge canal or a ship canal. The ship canal project was rejected as too expensive. Since that time, the cost has increased very greatly.

The St. Lawrence River is being intensively studied unofficially at the present time by Herbert Hoover, Hon. M. Am. Soc. C. E. Probably that waterway will some day be improved. When or how cannot be stated, but on the St. Lawrence River to-day there is being wasted about 4 000 000 h.p., which waste cannot be allowed to go on indefinitely. The power will have to be developed. With the increasing price of coal and the greater need for power, the time will come when the demand for that development will be so great that it cannot be resisted. It is a complicated question, because it involves international problems; it also involves very difficult, but not unsolvable, engineering problems. When it is developed for water power, it will require a comparatively small additional expenditure for navigation. What kind of navigation will take place is a problem that only the future can answer. Something of the same condition exists on the Tennessee River, which is one of the tributaries of the Ohio. The U. S. Corps of Engineers is making a survey at present of the Tennessee River water-shed for navigation and power development. The indications are that between 2 000 000 and 4 000 000 h.p. can be profitably developed. That will involve a system of dams which will practically canalize the river and will make navigation possible with comparatively little additional expense. With the demand for power in the South, which is increasing very rapidly and which is outgrowing the capacity of the present companies, it is only a question of time when that development will be made. Whatever navigation there will be, therefore, on that river, will be added to that on the Ohio. Taking into consideration the development of the Tennessee and of the Ohio, the growth of the Mississippi traffic, and the rapidly increasing interchange of rail and water freight, undoubtedly in time the improvement of the Ohio River will justify itself.

Upon what takes place on the Ohio and the Tennessee Rivers will depend very largely the development on other rivers. Three or four years ago, the streams which the U. S. Engineer Corps had under consideration were divided

into rivers of first importance and rivers of secondary importance. The Ohio, of course, is included under rivers of first importance. Of an appropriation of about $50 000 000, $80 000 was allotted to the rivers of secondary importance, showing a practical standstill with respect to the smaller rivers. Actually, there was a sum larger than $80 000—it amounted to about $700 000 or $800 000 for all the rivers in the country for maintenance, that is, for keeping them *in statu quo,* so that if they were subsequently improved there would be no great difficulties. If all work should stop, there would be an accumulation of sand-bars, which would eventually cost a great deal of money to remove.

In connection with the smaller rivers there was formerly a great deal of politics which controlled largely the appropriations and improvements. In 1902, conditions reached such a stage that Congress directed that a board known as the River and Harbor Board, be authorized to pass on all improvements. Since then there has been practically no improvement authorized by Congress that has not been recommended by that Board. About 70% of all the projects reported on by the Board have been reported unfavorably. Since 1920, Congress has adopted the method of making lump sum appropriations instead of itemized appropriations. Formerly, Congress directed where the money should be spent; it is now appropriated as a lump sum available for allotment by the Chief of Engineers, so that if anything is spent on worthless engineering projects, the Chief of Engineers is responsible.

The Muskingum River was improved many years ago by the State of Ohio, and turned over to the United States to carry. These improvements cost a considerable sum of money. The Big Sandy River was improved by the Government, as was also the Cumberland River, the first appropriation for the latter stream having been made in 1832. While the ton-miles of commerce on those streams is small, the only money being spent on them at present is that necessary to keep up the improvements already made. Those improvements consist of locks and dams, at each of which there is a small crew. The total expenditures on the Big Sandy amount to a few thousand dollars only per annum. The same is true of the Muskingum. On the Cumberland River System the last remaining dam below Nashville was completed in 1924; the expenditures on that stream will also be very small hereafter unless future developments justify further work above Nashville. So that, to say that what is now being spent or that the improvements now being made are for political reasons, is misleading.

W. M. Black,* M. Am. Soc. C. E. (by letter).—Colonel Kutz's valuable paper should be considered together with the papers by H. B. Luther and Frank H. Alfred, Members, Am. Soc. C. E., relating to the same subject, and the discussion on the writer's paper "Waterway and Railway Equivalents".† The diversity in the opinions expressed by the railway officials on the one hand and by the advocates of water transportation on the other is marked and, to the mind of the writer, unfortunate.

* Maj.-Gen., U. S. A. (*Retired*); Cons. Engr. (Black, McKenney & Stewart), Washington, D. C.

† *Transactions,* Am. Soc. C. E., Vol. 88 (1925), pp. 553-577.

The question of transportation is vital to the prosperity of the people. The solution of the many intricate problems involved in its development should be based on the general welfare rather than on the interests of any industry, locality, or section.

The railway is an essential factor of modern economic life. No other agency of transportation as yet devised can to-day do its work. Yet when it is considered that in times past the transportation agency of primary importance has been, successively, the trail, the waterway, and the railway, and that, to-day, the motor truck and the airplane are successfully displacing the railway car for certain transportation uses, it seems possible that some day, the railway in turn may be relegated to a secondary place.

It is a platitude to state that each transportation agency has its own truly economic place and work, and that the nation is entitled to have its transportation bills reduced to a minimum by having each agency perform its economic share of the work. Such is not the case to-day; and is it not because a destructive competition exists between the owners and managers of the various agencies?

Colonel Kutz's Table 9, giving the fixed overhead charges per ton-mile for transportation on the rivers of the Ohio Valley, shows that with the limited use made of these waterways to-day, not only are some of them uneconomical agencies now, but, also, that their time of usefulness seems past and that the propriety of the discontinuance of operations on them should be considered, in conformity with the policy already followed in the cases of some other waterways, as well as of certain branch railways. The other tables in the papers, together with data given in the discussion, show some of the reasons why the tonnage of the waterways is so limited.

Carriage by water, mile for mile, is inherently less costly than carriage by rail. There is less likelihood of breakage, and, within limits, actually quicker delivery. The advent of the motor truck, which has curtailed short-haul railway service, has only increased the value of the waterways by broadening the territory which they can serve.

Why, then, are not the waterways in greater use in their own sphere of usefulness? The writer believes it is because of the improper conception of the use of railways which has produced in the course of years that cumbersome and unstable structure, the railway freight rate tariff.

This tariff is full of inconsistencies and full of discriminations. It is so complicated that only an expert can use it to discover a rate. In 1921, the writer found it necessary to ascertain the rates on certain ordinary package freight in five cases of movement between large cities of the United States. It required 9¾ hours for an expert of the Interstate Commerce Commission to pick out the rates from the mass of matter he had to go over!

The railway freight rate tariff is a subject concerning which railway officials are very sensitive, both as to freight classifications and freight rates. It is defended by many strong arguments, and under existing conditions some of these arguments are unanswerable. It is, however, an inheritance from the days when railways had to struggle for existence as radical and impra-

ticable innovations, and from the later days of destructive competition among the rival roads. In those days public service in return for privileges granted was a secondary thought. The policy of the railway managements was based instead on the desire of gain for themselves. "The public be damned" slogan reflects this thought.

The railway freight tariff is an anomaly in the scheme of government of the United States. It is not in accord with the spirit of the Constitution that any body of men, other than duly elected legislative representatives, should be empowered to tax one community of the United States for the benefit of another, to enforce what is really a protective tariff in favor of one city or locality as against another, or to foster one class of products at the expense of another. This, however, is done by the existing railway freight rate and freight classification system. Proposals for any radical changes are strongly resisted by those now enjoying the favors conferred.

The entire structure is artificial and is almost as unstable as a house of cards. Change it anywhere and there is danger of a complete collapse. Is this a healthy condition for the principal agency of the basis of the nation's welfare—transportation?

In order to obtain its transportation at the lowest cost, the nation requires a co-ordinated transportation system, in which each agency—rail, water, highway, and air—shall perform its economic share of the work. Referring to the claim that "the development of inland waterways will relieve the railways of a large part of their freight traffic that is carried at low rates", Mr. C. H. Markham states:* "The truth about the latter argument is that almost any American railroad would starve to death if its heavy freight business were taken away from it, because that is the freight that pays best."

If this freight can be carried more cheaply by another agency, this is not an entirely fair argument from the standpoint of the general welfare. No sane person can wish the railroads to be other than prosperous. If the full use of waterways would, in truth, kill the railways, or even seriously injure their prosperity, some means of providing an adequate income for them must be furnished.

Since transportation is a fundamental element of commerce, it should be organized and managed on the most economic business basis. Should not a transportation company be prepared and able to utilize the most economical and advantageous class or classes of carrier for any specific cargo offered for a given destination? If each auxiliary transportation agency were used for the work it can do best, and the returns from all placed in a common fund, not only would the cost of transportation be reduced, but the destructive competition, with its resulting artificial tariffs, would also disappear. A transportation company should control and utilize the operation of carriers by railway, waterway, highway, and airway along a given line of traffic movement.

It is not fully apprehended how really artificial are the present-day tariff rates, and how little the relative rates are based on the relative costs of trans-

* *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 555.

portation. In other branches of industry the prices asked for products or for service rendered are based on the cost of production or of the service. For the railways, the cost of the service is known in the aggregate only. The relative cost of the transportation, including the necessary care, of the various classifications of freight is unknown. Similarly, the relative costs of the line haul and of the terminal services have not been determined, although the terminal service charges are "absorbed" in the freight rate charges.

Consequently, when railway revenues become insufficient there is no recourse other than that of an arbitrary increase of one or more of the specific rates. An example of the peculiar attitude taken toward freight rates is afforded by the recent action of the Interstate Commerce Commission in ordering an arbitrary decrease in the rate on a certain class of coal between the West Virginia mines and New England territory. Is it safe or sane to keep so vital a thing as the national transportation on such an unstable basis?

At one time, competition between railways was deemed necessary in order to secure an economic service. To-day, it is recognized that each railway line enjoys a natural monopoly for certain territory, and, further, that a railway affords a public utility service and that it, like other analogous utilities, serves the public best as a regulated monopoly. Is there any valid reason why the service should not be extended to cover other classes of common carriers, and thus to serve the public to greater advantage?

Water competitive railway rates are allowed by the Interstate Commerce Commission on the grounds that such lessened rates are necessary in order to permit the railways to meet the competition of the waterways. Those water competitive rates necessarily imply higher rates for interior points, and, therefore, unequal treatment for similar service. If it be the case that freight can be carried by water more cheaply than by rail (which is denied by some railway experts), and if transportation companies were authorized to operate inland waterway lines, the reasons for the water competitive railway rates would disappear, with the resulting discriminations against interior points. If, as is contended, water transportation is not cheaper than rail, why the water competitive rates?

It is impossible to consider the subject of interior transportation without being confronted with the basic subject of railway freight rates and freight classifications. Without a radical change in these, a harmonious economic system of interior transportation cannot be devised. The subject is so complex and so little is known as to actual costs, that a rational solution of the question cannot be had without an investigation and study which will be long and costly. Is not the question worthy of the time and expense?

Even with a solution presented, changes would have to be made slowly, step by step. In the meantime, cannot a start toward reform be made by permitting the railway companies, under due regulation, to take over and operate interior waterways lines within their respective zones, and the abolition of water competitive railway rates?

M. G. Barnes,* M. Am. Soc. C. E. (by letter).—The writer has been very much interested in Mr. Alfred's paper. Through a series of mathematical

* Chf. Engr., Div. of Waterways, State of Illinois, Chicago, Ill.

exercises the author has arrived at the conclusion that the ultimate cost of haul *via* the Ohio River is 40% in excess of the haul by rail, and that "even this figure is not comparable to the railroad cost per ton-mile, as a ton-mile by river is not the equivalent of a ton-mile by rail."

The conclusion is so opposed to the writer's conclusions as to the relative cost of rail and water haul, that he was impelled to make a more detailed analysis of the paper. He did not think that railroads could compete with transportation by water over such an important river as the Ohio. Mr. Alfred's train of thought reminds one of the argument pursued by the Bureau of Railway Economics in its consecutive *Bulletin No. 293,* in which the Bureau attempted to prove that the cost of transportation *via* the New York State Barge Canal was greater than the cost of transportation by rail. The argument made very interesting, if true, reading, but having reached such astounding conclusions the writer was in that case also impelled to investigate more closely. In checking the Bureau's arithmetic he found that it had quite conveniently misplaced the decimal point in computing the cost of haul by water, which resulted in finding "cost of operation, maintenance, and repair" ten times too great. When this correction was made, and using the Bureau's own argument, it was shown that the cost of haul by water was less than the cost of haul by rail, as one must assume would be the result when the figures are properly applied. Has not Mr. Alfred fallen into a similar error in his train of thought?

The author is challenging the economy of transportation by the Ohio River from Pittsburgh to Cairo as a unit, whereas he is using shipping statistics that apply almost entirely to local freight shipping over a reach of 358 miles of river, which he states was all that was completed in 1923, the year in which his shipping statistics were compiled. Through shipment on the Ohio River over an improved waterway such as the Government is now in the process of constructing, has not yet been possible. Several of the locks and dams are yet incompleted. Manifestly, it is not fair to use the present local shipments as an argument to show the wisdom or fallacy of improving the entire length of the Ohio River. Moreover, the Ohio River is only one unit in a system of waterways, as is one line of a railroad a unit in a railroad system, such as the Pere Marquette, for example. Obviously, it would be unfair to select some part of the Pere Marquette Railroad which might be operated at a serious loss, and argue from that that the entire railroad system is a failure.

The writer has compiled Table 18 as a modification of Mr. Alfred's Table 13, to show comparison between railroad shipments and water shipments over the Ohio River System. The data in the second column of Table 13 are derived from Tables 3 and 4 of the paper by Colonel Kutz.

A similar comparison with the completed portion of the Ohio River tonnage shows that the tons of freight per mile of length is twice as much as on the railroads of the United States.

It will be seen from Table 18 that the length of the improved waterways of the Ohio River System is practically 1% of the length of the railroads of the United States, whereas the freight shipments by the Ohio River System were 1.63% of rail shipments in the United States. Also, that the shipment per

mile of length on the Ohio River System was 70.0% greater than the average shipment by rail over the railroads of the United States. This is not such a bad showing for a transportation system yet incomplete and unusable in many places except for local business. The average haul is short because of the fact that through shipments cannot be made over the improved waterways.

TABLE 18.—Water and Rail Shipments Along the Ohio River.

	Railroads in United States.	Ohio River System, 1924.	Percentage of railroad.
Length, in miles	250 183	2 471	0.99
Tons of freight	2 333 000 000	38 071 601	1.63
Tons of freight per mile of length	9 065	15 400	170.00
Ton-miles	416 211 000 000	2 105 886 000	0.51
Ton-miles per mile of length	1 663 228	852 220	51.25
Cost, including equipment	$22 681 000 000	.....	.....
Cost per mile, including equipment	$90 658	.....	.....
Estimated cost of improvement	.....	142 161 023	.....
Estimated cost per mile of improvement	.....	57 532	.....
Balance for floating equipment and terminals to make cost equal to cost of railroads per mile	.....	33 126	.....
Total for Ohio System equipment and terminals	.....	81 854 346	.....

The estimated cost per mile of improvement on this river system is $57 532, whereas the cost per mile, including equipment, on the railroads of the United States, is shown by Mr. Alfred to be $90 658. This leaves a balance of $33 126 per mile of waterways in the Ohio River System to be used for floating equipment or terminals, or for the total length of the system of 2 471 miles, the handsome sum of $81 854 346 as available for floating equipment and terminals for the Ohio River System before the total sum has reached the average total cost, including equipment, of the railroads of the United States. It will be seen that the amount available for the floating equipment and real estate on the Ohio River System is surely adequate to take care of a very substantial business.

Mr. Alfred has computed the items of interest, depreciation, taxes, and maintenance on the Ohio River as $9 656 000 annually, and that "this amounts to a cost of 1.29 cents per ton-mile based on the volume of traffic for 1923." Here, again, the writer wishes to invite attention to the fact that at this time only 358 miles of the river had been completed, and that no through traffic over the improved waterway was possible.

The author states further "as the volume of traffic decreases, this cost will increase." He fails to state the converse of this—that as the traffic increases, the cost will decrease. Although the writer does not endorse the findings of Mr. Alfred in these four items he will take them at their face value and compute the value of the Ohio River improvement on this basis. By using the argument of H. G. Moulton, M. Am. Soc. C. E., Mr. Alfred arrives at a present cost of haul for coal over the Ohio River from Pittsburgh to Cairo of 2.7 mills per ton-mile. Adding about 10% to this for the shorter haul will give a shipping cost by barge of 3 mills per ton-mile, which is equal to the transportation cost on the Monongahela River over a distance of 42 miles,

as reported by Colonel Kutz, who also states that the rail charge for shipping coal over the same distance is 19 mills per ton-mile, or a difference of 16 mills per ton-mile in favor of transportation by water. Further, Colonel Kutz submits a chart (Fig. 1) showing the cost of haul of coal by rail for distances up to about 600 miles. In Table 12 Mr. Alfred finds that the average water haul for coal and coke in 1923 on the Ohio River was 83 miles. From Colonel Kutz's table for this distance is found the rail charge of about 16½ mills, or, say, 16 mills. This would show a saving of 13 mills per ton-mile in favor of water haul.

In the case of sand, gravel, and stone shown in Mr. Alfred's Table 12, the haul averages only 13 miles, and the difference between the water and the rail haul over such a short distance is even greater than for the coal haul of 83 miles, but for the purposes of this discussion it will be assumed that the saving is the same. In the case of the metal and metal products, Mr. Alfred finds the average haul is 318 miles.

Colonel Kutz shows that for a distance of 311 miles the rail charge for fifth-class freight, which is the same as for steel products, is 18.6 mills per ton-mile. Mr. Alfred feels that the cost by water for these higher class commodities should be greater than the cost for transporting coal. The writer agrees with Mr. Alfred on this subject and suggests an increase of 20% over the coal charge. This would give a cost of haul by water of 3.6 mills per ton-mile for fifth-class freight, such as steel products. It is interesting to note that Theodore Brent, Federal Manager for the Mississippi-Warrior Service, states that the average revenue to that barge line is about 3½ mills per ton-mile. This checks very closely with the writer's figure.

Mr. Alfred argues that if these commodities were forwarded by rail the distance would be less than 318 miles. That is probably true, but, on the other hand, for distances less than 400 miles the cost of haul by rail per ton-mile increases at about the same rate as the distance decreases, and hence this difference in distance is negligible. (See Table 8 and Fig. 3 of the paper by Colonel Kutz.)

TABLE 19.—Economy of Ohio River Transportation.

Commodities.	Tons.	Percentage of total.	Ton-miles.	Average haul, in miles.	Savings per ton-mile, in mills.	Total savings.
Coal and coke	6 014 708	73.0	503 315 936	83	13	$6 543 107
Sand, gravel, and stone	1 372 404	16.6	17 274 151	13	13	224 564
Metals and metal products	389 792	4.7	123 972 709	318	13.5	1 673 685
All other commodities	476 617	5.7	104 557 690	219	15.5	1 620 644
Total	8 280 521	100.0	749 120 486	90	....	$10 062 000

For example, in Table 14, Mr. Alfred finds the average length of water haul to be 44% greater than the rail haul. This relation applied to the 318-mile water haul gives an equivalent rail haul of 221 miles. By interpolation

from Fig. 3 of the paper by Colonel Kutz, the rail rate for 221 miles is 25 mills. The total rail charge then becomes $5.52, or 17 mills per ton-mile of water haul. In the same manner it may be shown that the rail rate per ton-mile of water haul for "all other commodities" is 19 mills. The saving to shippers for these two items is 13.5 and 15.5 mills per ton-mile. Inserting these figures in the totals given by Mr. Alfred in Table 12 gives Table 19.

Table 19 shows that the total saving to shippers on the Ohio River alone for the year 1923 was $10 062 000, which exceeds the $9 656 000 overhead charges found by Mr. Alfred.

Be it remembered that this is on a river 968 miles in length only 358 miles of which had been completed and opened. This is not such a bad showing for a stream in the condition of the Ohio River in 1923. When the Ohio River improvement has been completed steel products can be forwarded on regular schedules from Pittsburgh to St. Louis, Memphis, New Orleans, and other points, and heavy commodities, such as lumber, sulfur, bauxite, sugar, coffee, canned goods, and similar articles, can be brought to Pittsburgh from down-stream points. A very material through commerce will be created, which will show even greater benefits than now exist over a waterway admittedly incomplete. Surely with this increased through traffic the shipping interests will realize the converse of Mr. Alfred's statement and may well expect that as the volume of traffic increases the fixed charges per ton will decrease.

C. I. GRIMM,* ASSOC. M. AM. SOC. C. E. (by letter).—The paper by Colonel Kutz presents in condensed form much valuable data that have not been readily available to engineers and permits making an intelligent analysis of a subject that has frequently been discussed from an inaccurate or biased standpoint. Both Colonel Kutz and Mr. Alfred have as a result of an analysis reached the same general conclusion, namely, that present savings in transportation costs on the Ohio River are less than fixed charges plus the cost of maintenance and operation. While Mr. Alfred infers that the former never will be as great as the latter, Colonel Kutz estimates that the savings are approximately 60% of the fixed and operating charges on the completed reach of the river, extending from Pittsburgh to Cincinnati. The writer whose duties include the making of detailed studies of this subject accepts this figure as reasonably correct, realizing that the available data do not permit of mathematical accuracy in such an estimate.

Mr. Alfred has based fixed and operating costs on a completed project, assuming that the traffic will never be greater, but probably less, than at present. If his view of the future is accepted success cannot be predicted for the project, but there are many reasons for assuming a far more optimistic attitude. A railroad in an incompleted state and working at the low ratio of capacity that now prevails on the Ohio River, could not make much of a showing in competition with completed and interconnected lines.

The traffic density on the Ohio River at present is less than 1 000 000 ton-miles per mile of river, while its ultimate capacity is easily ten times this

* Asst. Engr., U. S. Engr. Office, Cincinnati, Ohio.

amount. The principal coal roads in the Ohio Valley had a traffic density of 4 000 000 ton-miles per mile of main track in 1922, which was not a year of heavy traffic, and with this traffic density, the fixed charges plus maintenance of way, was 1.9 mills per ton-mile, or about 40% of the corresponding charges on that part of the Ohio extending from Pittsburgh to Cincinnati.

The Monongahela River has a traffic density of 20 000 000 ton-miles per mile on its lower 60 miles, while for the entire 125 miles of improved river, the traffic density is about one-half as great, the traffic on the upper half being very light. It seems obvious that the capacity of the Ohio River exceeds by far that of a double-track railroad, but as its future use will be governed by its ability to get traffic rather than by its capacity to carry this traffic, the latter is not an important economic consideration.

Some further statistics, more or less general, that may be of assistance toward forming a general view of the traffic possibilities of the river are, as follows.

Population.—The population of the Ohio Valley in 1920 was 15 500 000, or 76 per sq. mile as compared with 116 for Illinois, 142 for Ohio, and 195 for Pennsylvania. In these three States, there is 1 mile of railroad for every 650 population. The population of this basin amounts to 10 000 per mile of Ohio River and canalized tributaries. In 1920 the population of cities and towns on the banks of the Ohio was 2 150 000, or 2 200 per mile. The population of the Ohio Basin increased 10.7% from 1910 to 1920 while the cities and towns on the river showed an increase of 13.7%, as compared with 14.9% for the entire United States.

Potential Tonnage.—The tonnage per capita handled by the railroads of the United States has been increasing rapidly as indicated by the following statistics:

1880	6.5 tons
1890	11.1 "
1900	13.2 "
1910	19.6 "
1920	24.0 "

These figures include originating tonnage and that received from other lines. Statistics show that originating tonnage is about 55% of the total, or that it was about 13 tons per capita in 1920, 5 tons of which was coal. The originating tonnage other than coal on the Upper Ohio is particularly heavy on account of the great steel industry practically all the furnaces and mills of which are situated on the river. The annual capacity of the blast furnaces on the Ohio and its tributaries is approximately 20 000 000 tons, with an average production of 15 000 000 tons.

The basin of the Ohio River produces 55% of the 600 000 000 tons of bituminous coal that is mined annually in the United States and nearly 200 000 000 tons of this coal is shipped from mines situated in counties that border on the river or its canalized tributaries.

The originating tonnage in the Ohio Basin in 1920 may be roughly estimated as follows:

Coal	300 000 000 tons
Other tonnage (at 10 tons per capita)	155 000 000 "
Total	455 000 000 "

The ton-mileage based on the average haul for the United States of 310 miles per originating ton is 141 050 000 000, less than 1.5 of which was handled by the rivers.

Growth in Tonnage.—The tonnage handled by the railroads of the United States has increased since 1880 as shown in Table 20.

TABLE 20.—Growth in Railroad Tonnage in the United States.

Year.	Tonnage.	Ratio of 1880.	Percentage of increase.
1880	320 000 000	1.	...
1890	700 000 000	2.18	118
1900	1 000 000 000	3.	43
1910	1 800 000 000	5.63	80
1920	2 500 000 000	7.8	39

The total increase has been equivalent to a steady rate of 66.7% each decade, while the rate since 1900 corresponds to 58% each decade. Since these figures do not include tonnage handled by waterways and highways, it is conservative to predict total future tonnage increases as 60% in each decade.

From the foregoing it appears that the tonnage in the Ohio Basin other than coal may be expected to increase about 100 000 000 tons from 1920 to 1930, while the tonnage of coal as correctly shown by Mr. Alfred will not increase greatly. There seems to be no doubt that the growth in this valley will demand extensive expansion of transportation facilities and that the Ohio River System if it provides economical transportation may easily absorb during the next twenty-five years a sufficient tonnage to justify the investment in locks, dams, terminals, and fleets, without depriving the railroads of the business they require for profitable operation, providing there is proper co-ordination between the railroads and this waterway system.

Coal has always been an important item in Ohio River tonnage as it is with the railroads in the Ohio Valley. The Ohio River tonnage from 1890 to 1925 was 60% coal. The 1924 tonnage was 53% coal and coke and 34% sand and gravel, with a similar percentage indicated by the 1925 statistics. The tonnage of the Chesapeake and Ohio, Norfolk and Western, and Hocking Valley Railroads was 80% products of mines (mostly coal) in 1922. The ton-mileage of coal, sand, and gravel handled on the Ohio is at present about 75% of the total, due to the fact that the average haul of coal, sand, and gravel is short. The average haul of coal on the railroads mentioned is long and their ton-mileage of coal will be at least 75% of the total.

The accompanying diagram (Fig. 6) shows, as far as records are available, the total Ohio River coal tonnage as well as the shipments from Pittsburgh to the lower river and shipments from Huntington, W. Va., and the Kanawha River. The former has disappeared, but the latter is now greater than at the date of opening the competing Chesapeake and Ohio Railroad in 1889, while as a result of developments in the steel industry other movements of coal have developed to replace the loss of the large tonnage of Pittsburgh coal moving to the lower river. The steel industry is extending down the river and its further development promises continued growth in tonnage, of river coal.

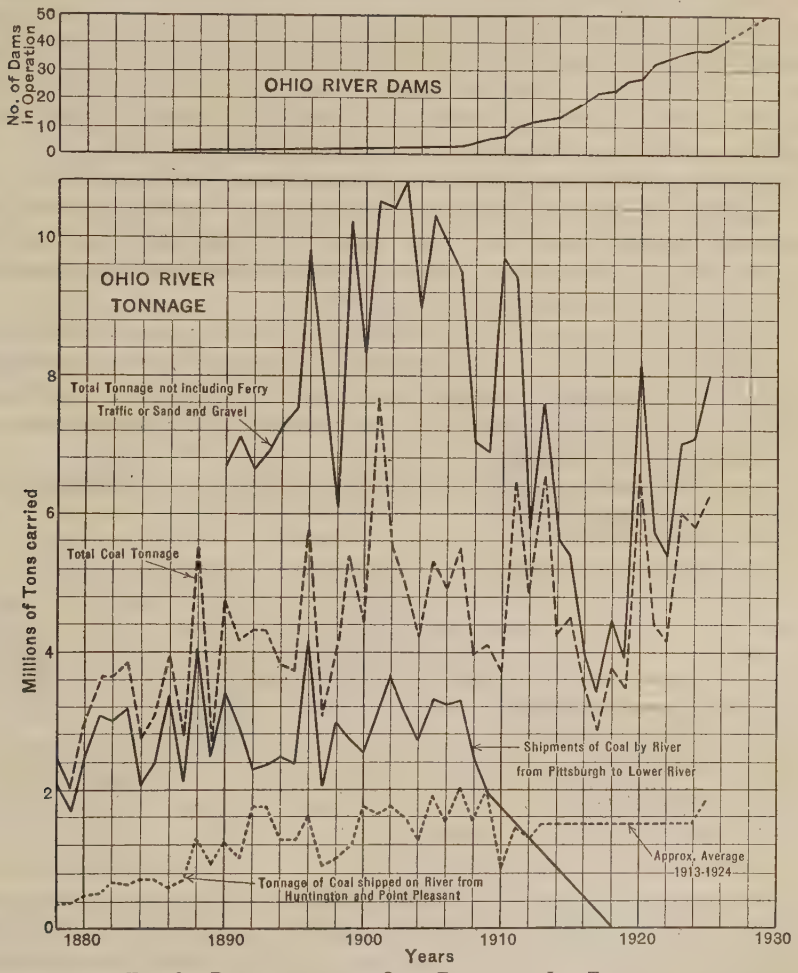

Fig. 6.—Development of Ohio River and Its Traffic.

The rapid growth in the demand for electrical energy will result in a large expansion of steam power plants in this great coal region and these plants by reason of their water requirements must locate on large streams. As the cost of transporting coal from the mines to the load center of a power system is

generally equal to, or less than, the cost of transmitting the power from a power plant at the mines to this load center, it is evident that steam plants having their load center near the Ohio River, or to the north and west of it, and their coal supply in West Virginia or Kentucky, will ship this coal to power plants on the Ohio. This is actually indicated by the action of two large power plants on the Ohio that receive their coal by river.

The increased use of oil as fuel, while it tends to decrease the rate of growth in coal production increases the field of water transportation since this commodity is particularly adapted to river transportation by reason of safety, low haulage costs, and low terminal costs. The oil traffic on the Ohio River has grown steadily since 1917, until it is now an important factor. The same may be said of the iron and steel products, and it is estimated that from 20 to 25% of the present Ohio River ton-mileage is in these two commodities, traffic in which has developed almost entirely during this period.

It will be noted from Fig. 6 that there was a decline in Ohio River tonnage from 1905 to 1918 coincident with the decline in shipments of Pittsburgh coal to the lower river, while from 1918 to 1925 there was a general increase in tonnage coincident with the increase in tonnage of iron, steel, and oil, and partly composed of these commodities.

Colonel Kutz estimates (Table 4) fixed charges on the completed project at 8.29 mills per ton-mile with 1924 traffic, while Mr. Alfred (page 1131), based on the 1923 traffic, estimates 12.9 mills. It is evident that traffic must increase so as to reduce the fixed charges well below these figures in order that the project may be justified.

From a former discussion by the writer* are quoted data (Table 21) relative to coal-carrying railroads.

TABLE 21.—Statistics of Ohio River Valley Railroads.

	Pittsburgh and Lake Erie Railroad.	Buffalo and Lake Erie Railroad.	Hocking Valley Railway.	Norfolk and Western Railroad.	Chesapeake and Ohio Railroad.
Products of mines, percentage..	64	90	83	80	79
Average haul, in miles.....	60	108	117	279	263
Average receipts, in mills per ton-mile.....	13.3	7.76	7.84	7.45	6.86
Average receipts per ton.....	$0.86	$0.84	$0.92	$2.08	$1.88
Interest on road plus maintenance of way in mills.....	2.31	1.58	1.96	1.82	1.60

To reduce fixed charges, plus cost of maintenance and operation on the river, to a figure as low as the corresponding charge on these roads, the river traffic must increase fivefold. This is, however, not a true criterion since the sum of other river transportation costs is less than those of railroads, as shown in the discussion referred to.

The average haul on the Ohio River is about 80 miles and the traffic as a whole is comparable with that of the short-haul (first three) railroads listed,

* *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 571.

but is practically all one-way, whereas these railroads have about 65% of their car-mileage in loaded cars. Taking these factors into consideration, it is estimated that the cost of handling all Ohio River traffic by rail would be $1.00 per ton, or 12.5 mills per ton-mile of river distance. The probable water cost is 5 mills per ton-mile, or $0.40 per ton, and the terminal differential is estimated at $0.20 per ton, leaving a saving of $0.40 per ton as compared with rail shipments. On this basis, the tonnage on the completed project must increase to 20 000 000 or 25 000 000 to effect annual savings equal to annual costs carried by the Federal Government.

The foregoing estimate involving the use of averages is subject to many inaccuracies and a detailed estimate based on an analysis of the savings on each specific movement is the only method of obtaining more accurate results. As shown by Mr. Begien, one of the important river hauls is a part of a longer through haul and this is true of many other river hauls. For such cases the estimate of savings is not simple, and results for specific movements may be widely different from those obtained by the methods of the preceding estimate. Data are not available for an analysis of all river movements, but a consideration of the major movements indicates that the foregoing estimate based on average conditions is reasonably correct.

As pointed out by Messrs. Alfred and Begien, dependability of service is a recognized advantage in a transportation facility and in this respect the railroads that compete with the Ohio have been far superior to the river in its uncanalized or partly canalized state. However, with the completion of the improvement, the railroads will possess no marked advantage in this respect. Navigation on the river will then be interrupted only by ice and extreme high water. Interruptions by the former will be greatest in the upper part of the river. At Lock No. 11, 76 miles from Pittsburgh, navigation has been suspended on account of ice an average of 7 days per year during the past 7 years, while high water has added 3 days more. On the Monongahela River during the past 25 years, ice and high water have interrupted navigation an average of 9 days per year. Velocities exceeding 3 miles per hour occur on the Ohio about 10% of the time in the steep upper end and about 5% of the time in the lower river, while velocities exceeding 2½ miles per hour prevail about 25% of the time. For an operation that is loaded down stream, towing conditions when the dams are lowered are no less favorable than those prevailing while the dams are up, until the river reaches a stage where the velocity is about 3½ miles per hour, but become less favorable as the velocity increases further and make towing impracticable when a velocity in excess of 4 miles per hour prevails.

The early growth of commerce on the Ohio River resulted primarily from its use in connection with marketing, which use gradually declined because of its inability in an uncanalized or partly canalized condition to meet railroad competition in this field. The recent increase in river tonnage has resulted primarily from its use as an agency of production. The former use resulted in long hauls of various products, while the latter involves shorter hauls of raw materials. It is recognized that extensive foreign and domestic markets to the south and southwest are open to the industries of the Ohio Valley and

it is expected that the improved facilities offered by the river when it is completed will again build up its marketing commerce. An industrial survey report made by the Technical Advisory Corporation of New York, N. Y., for the City of Cincinnati, refers particularly to these markets for Cincinnati products and states as follows regarding the Ohio River: "The Ohio River improvement is to be completed in 1928. This simply gives Cincinnati an opportunity—nothing more".

The situation as viewed by the writer is summarized, as follows:

1.—The Ohio Valley with its great mineral and other resources is one of the richest in the world.

2.—Population and industry in this valley will keep pace in growth with that of the nation.

3.—Industry and population of the valley will center in the future, as they have in the past, on the Ohio River.

4.—The Ohio River where canalized offers an economical and dependable means of transportation.

5.—With equitable relations between it and the railroads which are recognized as the major transportation agency of the valley, this river will carry in the future a commerce that will justify the expenditures made on it by the Federal Government.

Frank H. Alfred,* M. Am. Soc. C. E.—One of the most useful functions of the Society is the discussion of subjects like this. When discussion precedes the inception of the project, it is even more valuable than when it follows it, as in the present instance. Difference of opinion is to be expected and is desirable. Each party considers the subject from his own standpoint and it is thus illuminated from many angles. When all the facts have been assembled, there should not be much difficulty in agreeing on a conclusion. Twenty-eight engineers recently rendered a unanimous report on the causes and remedies of low water on the Great Lakes, in connection with the diversion of water for the Chicago Drainage Canal; thus affording a remarkable example of the openness of mind with which the engineer should approach his problems.

When internal waterways is the topic, however, especial care should be taken to distinguish facts from fancies; for this subject has been so obscured in the popular mind by a sort of sentimental haze that it is easy to mistake one for the other and to accept bald assertion as Gospel truth. It is astonishing to find this lack of discernment in quarters where it would be least expected. For example, General Taylor quotes from a Kansas enthusiast, presumably with approval. This quotation is taken from a pamphlet "published by the National Rivers and Harbors Congress for distribution among the agriculturists." It is a fair sample of propaganda on this subject and is also an excellent illustration of appeal to a special interest without considering the cost to others. This quotation in part is as follows:

"Since the farmer, in effect, pays the freight on all of his wheat to Liverpool (since that market fixes the price of all the wheat whether the wheat is actu-

* Pres. and Gen. Mgr., Pere Marquette Ry., Detroit, Mich.

ally exported or not), when we compute the value of Missouri River navigation to the Kansas wheat farmer, we cannot merely calculate the saving on the entire Kansas crop, because, if you raise the price of the export wheat 3 cents per bushel by reducing the cost of the freight to Liverpool by 3 cents, you automatically raise the price of all the wheat crop in Kansas."

This is followed by a computation which purports to show that the farmers of Kansas have lost $40 000 000 in 14 years on account of the lack of improvement on the Missouri River. This is based on an estimated saving in cost of transportation of 3 cents per bushel, a figure obtained "on good authority, in fact from experts." Assuming the existence of an expert wise enough to know what reduction in the freight rate would accrue, who pays the extra 3 cents to the Kansas farmer? Evidently, the person who buys his wheat. If 10% of this wheat is exported, 90% of the fortunate Kansan's increased emolument is contributed by his fellow citizens. If only 1% goes to Liverpool, they contribute 99% to his added profit. Statistics on this point are lacking. It would be of interest to know just what portion of the Kansas wheat crop finds its way to European markets, and also to know how the domestic consumer is to be convinced that he should pay Federal taxes for the privilege of contributing to the Kansas farmer's welfare.

In the case of river improvement, however, there is another difficulty which the twenty-eight engineers previously referred to did not encounter. They were dealing with facts, but any present conclusion as to the ultimate value of river improvements must depend on a forecast of their future use. It is easy to agree as to conclusions drawn from established facts; but where they must be based on probable future happenings, perhaps it is too much to ask even an engineer to lay aside the rose-tinted spectacles of hope.

The speaker has no prejudice against inland water transportation, and the railroads have no fear of it as a competitor. Many railroads are now engaged in it in some form or other and the speaker himself is "Rear Admiral" of a fleet of seven large car-ferries that operate across Lake Michigan, and are a very important part of the Pere Marquette's transportation system. Incidentally, he knows that the cost of this lake transportation per ton-mile of freight is as high as by rail, in spite of the fact that no maintenance-of-way expense is incurred. He maintains, however, that a broad distinction should be made between transportation on a great natural channel like the Great Lakes, or a great artificial channel like the Panama Canal where tolls are collected, and transportation on rivers, where immense sums are necessary to construct and maintain channels required even for boats of light draft.

Based on an experience of many years in the transportation field, his conclusion is that the future holds little of promise for river transportation, for the simple reason that except for the limited amount of traffic which originates and terminates on or near the river banks, it costs more to move freight from shipper to consignee by river than it does by rail. Transportation by river also requires more time and is less dependable. It is for these reasons that the rivers lost their traffic to the railroads and have never regained it and, in the speaker's opinion, never will regain it, no matter how much is spent on improving their channels. Patrick Henry's dictum as to how to judge the

future still holds, and there is certainly nothing in the past history of traffic on the Ohio River to justify optimism. The expected increase in traffic has always been just around the corner, where it bids fair to remain.

The railroad takes freight at the shipper's mine or factory and delivers it at the consignee's warehouse. This the vessel cannot do, unless both shipper and consignee are located at the water's edge. No comparison of transportation cost by rail and river is possible unless the terminal cost of delivery is included in the latter. The railroad rates include this cost on all but a negligible part of goods handled, but neither this cost nor any profit to the carrier is included in the figures which have been given in this discussion as representing the cost of river transportation. To give an idea what terminal costs amount to, the Pere Marquette Railway Company in 1923 had nearly one-half as many switching miles with locomotives at terminals as it had road miles in hauling the goods.

As to the alleged necessity for improved waterways to care for the greatly increased traffic of the future, why not let future generations attend to this if and when the need develops? The Ohio River improvement when complete will have cost $114 000 per mile, enough either to build and equip a double-track railroad, or to add a second track to each of the three existing single-track lines, which would give each railroad a capacity equal to at least ten times the present tonnage carried on the river. At this rate it will be a long time before extensive river improvements are called for on this account. Give the railroads a fair chance—which means simply enough return to attract the capital necessary for additions and betterments—and they will render cheaper and better service even to river communities than can be given by the river, and there will be no more of the congestion to which reference has been made.

It is hardly fair to refer to congestion that occurred under war-time conditions, or in 1920 when the railroads had not recovered from Federal control. The railroads are progressing, just like everything else. The total tractive power of locomotives used in the United States increased from 1 932 000 000 lb. in 1914 to 2 673 000 000 lb. in 1924, an increase of 38% in 10 years. In the same period the number of freight cars increased 16% and the average capacity of the freight car increased 12%, resulting in a total increase of freight car capacity of 30 per cent. In addition, there has been a large increase in the average distance which each freight car moves per day. Traffic in 1923 was 414 000 000 000 ton-miles as against 288 000 000 000 in 1914, an increase of 44 per cent. Taking all factors into consideration the railroads are capable of giving at least 60% more service now than they were ten years ago. In the second week of January, 1925, they handled the largest tonnage of coal ever handled in the history of coal mining or railroad operation. They actually moved 12 500 000 tons of coal in this one week. They never felt it; in fact, they did not know until afterward that they had moved nearly twice as much coal as in the previous week.

Let waterways be improved where the economic value of such improvement can be demonstrated, but let not assumption be mistaken for proof. Further,

let it be assured that the resulting benefit will be fairly well distributed among the general public, which pays the cost, and not accrue only to certain favored interests or localities.

C. W. Kutz,* M. Am. Soc. C. E. (by letter).—A review of the papers presented in this Symposium and the discussion thereon shows widely varying conclusions as to the value of the Ohio River as a transportation agency notwithstanding the fact that nearly all the economic comparisons are based on a consideration of the same basic data.

The principal points of disagreement may be grouped as follows:

1.—The annual charges on the waterway when the present project is completed;
2.—The benefits as measured by the difference between rail rates and water haulage costs when applied to existing tonnage; and
3.—Prospective tonnage.

Annual Charges.—The annual charges depend on first cost, cost of maintenance and operation, and depreciation. For purposes of comparison with a privately owned transportation agency, an item for lost taxes should also receive consideration. The writer estimated the cost of this project to be $103 000 000; Mr. Alfred used $110 000 000. The present project was adopted in 1910. There was expended under previous projects, including the amount for the purchase of the Louisville and Portland Canal, approximately $17 500 000. This amount also includes the cost of Dams Nos. 1 and 2—since replaced. If all this amount, as well as the cost of Emsworth Dam which replaced Dams Nos. 1 and 2, is considered as part of the first cost, the total will aggregate approximately $110 000 000. This total also includes the entire cost of the proposed power navigation dam at Louisville, but, as the Power Company will pay annually interest and depreciation on the difference between the cost of the navigation dam and the cost of the power-navigation dam, this difference, amounting to approximately $1 500 000, should be deducted from the total, leaving the net cost of the Ohio River Canalization Project as $108 500 000. If the cost is limited to that of work now used and useful in the interest of navigation, the total of $103 000 000 would be more nearly correct.

The writer used a 4% rate in determining interest charges, as did Mr. Alfred. Mr. Begien used 4½ per cent. The 30-year Treasury bonds, bearing 4% interest, sold at a premium, and the trend is toward lower, rather than higher, rates.

Mr. Alfred assumes an item of $2 000 000 for maintenance, plus 1½% for depreciation, the latter being based primarily on the age of Dams Nos. 1 and 2 when replaced. The replacement of these dams in 1921 by a fixed dam is not a fair index of the length of useful life of locks and dams of the Ohio River type, as their replacement was primarily a betterment, for the purpose of improving conditions in Pittsburgh Harbor. The replacement of Dam No. 3 and Dam No. 4 by a single fixed dam is also under consideration and for a similar reason.

* Col., Corps of Engrs., U. S. A., Cincinnati, Ohio.

The movable parts of these structures such as wickets, gates, valves, etc., have only a limited life and require replacement from time to time, but this is not equally true of the concrete walls and foundations. Based on experience, the cost of maintaining and operating Ohio River locks and dams, including the average annual cost of replacing depreciable parts, was estimated at $40 000 per lock and dam, or $2 000 000 for the entire river. A reconsideration of this item leads to the belief that it is too small and that the average annual cost during a long period will be approximately $2 250 000.

If this type of waterway is to be superseded eventually by some superior form of transportation agency, as were the old canals of 100 years ago, an economic comparison should properly include in the annual charges an item whereby the entire first cost will be amortized during the useful life of the project. Although this supposition might be applied with almost equal force to the privately owned railroads, to provide against such a contingency for the waterway only it is proposed to assume a life of 75 years and set up as part of the annual charges an item for depreciation of 0.22% of the first cost, an amount which is sufficient when compounded at 4% to amortize the entire first cost during the assumed life.

Mr. Alfred includes in his estimate of annual charges an item of taxes of 1.46%, the average paid by the railroads of the United States in 1923. As to the propriety of including such an item, the following is quoted from a report made by J. M. Clark, Associate Professor of Economics, Chicago University, a number of years ago, in connection with preliminary investigation of canal routes connecting Lake Erie with the Ohio River:

"Another question is whether taxes should be charged on the public investment, on the ground that if that capital had been left in the market to be used in private investments, the Government would have received taxes on it. The principle is sound: a public investment which yields the Government only what it has to pay out again on its bonds, leaves the Government poorer than if the same funds had gone into a private investment on which the Government receives taxes. The fact that the bulk of the taxes would not go to the Federal Government does not affect this principle: it merely makes the loss fall on the States.

"There is, however, one real question. Does an investment of this sort always result in reducing private investments by just the same amount? 'Orthodox' economics would say yes: but, in cases where the financing can be done partly through credit expansion, it seems probable that the correct answer is no; $100 000 000 of Government funds invested in this way would displace some private investments, but less than $100 000 000. It would depend on whether the credit mechanism had some reserve lending power at the time the loans were floated, and also on the existence, at the time, of a certain reserve of labor and plant capacity which could be drawn upon without diverting labor from other things. These conditions might or might not prevail. * * * If taxes are counted at the usual rate on one-half of the investment rather than on the whole, all reasonable allowance will have been made for the elasticity of the industrial system."

Although there is room for a difference of opinion as to the inclusion of such an item, the writer believes that full justice will be done the railroads by the adoption of Professor Clark's views. Accordingly, in the revised summary of annual charges, taxes will be included at 0.73%—one-half the average

rate paid by the railroads in 1923, which is equivalent to the full rate on one-half the investment. The total annual charges on completion of the project will then become:

Interest at 4% on $108 500 000	$4 340 000
Taxes at 0.73%	792 050
Depreciation (obsolescence) at 0.22%	233 400
Maintenance and operation (including replacement of depreciable parts)	2 250 000
Total	$7 615 450

This revised total is $1 500 000 greater than the annual charges given by the writer in Table 3; $600 000 greater than the estimate of Mr. Begien, but still $2 040 000 less than that of Mr. Alfred. Measured by the expenditures the project is 80% completed, so that in an economic comparison based on 1925 tonnage it will be fair to use 80% of $7 615 450, or $6 092 000, as the measure of the annual charges in that year.

Tonnage in 1925.—Some of the papers in the Symposium use mileage and ton-mileage data for the calendar year 1923 and others for the calendar year 1924. As a study of these data and of the reports from which they were compiled disclosed certain discordant features, the method of collecting tonnage statistics on the Ohio for 1925 was changed, a higher standard of accuracy being established. This fact will undoubtedly account for the large increase in the quantities of sand and gravel, as reported for 1925, and may account for part of the other increases. In Table 22 comparison is made between the tonnage of 1923, 1924, and 1925, as reported, no attempt being made to correct any of the errors, plus or minus, that are believed to exist in the reports for 1923 and 1924.

TABLE 22.—Variation of Ohio River Tonnage.

Commodities.	Traffic for Year:		
	1923.	1924.	1925.
Coal and coke, in tons	6 041 708	5 811 552	6 881 354
Iron and steel, in tons	377 156	550 363	539 464
Oil and gasoline, in tons	50 187	82 200	275 532
Packet, in tons	277 073	220 029	262 393
Unclassified, in tons	332 471	455 657	998 521
Sand and gravel, in tons	1 201 925	3 746 882	6 768 585
Total, in tons	8 280 520	10 866 683	15 725 849
Total, in ton-miles	708 302 795	670 486 423	845 000 000
Total, in ton-miles, exclusive of sand and gravel	693 865 289	621 391 897	757 000 000

Mr. Alfred deduced annual charges of 12.9 mills per ton-mile, but by using the revised annual charges and the tonnage of 1925 this rate becomes 7.25 mills per ton-mile.

Benefits of Savings Based on 1925 Tonnage.—While Mr. Alfred's annual charges on the waterway are regarded as too high, his water haulage cost, 2.7

mills per ton-mile, is too low. This rate does not differ greatly from the 2.5-mill rate set up by the writer for hauls of 250 miles; but it is not applicable to hauls of 86 miles (the average on the Ohio, exclusive of sand and gravel). Furthermore, his comparison of the sum of the two (annual charges per ton-mile plus water haulage cost per ton-mile) with the average railway revenue is unfair, as it fails to take into consideration the difference in the average length of haul, that on the railways being more than 200 miles whereas that on the Ohio is less than 90 miles.

The most direct method of showing benefits is by analyzing specific movements as was done by Mr. Begien in Table 17, and that method will be used in connection with the analysis of the 1925 tonnage (Table 23). Some elements in Table 17, however, call for comment. The canalization project, Huntington, W. Va., to Cincinnati, was not completed until late in 1925, but even under this handicap cost data covering operation in 1925 place the water haulage cost at 50 cents per ton as against 55 cents. It should be less hereafter. An elevating cost of 25 cents is fair for unloading plants of the old type. With modern plants on the Monongahela the cost is less than 10 cents. Making allowance for the smaller movement at Cincinnati, a cost of 15 cents is deemed to be fair. With these changes there is a saving of 68 cents per ton to river-side plants, and to householders within hauling radius of the river terminal 43 cents per ton on coal which requires a switching haul and 27 cents per ton on coal re-shipped by rail to Indianapolis, Ind. An average saving on this movement is nearer 40 cents than 20 cents, as assumed by Mr. Begien.

In connection with this rail-river-rail movement of coal to Indianapolis, the river is not regarded by the railroads as an integral part of the country's transportation system and is not accorded the same treatment as would be given a railroad; for coal brought to Cincinnati by river for shipment to Indianapolis pays a higher rate (Cincinnati to Indianapolis) than that brought in by rail, the differential being 18½ cents per ton.

Mr. Barnes' estimate of savings is subject to a correction due to the fact that many of the Ohio River hauls which go to make up the average are parts of through hauls involving tributary streams and in some cases parts of through rail and river hauls. In such cases it is necessary to compare the through water rate or through rail-river rate with the through rail rate and apportion the savings between rivers. This may be illustrated by reference to the largest coal movement—Monongahela River points to the Upper Ohio. The total difference or saving averages 94 cents per ton on a total haul of 88 miles (50 miles on the Monongahela and 38 miles on the Ohio). The share accruing to the Ohio is 44 cents, or 11.5 mills per ton-mile.

It has been alleged that the economic comparisons are faulty in that they fail to include in the cost of transportation by river either the terminal cost of delivery or any profit to the carrier. In Table 23 based on the tonnage of 1925, as well as in all other comparisons made by the writer, a terminal differential has been included. As to whether profit was included depends on the type of service, that is, whether by private carrier, contract carrier, or com-

mon carrier. In dealing with private carrier movements cost only was considered, the cost including a 6% return on the investment in floating plant and on the privately owned facilities. Although such a return may not be regarded as embodying a profit, it is equal to or in excess of what the railroads are permitted to earn on their investment under the Transportation Act. In dealing with contract carrier or common carrier movements, rates have been used which do include an item of profit.

In preparing Table 23, cost data covering a large number of movements were studied, but in order not to disclose costs of individual movements received confidentially, they have been consolidated into groups and the rates and savings listed are the average for the group.

The saving on sand and gravel is more or less indeterminate. While a series of comparisons indicate an average saving of $0.50 per ton, only part of this amount can be fairly credited as a benefit resulting from the canalization project as the industry would exist without the dams. On the other hand the dams in many cases double the length of the season and give access to deposits that could not otherwise be profitably mined. The saving of $0.20 per ton is the estimated reduction in the cost of producing sand and gravel.

It will be noted from Table 23 that the accumulated savings for 1925 amount to 87% of the annual charges for that year and to 70% of the estimated annual charges on completion.

Prospective Tonnage.—If Mr. Alfred is right in his assumption that the commerce of the Ohio will not increase but rather decrease, his conclusion is justified although his reasons are not convincing. It is true that the per capita production of coal is decreasing—and that the actual production, with minor fluctuations, has remained stationary since 1913, but the quantity moving on the Ohio has been increasing since 1920 when the movement from Pittsburgh to points on the Mississippi River ceased.

It is true that coal will move increasingly to central power stations as a substitute for coal formerly moved to local stations, but as such stations require 500 tons of condensing water for each ton of coal consumed they must locate on large rivers. Furthermore, if they can secure their coal by water, it is more economical to build such stations near the center of distribution than at the mouths of coal mines 200 miles distant.

It is true that petroleum is taking the place of coal, but the prospect that the Ohio River will receive a large share of this substitute tonnage is shown by the remarkable increase in this item in 1924-25.

While in all probability coal will always remain the largest single item of tonnage, the prospective movement of steel and iron to points on the Mississippi River bids fair to yield the largest returns eventually. Although a seasonal movement is all that is possible at present, the large steel companies in the Ohio Valley foreseeing the approaching completion of the Ohio improvement, already have taken steps to move their products by water on a large scale. In addition to seasonal movements to the Lower Mississippi, a common carrier service has been established whereby such products are being shipped by

river to Louisville, thence by rail to St. Louis, and Memphis, pending completion of the canalization project.

Mr. Begien makes the point that "the comparatively few industries and individuals who make use of river transportation contribute a very small part toward the interest and carrying charges of such improvements" and that in connection with the movement of coal by river none of the saving in transportation costs is passed on to the consumer.

The theory underlying the improvement of rivers at public expense assumes that the savings in transportation costs will be transmitted to the taxpayers who pay the annual charges, or to a large and representative group thereof. Not all the tax-paying public is benefited by a given improvement, but it may benefit to an equal extent from some other similar public improvement. If, however, the saving is not passed on as alleged then some means should be devised for placing the maintenance burden on the users. This could be done either through the collection of tolls or by a licensing system similar to that which governs the use of highways created at public expense, as was suggested a number of years ago by a prominent waterways advocate.

This question, however, is separate and distinct from the one at issue, namely, whether a canalized Ohio River will serve as an economic link in the country's transportation system. The writer believes that the use now being made of the river, the savings now being effected, and the prospective increase in use on completion of the project in 1928 justify an affirmative answer.

The Ohio River's full usefulness, however, will not be realized until the Interstate Commerce Commission is given the same control over rates by river as it has over rail rates, and until the railroads recognize the value of the river by granting joint rail and river rates as freely as they grant joint rail rates.

Paper No. 1591

THE ORADELL DAM OF THE HACKENSACK WATER COMPANY*

By Nicholas S. Hill, Jr.,† M. Am. Soc. C. E.

With Discussion by Messrs. Stuart K. Knox, Howard T. Critchlow, A. T. Ricketts, Thaddeus Merriman, Lazarus White, Albert C. Arend, Paul E. Gisiger, and Nicholas S. Hill, Jr.

Synopsis

This paper describes a unique type of dam of considerable size designed by the writer in 1911 and built by the Hackensack Water Company in 1920-22. The unusual design was the outgrowth of an attempt to plan a dam to meet special conditions found at a particular site. It was not intended to develop a type of dam which would be applicable to conditions likely to be found frequently, nor is it suggested that the type described offers a more economical substitute for the usual types of dam under ordinary conditions.

The special conditions for which, in combination, this design was intended to provide were:

1.—Spillway crest with maximum height about 20 ft. above the stream bed.
2.—Maximum possible length of dam between abutments, 402½ ft.
3.—Flood flows which would produce a head of 3 ft. over any practicable length of weir (402½ ft.).
4.—Firm foundation of hardpan and shale 15 to 45 ft. below the stream bed.
5.—Porous sand and gravel overlying the deep firm foundation, with intercalated and lenticular masses of stiff dense clay over part of the section.
6.—Impracticability, because of cost, of adopting a masonry section of the gravity type extending to the deep underlying hardpan and shale.

* Presented at the meeting of November 4, 1925.
† Cons. Engr., New York, N. Y.

7.—Impracticability of allowing a head of more than 1 ft. over the spillway crest, because of flooding of railroad and other unowned lands.
8.—Necessity of providing a dam section which might be overtopped without damage in times of flood.
9.—Necessity of holding foundation and toe pressures within lowest possible limits.
10.—Necessity of providing solid cut-off all the way down to the underlying hardpan and shale.

Introduction

The Hackensack Water Company, chartered in 1869, is one of the largest private water companies in the United States. At the time the Oradell Dam was constructed it supplied water to forty-eight municipalities or civil divisions in Hudson and Bergen Counties, New Jersey, all lying within the Metropolitan Area of New York, N. Y. The most populous of these communities were Hoboken, West Hoboken, West New York, North Bergen, Weehawken, and the Town of Union, in Hudson County, and Hackensack, Englewood, Rutherford, and Ridgefield Park, in Bergen County.

According to the 1920 Census, the total population in the territory supplied was approximately 340 000, of which about 92% was connected to the mains of the Company. It is estimated that this population will have increased to 530 000 by 1940.

The daily volume of water delivered for distribution increased from about 26 000 000 gal. in 1912 to from 35 000 000 to 36 000 000 gal. in 1918, 1919, and 1920. It is estimated that the water delivered for distribution will have increased to more than 80 000 000 gal. daily by 1940. From 40 to 45% of the consumption is, and probably will remain, industrial in character.

The supply is taken from the Hackensack River at New Milford, N. J., just above tide-water, at which point the stream has a drainage area of 115 sq. miles. At New Milford the entire supply is filtered through mechanical gravity filters and pumped for distribution at heads of 300 and 600 ft.

The Water Company has two impounding reservoirs on the water-shed above New Milford to regulate the flow and augment the supply during dry weather. The necessity for impounding storage is indicated by the fact that the natural flow of the Hackensack River at the New Milford intake decreases to 10 000 000 gal. per day or less in extremely dry seasons. The safe yield of the stream with the present storage (about 3 900 000 000 gal.) is estimated to be 40 000 000 gal. per day. Prior to the construction of the new Oradell Dam, the safe yield was only 32 000 000 gal. per day, and the impounding storage 2 190 000 000 gal.

The new Oradell Dam creates a storage reservoir of 3 023 000 000 gal. capacity, which in conjunction with the smaller Woodcliff Reservoir of 889 000 000 gal. capacity, constructed in 1906, comprises the total impounding storage of the Water Company on the Hackensack River. The new dam is situated on the main stream just above Oradell, N. J., from which it takes its name. The site is only about ¾ mile up stream from the New Milford pumping station and intake.

Aside from the much smaller Saddle River, the basin of which adjoins that of the Hackensack on the west, the Hackensack River is the only readily available source of water supply for the large and rapidly growing population served by the Hackensack Water Company. With proper storage it is estimated that the Hackensack River may be made to supply the needs of this territory until 1940, when the population supplied will exceed 500 000.

Since 1903, the Company has maintained a dam on the present site at Oradell, which originally was an old mill dam of low elevation (spillway crest, 8.60 ft.*) and negligible storage. The basin above the dam was a swamp quite heavily timbered. Beginning in the spring of 1911, the work of creating a storage reservoir at Oradell, which had been started in 1903 and then abandoned in favor of the Woodcliff site, was resumed. The clearing of the basin was again undertaken and a temporary timber crib dam, with wooden sheet-pile cut-off, was constructed on the site of the old mill dam. The crest of this crib dam which was about 11 ft. above the stream bed (or Elevation 11), created a storage basin of sufficient depth to float a dredge. Two suction dredges, one 12 in. and the other 20 in., were constructed on the bank of this small basin, and launched. Between 1911 and 1920, the basin, up stream from the dam, and below the 11-ft. flow line, was dredged to Elevation 0, the excavated material being used to build up the banks and fill in depressions, to which it was pumped through pipe lines supported on floats.

Coincidentally with the starting of this work, borings were made across the valley of the Hackensack River below the temporary crib dam, to determine the best site for a permanent dam to create a reservoir having a flow line 20 ft. above the stream bed. As a result of these borings the location for the permanent dam was chosen on a line at right angles to the thread of the stream and 50 to 90 ft. down stream from the curved crib dam. The permanent dam was designed in 1911 and its construction was begun in 1920, at which time the dredging was practically complete. By the close of 1921 the spillway section had been built to Elevation 16. The dam was completed to Elevation 20 in 1922.

Considerations Controlling the Selection of the Oradell Reservoir Site

The primary consideration controlling the selection of the Oradell Reservoir site was the desire to obtain a considerable volume of storage in the lower reaches of the drainage basin, near the intake, at a point so located that all branches of considerable size would be tributary to it, thus insuring the highest possible degree of stream regulation and control over flood flows.

The selection of any site other than that at Oradell would have excluded from the drainage basin tributary to the reservoir, an area of at least 25 sq. miles, or 22% of the total drainage area. The run-off from this area would have been ineffective in replenishing any other reservoir, following depletion, and the flood flows from its 25 sq. miles entirely uncontrolled

* All elevations given in this paper refer to Atlantic mean high tide.

except in so far as regulation could be effected by the method of operating the suction basin and pumping station at New Milford.

Studies indicated that the cost per 1 000 000 gal. of developing storage in Oradell Reservoir would be no higher than at any other desirable site.

Considerations Controlling the Selection of the Flow-Line Elevation of Oradell Reservoir

The divide between the Hackensack drainage and that of the Sparkill, a tributary of the Hudson, has an elevation only about 30 ft. above mean sea level, or 27.5 ft. above the Company's datum which is mean high tide. The two-track New Jersey and New York Railroad at Oradell is about at Elevation 23. Surveys of the reservoir basin below Contour 25, which were started in 1910, indicated that the placing of the spillway crest above Elevation 20 would necessitate the relocation of railroads and highways and the purchase of land areas the cost of which would have been greater than warranted by the advantages obtained. It was decided, therefore, after due study and consideration, to fix the spillway crest at Elevation 20 and to provide in the dam a sluice-gate section of a capacity sufficient to pass all extremes of flood with a head not exceeding 1 ft. over the spillway crest. In this way it is expected that troubles due to back-water and flooding above the dam will be avoided.

Flood Flows and Proportions of Sluice-Gate and Spillway Sections

The severity of the floods which occur on the Hackensack River is not extreme when measured in second-feet per square mile. Considerable trouble from flooding, however, has been experienced at times of extremely high run-off because of channel obstructions below the dam at Oradell. There are islands in the stream between Oradell and the pumping station at New Milford. The New Milford pumping station is located on an island, the surface of which is at a general elevation of 10 ft.

The suction basin has been created by damming the various arms of the stream between the islands and the mainland in the vicinity of the pumping station. The crests of these dams stand at Elevation 4.93, so that under normal conditions of stream flow the flow line in the suction basin and stream between Oradell and New Milford stands at about 5 ft.

On one occasion, during a period of very high run-off, the water surrounding the New Milford pumping station rose for a short time to a height above the engine-room floor, which stands at Elevation 10. Following this experience the suction basin and stream channels between Oradell and New Milford were considerably enlarged and improved by dredging. This work was done about 1911 or 1912.

As a result of the removal of obstructions and other improvements accomplished at this time, it is believed that the water level below the New Milford pumping station cannot now rise to an elevation exceeding 8 ft., and that the maximum elevation of back-water at the toe of the Oradell Dam, ¾ mile above the pumping station, cannot in the future exceed Elevation 12.25. The

minimum net head on the sluice-gates in the Oradell Dam, with 1 ft. over the spillway crest, will, therefore, not be less than 21.00 — 12.25, or 8.75 ft., at times of most extreme flood.

It is believed that the most extreme flood likely to occur on the Hackensack River will not exceed 46 000 000 gal. daily per sq. mile of tributary drainage area. Unfortunately, the run-off data on the Hackensack, which are meager, do not afford a basis for determining the extent of the floods which have occurred in the past. This figure, therefore, is an estimate. As a basis for the estimate, a study was made of the recorded flood flows on many streams of similar size in New Jersey and New York, some of which are given in Table 1.

TABLE 1.

Name of stream.	Area of water-shed, in square miles.	Maximum recorded flood flow, in millions of gallons per day, per square mile.	Date of occurrence.
Pequannock, N. J.	85.0	41.8	Feb. 6, 1896
Ramapo, N. J.	86.0	36.2	"
Wanaque, N. J.	101.0	46.1	"
Rockaway, N. J.	118.0	29.8	"
Paulins Kill, N. J.	126.0	34.9	"
Musconetcong, N. J.	130.0	29.1	"
Ramapo, N. J.	160.0	42.7	Sept. 22, 1882
Esopus Creek, N. Y.	234.0	43.6	Feb. 15, 1908

With these figures, a comparative study was made of the Hackensack River and the other streams mentioned, and in almost every case it was found that the drainage basins of the other streams were steeper and had a more rapid run-off than that of the Hackensack.

The length of spillway and the number of sluice-gates were proportioned, therefore, to pass a flood of 46 000 000 gal. daily per sq. mile, equivalent to 71 sec-ft. per sq. mile, or a total of 8 094 sec-ft., with 1-ft. head on the spillway crest, this flood to be passed when the back-water against the down-stream face of the dam stands only 7.75 ft. below the spillway crest elevation of 20 ft.

In connection with these assumptions as to the maximum probable flood flows, it may be noted that a flood in excess of the assumed maximum will not endanger the stability of the dam, which has a sufficient margin of safety to permit a head of 3 ft. on the spillway crest. The top of the sluice-gate section and the abutment and wing-walls were also placed 3 ft. above the spillway crest. With this head on the crest, and back-water on the down-stream face at 7.75 ft. below the spillway crest, the dam will pass a flood of 75 000 000 gal. per day per sq. mile, which is equivalent to 4⅓ in. of depth on the drainage area in 24 hours. It is not believed that such a flood can occur, but if it should, it will result in nothing more serious than the temporary flooding of certain railroad and unowned lands above the dam.

Stratigraphy at the Dam Site

In June and July, 1911, thirty-one test borings, ranging in depth from 20 to 45 ft., were made in the vicinity of the proposed dam.

The contract for the boring called for thirty-one 3-in. borings, by the auger, hydraulic, and drive-well process, at points designated by the writer. Casings, 3 in. in diameter, were driven to impenetrable hard bottom, of hardpan, boulder, or rock, and samples furnished for every 2 ft. of depth and at changes in the stratification. The price for this work was $3 per ft. In addition, diamond drill core borings were made, as directed, in test wells which had been driven to refusal, and core samples furnished. The diamond drill core borings were made with a $\frac{15}{16}$-in. diamond core bit, at a cost of $8 per ft.

The contract also called for auger borings to be made wherever samples could be obtained. When material could not be brought up with the auger a sand bucket was used. Wash borings were made only when the auger and sand-bucket methods failed.

The location of the borings, and the stratigraphy disclosed by part of the borings are shown on Fig. 1. The outlines of the dam shown in this view are those of the original mill dam previously mentioned, the crest elevation of which was 8.6 ft. Two lines of borings, 15 ft. apart, with staggered holes, were made entirely across the valley just below the old dam. This was regarded as the most desirable location for the new dam because of the surface topography. A third line of borings was made across the valley about 375 ft. down stream from the first two lines, and these parallel lines were connected by a series of borings which approximately paralleled the thread of the stream.

The nature of the foundation as disclosed by the borings was disturbing. The hardpan or shale which lay at a depth of only 10 to 15 ft. below mean high tide at the extreme westerly end of the sections, fell off to a depth of 45 ft. below mean high tide at the easterly end.

A masonry dam of the gravity type might have been extended to this foundation, but its cost would have been prohibitive. The overlying materials were pervious and of unsatisfactory bearing value. An earth dam with a sheet-pile cut-off, and a large sluice-gate section for passing flood flows, would have served, but it was considered unwise to rely solely upon sluice-gates for the discharge of floods, and an earth dam if overtopped would have been destroyed.

The purpose of the design adopted was to retain the advantages of an earth dam with sluice-gate section and sheet-pile cut-off, and, at the same time, insure it against damage from overtopping the crest.

Design of Sluice-Gate Section

No difficulty was presented by the sluice-gate section, which was located at the extreme westerly end of the dam, opposite the main channel, where the underlying hardpan or shale lay reasonably near the surface. The sluice-gate section, therefore, was carried down to a secure underlying foundation at all points.

The sluice-gate section, from the west abutment to the wall which separates it from the spillway section, was divided into seven equal bays by concrete piers (as shown by the general plan, Fig. 2, and the horizontal and vertical

section, Fig. 3). Each pier was founded on the underlying hardpan. The space between the piers was floored over at Elevation 0 with a reinforced

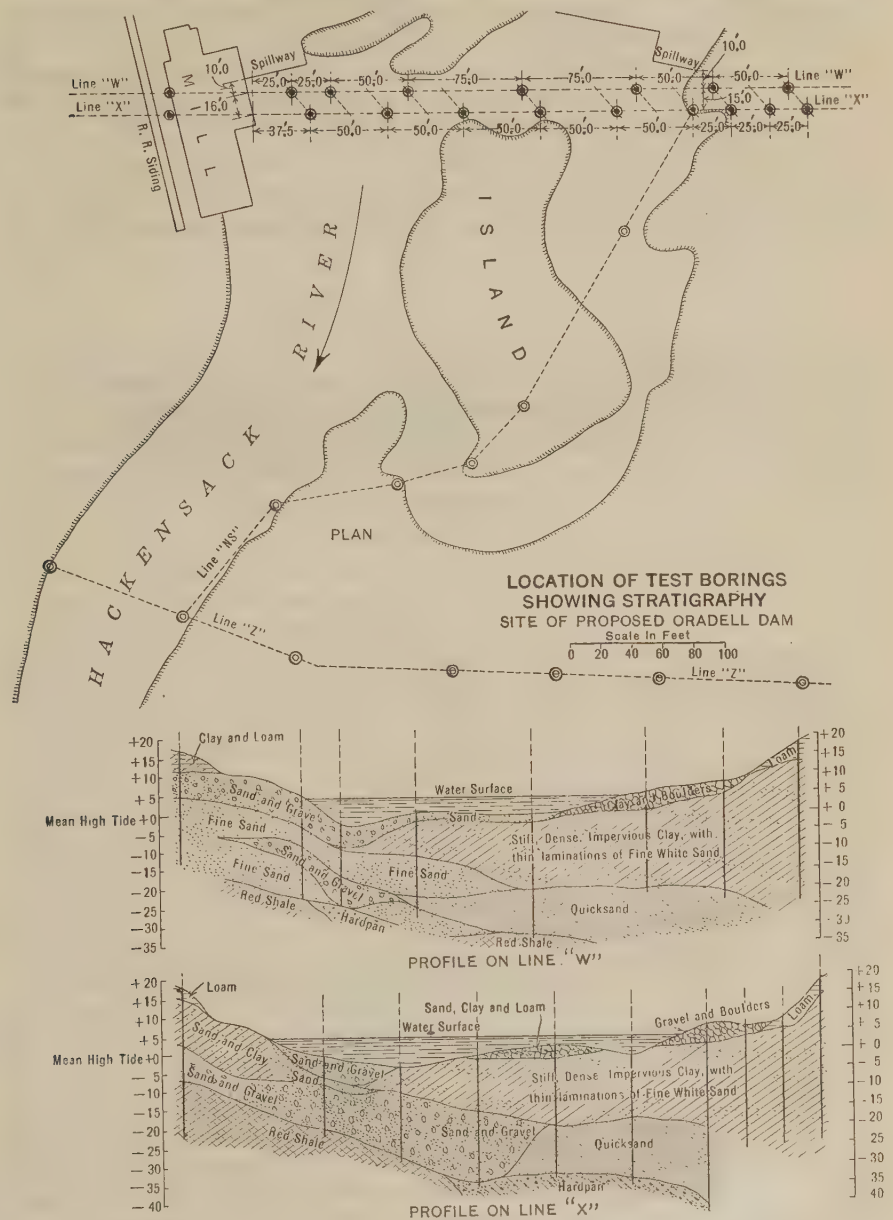

FIG. 1.

concrete slab, and a concrete cut-off wall reaching from end to end of the sluice-gate section was extended from the under side of the floor to the hard-

pan, thus affording a solid masonry cut-off the full length of the sluice-gate section. Above the floor on the line of the cut-off wall were placed the seven rectangular sluice-gates, each 7 by 9 ft. in size, one in each bay. The sills of the gates were placed at Elevation 0. Each gate is operated manually from a stand seated on the concrete platform or walkway which extends from end to end of the sluice-gate section spanning the tops of the piers which separate the bays.

Under normal conditions all water passing the dam will be passed through the sluice-gates. No water will be allowed to flow over the spillway except during the most extreme flood. Views of the sluice-gate section are shown in Figs. 4 and 5.

Design of Spillway Section

The spillway section, as may be seen from the general plan, Fig. 2, and the horizontal and vertical section, Fig. 6, is essentially an earth dam 50 to 90 ft. thick at the base. The up-stream face of the embankment was formed by the existing earth and timber crib dam with its wooden sheet-pile cut-off extending about 20 ft. into the earth. The down-stream face and toe are encased in a reinforced concrete envelope, supported on round piles, each capable of sustaining a load of 20 tons. (See Fig. 6.)

At the up-stream edge of the floor of the concrete envelope there is a continuous line of interlocking steel sheet-piling which is also carried far into the easterly bank, following along the face of the easterly concrete abutment. These sheet-piles extend to the hardpan. Their tops are embedded in the floor of the concrete envelope and in the concrete of the easterly abutment wall. Together with the concrete cut-off wall of the sluice-gate section, they form a continuous cut-off entirely across the new dam, approximately on the line of the up-stream edge of the concrete envelope. (See Fig. 6.)

The fill between the existing earth and timber crib dam and the concrete envelope, which forms the body of the new dam, is hydraulically placed and of stiff clay. This fill forms a stable and impervious dam in itself, except that it is not proof against the inroads of burrowing animals, nor against scouring if it should be overtopped.

The reinforced concrete envelope, supported on round piles, performs the function of a masonry core-wall by resisting the inroads of burrowing animals in the fill above the steel sheet-pile cut-off, and also would protect the top and down-stream face of the fill against scouring if this section of the dam should be overtopped, or because of failure promptly to control the sluice-gates.

The heads of all round piles are embedded from 1 to 2 ft. in the base of the concrete envelope, as shown on Fig. 6. This ties the piles and the whole concrete envelope together, giving resistance against sliding and upward thrust as well as support against downward thrust.

The interlocking steel sheet-piles of the cut-off wall were driven to refusal and their tops cut off evenly at Elevation +3.00 (see Fig. 6), by an oxy-acetylene torch. Their upper ends, therefore, are embedded in the concrete

envelope to a depth of 1 to 4 ft. Reinforcing rods, ¾ in. square, 4 in., center to center, were placed in the bottom slab of the concrete envelope and bent over the tops of the steel sheet-piles. The rods extend back into the floor slab for a distance of 65 diameters, thus effecting a strong bond between the steel sheeting and the concrete envelope and insuring a strong resistance against sliding.

It will be noted from Fig. 6 that the spillway section has a substructure of piling and concrete, and that the part of this substructure between Elevations +2.00 and +4.00 forms a solid, level, reinforced concrete floor 2 ft. thick across the full length of the spillway section. On this floor, structural steel frames, triangular in shape, were set up at 10-ft. intervals and secured to the floor by anchor-bolts. The reinforcing rods for the concrete overfall or facing of the spillway section were threaded through the front members of the steel frames, and when all steel was set the inclined facing slabs were poured, the structural steel frames being encased at the same time in concrete counterforts 2 ft. thick. The horizontal top slab forming the spillway crest was not poured until after all the earth fill had been placed and given ample opportunity to settle.

Earth fill, deposited by the hydraulic process and thoroughly puddled, occupies the triangular space between the floor and face slabs, between counterforts, and extends back to the top of the existing timber crib dam. The sloping top surface of this fill is paved for a distance of 15 ft. back from the up-stream edge of the spillway crest.

In each panel between counterforts of the spillway section a pair of 2-in. weep-holes were placed through the face slab of the concrete envelope at the floor level. The upper ends of these 2-in. pipes were screened with fine copper mesh, and the acute angle between the floor and face slabs of the envelope was then filled with a triangular fillet of graded gravel and sand, which was intended to facilitate the drainage and consolidation of the fill and, at the same time, prevent the washing out of the filling material. The weep-holes should also relieve the face slab from any direct water pressure which might otherwise occur if the fill should settle away slightly from the concrete.

It will be noted that a considerable volume of concrete was saved by the adoption of the type of construction shown, thus lessening the dead weight of the dam, and also that under the extreme conditions of loading described later the downward pressure is considerably reduced (as compared with the pressures which would have obtained with a solid masonry section) by the action of the upward water pressure on the under side of the face slab.

Other Features of Design

The westerly abutment of solid gravity section was carried down to hardpan. Its up-stream end was curved on a 30-ft. radius and extended into the bank for a distance of 80 ft.

The easterly abutment, also of solid masonry and similar in form to the westerly abutment, was extended down to Elevation —3.00 and founded on round piles driven to hardpan. As previously stated, the easterly abutment

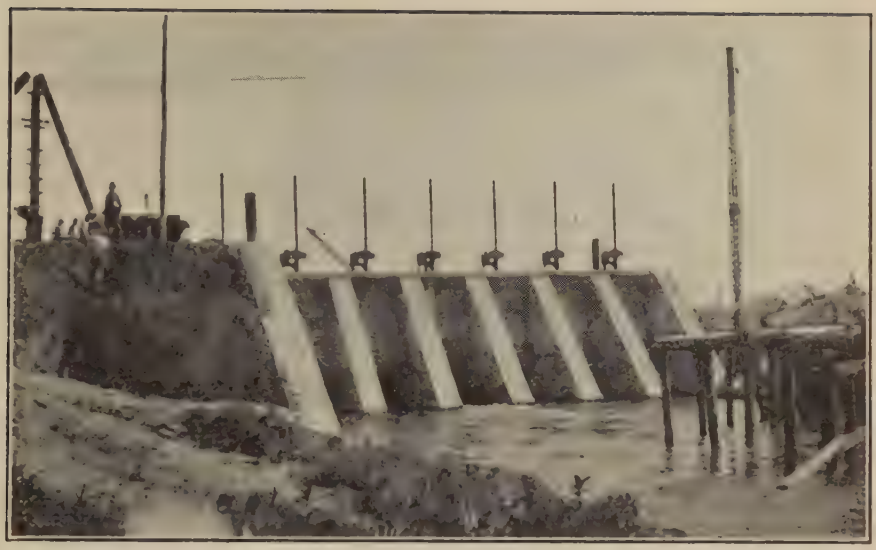

FIG. 4.—VIEW OF SLUICE-GATE SECTION, ORADELL DAM.

FIG. 5.—VIEW OF SLUICE-GATE SECTION, ORADELL DAM.

was also provided with a steel sheet-pile cut-off where necessary to intercept possible under flow.

The approach to the sluice-gates, which has a uniform elevation of —0.5 ft., was paved with a reinforced concrete slab for about 90 ft. up stream from the gates and across the full width of the sluice-gate section.

In order to retain the earth filling back of the concrete envelope of the spillway section and to separate this fill from the channel approach to the sluice-gates, a dividing wall was constructed, on a slightly curved sweep, as shown in Fig. 2. This wall extends from its junction with the dividing wall between the concrete envelope and the sluice-gate section for about 80 ft. up stream. It is of solid masonry to a depth of 3 ft. below the floor of the approach to the sluice-gates, and is supported on round piles which extend to the hardpan. It is also provided with a sheet-pile cut-off which is carried to hardpan.

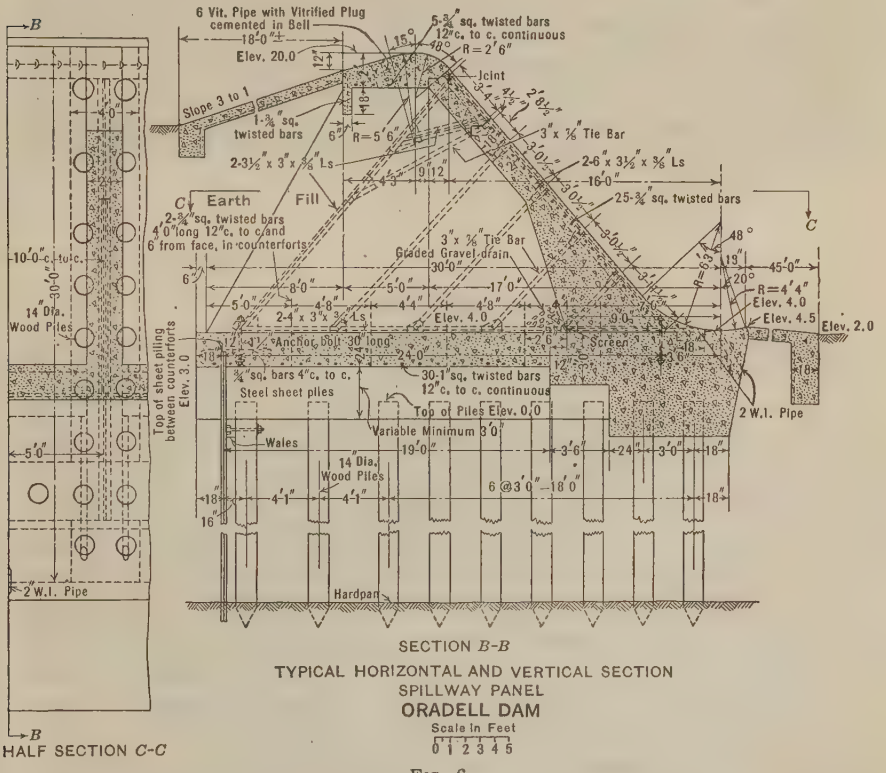

FIG. 6.

Below the toe of the concrete envelope of the spillway section, and the down-stream edge of the sluice-gate section, the stream channel is paved for a distance of 45 ft. across the full width of the dam between abutments. This pavement or apron is of reinforced concrete 8 in. thick and is turned down into the earth for a distance of several feet at its down-stream edge.

The concrete envelope was keyed into the face of the easterly abutment wall and into the face of the dividing wall between the sluice-gate and spillway sections, thus forming expansion joints at these points. There are no expansion joints in the 330 ft. of concrete envelope except at the ends, as noted. The concrete envelope has been subjected to a wide range of temperature with full water pressure behind it. The end joints have opened as much as $\frac{1}{8}$ in. No visible cracks have occurred at intermediate points in the envelope and no visible leakage has appeared at any point. There are practically no damp spots visible on the face of the envelope under full water pressure.

The abutment walls, which are unreinforced, were cast in sections with tongue and grooved joints at approximately 30-ft. intervals. Under extreme range of temperature each of these joints has opened about $\frac{1}{8}$ in.

Unit Stresses

Each round pile under the spillway section was driven to sustain safely a load of 20 tons as determined by the so-called *Engineering News* formula for drop-hammer driving. As previously stated, all steel sheet-piles were driven to refusal.

All concrete was mixed in proportions of 1 : 2.5 : 5, and all reinforced concrete was designed on the basis of the following units:

$K = 0.65$	$C = 450$
$p = 0.0052$	$r = 15$
$S = 14\,000$	$E_c = 2\,000\,000$

Construction Methods

No cableway was used in the construction of the dam. Excavated material was handled with derricks. All concrete was mixed in a single mechanical batch mixer situated on the bank nearest which work was being done, and handled to place by derricks and the ordinary steel double-side dump-cars running on portable narrow-gauge track.

A Blaw-Knox steel form and form carrier was used in casting the face slab of the concrete envelope which was poured in 30-ft. sections. The joints were made at the center of the counterforts in order to secure water-tightness. The heavy face reinforcement was carried through these joints. The steel form and form carrier are shown in Fig. 7.

Two types of pile-driver were used on the work. The round and steel sheet-piles across the full length of the spillway section were driven by a drop-hammer weighing 2 950 lb. The other piles were driven with a double-acting steam hammer suspended from a derrick boom. The total weight of this hammer was 3 500 lb., and the weight of the ram was 575 lb. The steam cylinder was 6 by 10 in., and at a steam pressure of 60 lb. per sq. in., the strokes averaged about 170 per min.

Experiments were made on test piles to determine the ratio of penetration per stroke to give the same bearing value, the double-acting steam hammer

FIG. 12.—VIEW OF COMPLETED ORADELL DAM FROM DOWN-STREAM SIDE.

being compared with the drop-hammer under the particular conditions which obtained on this work. The experiments suggested the following as a desirable general formula applicable to all methods of pile-driving, including drop-hammer, single-acting steam hammer, and double-acting steam hammer:

$$L = \frac{2\ W \times h}{S + \frac{\text{Constant}}{N}}$$

in which

L = the safe bearing value, in pounds per pile;
W = the weight of the ram, in pounds, for drop-hammers and single-acting steam hammers, and the weight of the ram plus the mean effective steam pressure for double-acting steam hammers;
h = the length of stroke, in feet;
S = the penetration, in inches, under the last blows of the hammer;
N = the number of strokes per minute.

The constant in the second term of the denominator should be determined by a comprehensive series of experiments.

The average number of piles driven per day on the spillway section was 33 for round piles, and 15 for steel sheet-piles. The driving of these piles occupied 2 months with a crew of 8 men.

As the driving of the steel sheet-piles progressed, some difficulty was experienced from the tendency of the joints between the sheet-piles to spread at the top while held tightly together at the bottom, thus causing the piles to get out of plumb. This was corrected by the occasional driving of wedge-piles as required. Fig. 8 shows one of the wedge-piles which was made on the ground by cutting and riveting together two of the ordinary piles. Fig. 9 shows the operation of cutting off the heads of the steel sheet-piles after driving by the oxy-acetylene torch.

The hydraulic fill back of the spillway section was distributed from an elevated hopper constructed on the easterly abutment of the dam adjacent to a large spoil pile. The filling material was elevated to this hopper by derricks. A hose stream was then played upon it, by which the filling material was washed down through a steel pipe having flexible joints, to the desired point of discharge. This operation is shown on Fig. 10. By the construction of proper dikes most of the filling material was deposited under water, and all of it was thoroughly puddled.

Fig. 11 is a general view, from the easterly abutment, of the spillway and sluice-gate sections as the dam was approaching completion, but before the completion of the hydraulic fill or the placing of the top slab. The hydraulic fill was completed late in the fall of 1921. The top slab was not cast until 1922. Fig. 12 shows a general view of the completed dam from the down-stream side.

Stability—Spillway Section

Forces.—Two conditions of loading, subsequently referred to as *A* and *B*, were selected as representing the most extreme conditions which might conceivably occur. The spillway section (concrete envelope) was made stable under both these extreme assumed conditions of loading.

Condition A.—The concrete envelope was assumed to have been constructed to its ultimate height (crest elevation, 20 ft.), and then subjected to a maximum flood overtopping its spillway crest by 1 ft. before any of the earth fill had been made. This condition could have occurred only during the construction period and only in event the dam had been built to its full height at the first operation. As actually constructed (concrete envelope and earth fill carried to Elevation 16 and raised later to Elevation 20), the nearest approach to Condition *A* which can be imagined would be that in which, after construction to the full height, the earth fill should settle away slightly from the inner face of the concrete slab, at a time when water was flowing over the spillway, thus causing full water pressure against the slab; but as constructed this could not occur without, at the same time, having the benefit of the weight of a considerable portion of the earth fill on the floor of the envelope in resisting overturning.

Condition B.—The same conditions as to loading as Condition *A* were assumed except that the resisting moment and downward pressure due to the weight of earth on the floor of the envelope was also taken into account.

With one exception which represented a most extreme condition not possible to be found save under very exceptional circumstances during the construction period, the four resultants tested cut the base practically at the mid-point.

DISCUSSION

STUART K. KNOX,* M. AM. SOC. C. E.—The most interesting part of the Oradell Dam is the spillway, which extends throughout the greater part of its length. This is an earthen section protected on its down-stream side by a concrete envelope, so that it may be overtopped without injury. It is this concrete envelope with its support of round piles and its steel sheet-pile cut-off, which constitutes the novel feature of the design.

When the plans for the dam were prepared, about 1911, the ideas were supplied by Mr. Hill. The speaker's function was merely that of developing the author's notions and in working out details. He recalls that when this particular idea was suggested, it did not, at first, appeal to him. His first impression of the proposed construction was that of a reinforced concrete dam perched on stilts, in a somewhat precarious position; of a buttressed dam turned hindside before. He feared the difficulty of insuring the structure against undermining, and that its purpose would thereby be defeated.

However, these unfavorable first impressions were quickly removed after a detailed analysis had demonstrated the practicability of the construction proposed. After careful examination of the stresses and of the resultant forces to which the dam would be subjected under the most extreme conditions of loading that could be imagined, he became convinced that the design represented an intelligent and effective solution of a really difficult problem, and that is still his opinion.

The actual conditions of loading to which the concrete envelope would be subjected were unusually difficult to predetermine. Three or four conditions were assumed, therefore, which it was thought represented the greatest possible extremes. The stresses and resultant forces were computed on the assumption that the full water pressure had been applied to the concrete envelope itself, without any earth fill, a condition which might conceivably have arisen after the concrete envelope had been completed and before the back-fill had been placed. They were also computed on the basis of the back-fill having been placed before the water pressure was applied. Sets of calculations were made on the assumptions that there was, and that there was not, upward water pressure on the bottom of the concrete envelope.

The stresses were first computed graphically and finally were carefully checked analytically. The resultant of the forces under each of the various assumed conditions of loading cut the base of the envelope close to its center.

HOWARD T. CRITCHLOW,† ASSOC. M. AM. SOC. C. E. (by letter).—In 1912 the State of New Jersey passed a law (Chapter 243, P. L. 1912) authorizing the State Water Supply Commission to have supervision over the erection and maintenance of dams on certain rivers and streams or reservoirs within the State or between it and any other State, in order to protect life and property which might be endangered by the improper construction of any dam and

* (Nicholas S. Hill, Jr.), New York, N. Y.

† Chf., Div. of Waters, Dept. of Conservation and Development, Trenton, N. J.

reservoir. In 1916, the Board of Conservation and Development became the successor of the Commission. As Hydraulic Engineer of the Department the writer was called on to examine the plans for the Oradell Dam on the Hackensack River.

On account of the unique design and the importance of the structure, the Board appointed a committee of experts, consisting of William H. Burr and Arthur H. Pratt, Members Am. Soc. C. E., and the writer, to examine the plans and specifications and determine whether they were in accord with good engineering practice. It is to the credit of the author and his associates that the Committee of Experts found so little to criticize in the plans for the structure. After careful consideration of the foundation materials immediately beneath the concrete envelope, the Committee recommended that protecting paving below the spillway and sluice-gate sections be extended farther down stream in order to protect the structure against scouring of the unconsolidated materials on which it rested. It was also pointed out that, inasmuch as the sluice-gate section was designed to handle a large part of the flood waters, the gates must have adequate attendance to insure that they may be opened promptly and be kept clear of ice and floating débris which might cause plugging of the openings or fouling of the gate mechanism.

In checking the capacity of the sluice-gates and spillway to pass extreme floods, a rate of 100 sec-ft. per sq. mile was considered. With this assumption the head on the spillway with all sluice-gates open would be about 2.2 ft. Although this head is 1.2 ft. higher than that assumed by the author the dam can safely sustain such a flow with all the gates open. The author bases his assumption of maximum flood flow of 71 sec-ft. per sq. mile largely on data in Table 1 which is given in millions of gallons per day instead of the usual second-feet. Some of these records do not represent the maximum floods. The discharge of the Pequannock River at Macopin Dam (drainage area, 62.5 sq. miles) is recorded* as 201 350 000 cu. ft. in 10 hours from 10:00 P. M., October 9, to 8:00 A. M., October 10, 1903, which represents an average discharge of 88 sec-ft. per sq. mile for 10 hours. What may have been the maximum rate is not recorded, but it must have been considerably more than 100 sec-ft. per sq. mile.

In examining the stability and safety of the Pompton Lakes Dam on Ramapo River, New Jersey, which was built in 1908 prior to State supervision, the writer had occasion to study the flood records on this stream. The following is quoted from his official report:

"The drainage area of the Ramapo at the confluence with the Pompton River is 160.7 sq. miles, while at the Pompton Lakes Dam 1.5 miles above the mouth, the drainage area is 159.5 sq. miles. In Volume III of the New Jersey Geological Survey (1894), page 155, it is stated that during the flood of September, 1882, the Ramapo had a maximum discharge of 10 540 cu. ft. per sec., which is equivalent to a water level in the lake of about 4.5 ft. above the elevation of the crest of the dam. In the U. S. Geological Survey *Water Supply Paper No. 88,* page 35, it is stated that during the flood of February-March, 1902, 'on the Ramapo River at Pompton Furnace the highest water was observed at 6:00 P. M. on March 1, when it reached 4.1 ft. above the dam crest'.

* *Water Supply Paper No. 92,* U. S. Geological Survey, p. 16.

In the Annual Report of the New Jersey Geological Survey for 1903, pages 27 and 28, it is stated that during the flood of October, 1903, 'the Ramapo at about 5:40 A. M. of October 9, when the Pompton Steel Works dam broke, had reached a discharge of 7 123 cu. ft. per sec. * * * Undoubtedly the maximum discharge was much in excess of this.' This same report in Table V, on page 27, states that the maximum discharge of the Ramapo during the flood of 1896 was 8 731 cu. ft. per sec. Thus it is seen that during a period of less than 25 years there were 4 floods that caused a lake level of over 4 ft. above the crest of the dam and a possibility that during the flood of 1903 the level would have been 5 ft. above the crest if the dam had not broken. [The crest of the old dam was of the same elevation as the existing structure.] Therefore, in analyzing the strength of the dam and wing-wall a flood level 5 ft. above the crest of the dam has been considered."

A 5-ft. head on the Pompton Lakes Dam (300 ft. long) is equivalent to a discharge of 85 sec-ft. per sq. mile, as compared with the record of 66 sec-ft. per sq. mile given in Table 1 for the flood of September, 1882. The flood of October, 1903, appears to have been a more severe flood than that of September, 1882, on North Jersey streams. Unfortunately, few permanently established stream-gauging stations were being operated during that flood. Thirty-six permanent gauging stations are maintained in New Jersey, twenty-six of which are equipped with continuous water-stage recorders. No extreme flood heights have yet been recorded. The heights given in Table 2 are, however, of record.

TABLE 2.—Recorded Run-Offs.

Tintern Manor Reservoir, on Swimming River.....	48	180	Earth dikes
Oak Ridge Dam, on Pequannock River.....	27.3	190	Earth dikes

The Oradell Dam is the most important structure in New Jersey equipped with sluice-gates for passing flood waters. As the author points out, however, this was necessary in order to hold down the water level in the reservoir and

prevent the flooding of railroad and other unowned land. There are many dams in streams in the Coastal Plain of New Jersey that depend entirely on manual control of sluice-gates to pass flood waters. Most of these are structures built prior to State supervision. It is very desirable to eliminate so far as possible the necessity for operating gates to pass floods and to rely on overflow or other automatic spillways. In the Oradell Dam, under present conditions of operation as a water-supply reservoir and with attendants constantly on duty at the pumping station immediately below the dam, it would seem that adequate provision has been made for gate control.

In some structures where inadequate spillway capacity is provided and it becomes the writer's duty to require enlargement and often added construction cost, he is met with the argument that the builder is not justified in making the increased expenditure to take care of a condition which may occur only once in a lifetime. Engineers use factors of safety of as much as six or more in many of their designs and yet the hydraulic engineer is often limited to a factor of two in many parts of his design. The writer is very strongly of the opinion that an endeavor to save money by providing a spillway of other than liberal capacity is poor economy for the owner as well as for the general public.

A. T. Ricketts,* M. Am. Soc. C. E.—The wedge-piles one of which is shown in Fig. 8 were made to meet a difficulty experienced in driving the sheet-piling due to a tendency of the piles to drive out of plumb. The tops, which were held in perfect alignment by waling strips, traveled ahead of the lower ends. After 50 or 75 ft. of piling had been driven the inclination of the piles was sufficient to cause lateral vibrations under the hammer. An attempt was made to correct the difficulty by beveling the points so as to spread the joints at the bottom, but this was not successful.

No difficulty was experienced in driving the wedge-piles with their broad ends down. The angle of the wedge was made slightly greater than the inclination of the last straight pile driven so that the top of the pile following the wedge-pile inclined slightly toward the piles in place. Two or three of the wedge-piles were used under the spillway section.

Thaddeus Merriman,† M. Am. Soc. C. E.—Mr. Critchlow touched on a very important point when he spoke of the spillway capacity. The maximum recorded floods as reported by the author are about 70 cu. ft. per sec. per sq. mile. This figure, however, does not represent the possibilities. Since the design of the Oradell Dam was made there has been recorded a flood discharge of 171 cu. ft. per sec. per sq. mile from a drainage area of 192 sq. miles on Esopus Creek in the Southern Catskills, New York State. Had the storm which produced this flood been centered over that water-shed, the resulting discharge would have been substantially greater.

Among the great storms on record is that of October, 1869,‡ which was central near Canton, Conn., where the total rainfall was 12.35 in. At Middle-

* Associate Engr., Nicholas S. Hill, Jr., New York, N. Y.

† Chf. Engr., Board of Water Supply, City of New York, New York, N. Y.

‡ *Transactions*, Am. Soc. C. E., Vol. VII (1878), p. 224.

town, Conn., out of a total precipitation of 9.37 in., 7.15 in. fell in 24 hours. This quantity of rainfall in 24 hours compares with 10.42 in. as measured* at Newark, N. J., on October 8 and 9, 1903.

The design of the Oradell Dam is most interesting and instructive, because, at first glance, it seems to be turned 180° from a normal position. Close study, however, reveals a most carefully executed design, admirably adapted to meet local conditions.

The design of any structure constitutes about one-half the entire story; the other half is in the kind and quality of the materials of which the structure is put together. This dam was built of concrete and it would be of value if, for the purpose of record, the author would describe the sands and the aggregates that were used. A statement as to the source of these materials, as to the kind of cement used, and as to the methods of mixing and proportioning, with particular reference to the water-cement ratio, would be most helpful to future students of concrete.

With regard to most structures the history of the materials entering into them is unknown and it is therefore practically impossible to trace back and determine the probable causes of disintegration or failure if it occurs. Records of this kind regarding many structures of the past twenty years would, to-day, be of great value.

Lazarus White,† M. Am. Soc. C. E.—The writer wishes to call attention to the dangers of a dam founded on wooden piles. In case of settlement of the material below the dam a space will be created through which circulating water may wash away such material with the danger of "piping". Of course the steel sheet-piling cut-off is designed to prevent this, but the danger is there in case of any defect of the cut-off.

The wooden piles were driven to sustain safe loads of 20 tons as determined by the *Engineering News* formula. The speaker's experience has demonstrated to his satisfaction the utter unreliability of the so-called *Engineering News* formula when checked with tests made by reliable hydraulic apparatus. In one piece of work not very far from the Oradell Dam, piles were driven to "refusal" in a stiff clay; a few weeks afterward they could sustain loads of only a few tons each from a hydraulic jack. He does not believe in the variation of the *Engineering News* formula proposed as "a formula applicable to all methods of pile-driving, including drop-hammer, single-acting steam hammer and double-acting steam hammer." In his opinion, the only safe way to determine the value of piles is to test a group of them against an actual load. Where piles are closely spaced the test of a single one may be deceptive because of overlapping effects.

As to the rusting of steel sheeting when buried below the ground, the speaker has often noted that it lasts very well. Steel sheeting dug up after being buried for about ten years was surrounded by a coating of rust which, when removed, disclosed that the sheeting itself retained nearly its full cross-section. This is also true of steel pipe buried in the ground. The coating of iron rust which forms in contact with the steel preserves it from the attack of oxygen in the ground or in circulating water.

† Pres., Spencer, White & Prentis, Inc., New York, N. Y.

ALBERT C. AREND,* M. AM. SOC. C. E. (by letter).—The writer believes that the conditions found to exist at the Oradell Dam are very similar to those found at points on the Big Blue and Republican Rivers, in Nebraska, but where no funds have been available to provide for such costly construction. These structures were evidently safe during all stages of construction work, and consequently they must have been unnecessarily safe after the earth fill was properly completed.

The author's list of ten special conditions does not include any specific cost limitation although Provision No. 6 indicates that there was a limit.

The life of the completed work will evidently be measured by that of the steel sheet-piling. The end of the east abutment, where the steel sheet-pile cut-off stops, is evidently the weakest point of the structure, and the next weakest point would probably be where this solid masonry wall ends in the clay and white sand.

This criticism merely calls attention to the comparative inconsistency of a very safe structural design having ends or connections of only one-half or one-fourth the resistance of the connecting or adjacent parts. "A chain is still as strong as its weakest link."

It would be interesting to know the cost of this dam, and what the cost studies showed in comparison with a masonry section of gravity type extending to hard foundation. Then, if not already investigated, comparison could be made of the cost of a Taintor gate section of equal capacity and of an earth dam with sheet-pile cut-off.

Where the density of population to be served (or menaced) and the volume of business warrant the cost of an abnormally safe type of design, that part of the cost which might be termed security insurance is undoubtedly justified when it does not become a financial hindrance to the project; but how much less security, because of cost, would be justified where the population requirements, the volume of use, and the returns on the investment would not provide for any more than a necessary minimum cost? That is often the controlling and most important business feature connected with such work, and the writer would appreciate some discussion on this particular phase of the design.

PAUL E. GISIGER,† ASSOC. M. AM. SOC. C. E. (by letter).—The dam described is of a very unusual and interesting type and its designers and builders are to be congratulated for discarding precedent and originating something new.

Studying the cross-section of the Oradell Dam, the question arises as to whether it would not be of advantage to go one step further, discarding the earth back-fill on the base slab and letting the water itself be part of the weight of the structure. Such a condition has in fact been assumed in the design, since it could have occurred while the dam was under construction.

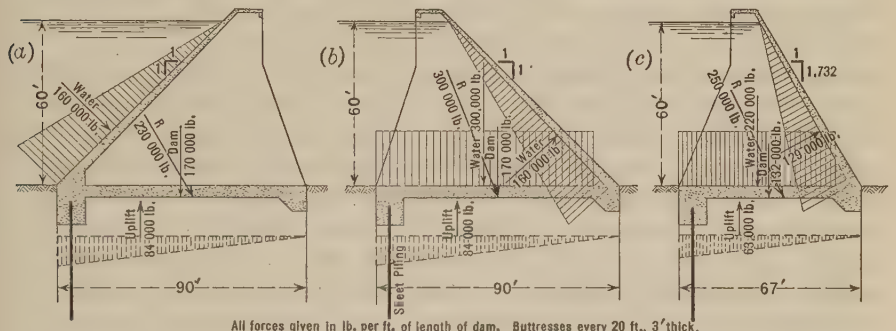
It is easy to show that a dam of this type, the reverse of the conventional reinforced concrete structure, can be designed for the same degree of safety with a considerably smaller cross-section; and it is hard to understand why

* Cons. Engr., Omaha, Nebr.

† Care, Pennsylvania Water & Power Co., Baltimore, Md.

this never has been done before. An aversion to putting tension in the buttresses and in their connection to the face slab may partly account for this reluctance, but it did not stop engineers from building reinforced concrete retaining walls of such a type. A very good solution of this detail problem has been found in the Oradell Dam by the use of structural steel.

The writer has analyzed three skeleton designs of reinforced concrete dams, assuming similar height and foundation conditions. Fig. 13 (*a*) shows a dam of conventional design, Fig. 13 (*b*) the same cross-section with water acting from the other side, and Fig. 13 (*c*) a reduced cross-section, which is even safer than Fig. 13 (*a*). The accompanying computations show that for two dams of the same cross-sectional area, Types (*a*) and (*b*), the one with water standing on the base slab, Type (*b*), is considerably safer against sliding and overturning; but, for the same safety as with the conventional type, Fig. 13 (*a*), the cross-section of the other type, Fig. 13 (*c*), can be reduced by at least 25 per cent.



All forces given in lb. per ft. of length of dam. Buttresses every 20 ft., 3′ thick.

Volume of Dam = 42 cu. yds. per lin. Foot

$$\frac{\text{Stabilizing Moment}}{\text{Overturning Moment}} = 2.2$$

$$\frac{\text{Sum of Vertical Forces}}{\text{Sum of Horizontal Forces}} = 1.75$$

Volume of Dam = 42 cu. yds. per lin. Foot

$$\frac{\text{Stabilizing Moment}}{\text{Overturning Moment}} = 2.4$$

$$\frac{\text{Sum of Vertical Forces}}{\text{Sum of Horizontal Forces}} = 2.35$$

Volume of Dam = 32 cu. yds. per lin. Foot

$$\frac{\text{Stabilizing Moment}}{\text{Overturning Moment}} = 2.2$$

$$\frac{\text{Sum of Vertical Forces}}{\text{Sum of Horizontal Forces}} = 2.10$$

FIG. 13.—ANALYSES OF SKELETON DESIGNS OF REINFORCED CONCRETE DAMS.

A further advantage that should not be under-estimated is the easy adaptation of this cross-section to a spillway, whereas with the usual type the transition from dam to spillway as a rule presents many difficulties.

The objection might be raised that, due to the weight of water on the base slab, the foundation pressures become higher. This would be erroneous, however, since the load, instead of being concentrated under the buttresses as in the conventional type, will be almost evenly distributed over the whole base.

NICHOLAS S. HILL, JR.,* M. AM. SOC. C. E. (by letter).—In several of the discussions comment is made upon the flood flow assumed in proportioning the sluice-gate and spillway sections. These sections have a discharging capacity of 71 cu. ft. per sec. per sq. mile when the water in the reservoir stands 1 ft. above the spillway crest. It was desired not to exceed this elevation because of back-flooding but, as stated, a flood in excess of this quantity

* Cons. Engr., New York, N. Y.

will not endanger the stability of the dam which has a sufficient margin of safety to permit a head of 3 ft. on the spillway crest. With this head the discharging capacity of the sluice-gate and spillway sections is 115 cu. ft. per sec. per sq. mile.

This discharge capacity is considerably greater than that of the Boonton Dam on the Rockaway River, mentioned by Mr. Critchlow. This dam has been in service for twenty years and, as far as the writer knows, its spillway capacity has never been overtaxed nor its sufficiency questioned. The discharge capacity of the Oradell Dam is also greater than that of the Pompton Lakes Dam on the Ramapo River, although less than that of the Wanaque Dam now building on the Wanaque River. The drainage areas tributary to these dams are roughly comparable in size and they are not far distant from each other.

The question of relative size of drainage area is, of course, important in comparing rates of flood discharge to be anticipated, as are also the topography of the water-shed and other factors. The writer himself has investigated and found well authenticated a flood discharge of 557 cu. ft. per sec. per sq. mile from a small area of 1.7 sq. miles. In the closing discussion on his paper, "The Design of Earth Dams", Joel D. Justin, M. Am. Soc. C. E., has compiled a table (Table 9*) which indicates recorded floods on Pennsylvania streams in excess of 4 000 cu. ft. per sec. per sq. mile from areas less than 1 sq. mile in extent. This table, which is entitled "Maximum Recorded Floods in American Rivers", shows a discharge rate of 3 200 cu. ft. per sec. per sq. mile from a drainage area of 0.2 sq. miles on Beacon Creek near Fishkill, N. Y., and a discharge rate of 2 300 cu. ft. per sec. per sq. mile from a drainage area of 1.5 sq. miles on Mad Creek, Le Roy, N. Y. With only a few exceptions, however, the flood discharges from areas exceeding 100 sq. miles in extent are less than 100 cu. ft. per sec. per sq. mile.

Mr. Merriman mentions the fact that in the storm of October 8 and 9, 1903, the quantity of rainfall in 24 hours as measured at Newark, N. J., was 10.42 in. While this is true, it is believed to have little bearing on the maximum intensity of flood flow to be anticipated on the Hackensack River. In this same storm the rainfall was 11.45 in. as measured at Paterson, N. J., which is only a few miles from the Oradell Dam. There are published figures which indicate that on July 26, 1819, 18 in. of rain fell at Catskill, N. Y., in a period of 7½ hours, and there are records which indicate that in the storm of August 5, 1843, 16 in. of rain fell in 3 hours at Concord, Pa., and 10 in. in 2 hours at Brandywine Hundred, Pa. Storms of extreme intensity are likely to be local and the average over a water-shed comparable with that of the Hackensack, to be smaller than those indicated by these maxima.

Mr. Merriman states that since the Oradell Dam was designed there has been recorded a flood discharge of 171 cu. ft. per sec. per sq. mile from a drainage area of 192 sq. miles on Esopus Creek in the Southern Catskills, New York State. Such data have a more direct bearing than the references to rainfall. However, the Esopus is a mountain stream. The Ramapo, Rockaway, and

* *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), pp. 135 to 139, inclusive.

Wanaque Rivers mentioned by Mr. Critchlow are highland streams. These considerations are important in estimating the maximum intensity of flood discharge to be anticipated.

Although the drainage area of the Hackensack River is not far distant from those of the rivers just mentioned, and does not differ greatly from them in extent, there are important factors of a geographic, topographic, and geologic nature which operate to make the period of accumulation of storm waters on the Hackensack relatively long. Among these may be mentioned the shape of the water-shed, the porosity of its soil, the large extent of its flats and swamp areas, the evenness of its topography, and its low elevation. The maximum elevation on the Hackensack water-shed is only 830 ft., above mean tide, and the greater part of its area does not exceed 300 to 400 ft. in elevation. It is the opposite of flashy. The slopes are flat. There is practically no outcropping rock. The dry-weather flow is much better sustained than on such streams as the Croton River, due to the porosity of the soil. Conversely, the flood flows are less. The temporary retention of the flood flows on the flats, and in the swamp areas, contributes to a leveling of the peaks of flood as do the other factors mentioned. All these matters were studied and taken into account in fixing the discharge capacity required. In the light of these studies the writer does not feel apprehensive concerning the adequacy of the flood-flow assumptions made in proportioning the Oradell Dam.

In reply to Mr. Merriman's questions regarding materials and methods used for the concrete, the ingredients of the concrete were trap rock from near-by sources, sand of excellent quality from a local pit at New Milford, N. J., and Vulcanite Portland cement. These were mixed in the proportions 1 : 2.5 : 5 for mass concrete and 1 : 2 : 4 for reinforced work. The ingredients were measured to insure proper proportioning. The consistency may be described as "medium". As stated by the writer a batch mixer was used, and the concrete handled to place by derricks and the ordinary double-side dump-cars running on portable narrow-gauge track, so that a wet mix was unnecessary.

Mr. Arend speaks of the construction as "costly". This was not the case. The most important object of the designer, the one that led him to the adoption of this unusual design, was to secure a structure adapted to the conditions at a minimum of cost. An earth dam with sheet-pile cut-off was not adapted to the conditions. The use of Taintor gates was considered. A masonry section of gravity type extending to hard foundation would have been much more costly than the design adopted. Having determined that the selected type was more economical than the others available, the only remaining opportunity for economy lay in lightening the section. In view of its novelty the writer would not have felt justified in assuming less rigid conditions in the design of the dam. The total cost of the construction was approximately $390 000.

Mr. Arend seems to the writer to misapprehend some features of the design. He states that the end of the east abutment is the weakest point, that "a chain is still as strong as its weakest link", and that a safe structural design having ends or connections of only one-half or one-fourth the resistance of the con-

necting or adjacent parts is "inconsistent", which is granted. The premises, however, are believed not to accord with the facts. The misunderstanding perhaps arises from a belief that the sheet-pile cut-off terminates at the face of the east abutment, whereas it is stated in the paper that the cut-off is "carried far into the easterly bank, following along the face of the easterly concrete abutment."

Mr. Gisiger has presented some interesting cost comparisons which constitute a valuable supplement to the paper.

Paper No. 1592

UTILIZABLE CAPACITY OF STEEL MEMBERS OF STRUCTURES*

By Henry S. Prichard,† M. Am. Soc. C. E.

With Discussion by Messrs. C. A. P. Turner, H. F. Moore, G. B. Woodruff, R. von Fabrice, F. E. Schmitt, and Henry S. Prichard.

Synopsis

This paper gives the results of a study to determine the fundamental facts on which the utilizable capacity of steel members of structures depends, and to devise methods whereby the utilizable capacity of any member can be determined, as nearly as practicable.

The utilizable capacity of any steel member is measured, as the case may be, by the greatest load which statically or repeatedly, or by the greatest opposite loads which, alternately, can be applied during the lifetime of the structure (as determined by other considerations) without causing failure, ruin, or seriously objectionable deformation (plastic, elastic, or combined plastic and elastic).

The subject is sub-divided and developed as follows:

Part 1.—Constitution, Elasticity, Deformation, Elastic Fatigue, and Permanent Fatigue of Steel and Iron. (Pages 1216 to 1217.)

Part 2.—Originally Imperfect Elastic State of Specimens of Steel and Iron; the Development, by Repeated Cycles of Stress, of Fields of Seemingly Perfect Elasticity of Chosen Range and Position; and the Limitations to Such Development Imposed in Practice by Critical Deformation. (Pages 1217 to 1218.)

Part 3.—Explanation of the Perfecting of Elasticity within Limits by the Modification of Initial "Auto-Stresses". (Pages 1218 to 1220.)

* Presented at the meeting of December 9, 1925.

† Analytical Engr., Am. Bridge Co., Pittsburgh, Pa.

Part 4.—Endurance Tests and Their Significance; and the Possibility of Remote Fatigue. (Pages 1220 to 1228.)

Part 5.—Interpretation of Tests as Criteria of Utilizable Capacity of Members in Direct Tension or Compression. (Pages 1228 to 1236.)

Part 6.—Utilizable Capacity of Compression Members. (Pages 1237 to 1249.)

Part 7.—Utilizable Capacity of Tension Members and of Members Subjected to Alternate Stresses; and the Results of Loading Tension and Compression Members Beyond Their Useful Limit Points. (Pages 1249 to 1254.)

Part 8.—Beams and Plate Girders under Transverse Loads. (Pages 1254 to 1262.)

Part 9.—Combined Compression and Flexure. (Pages 1262 to 1265.)

Part 10.—Combined Tension and Flexure. (Pages 1265 to 1267.)

Part 11.—Variation of the Characteristic Useful Limit Point Between Different Members of Nominally the Same Grade of Steel. (Pages 1267 to 1269.)

Part 12.—Limitation of the Useful Limit Point and Maximum Tensile Strength, as Criteria of Utilizable Capacity, to Steel of Good and Suitable Quality and Workmanship. (Page 1269.)

Part 13.—Factor of Safety. (Page 1270.)

In the systematic development of the subject under the headings noted, pertinent conclusions are successively reached which are briefly stated, as follows:

(*a*) Owing to the presence in plates, shapes, and bars, as they come from the mill yard, of a balanced system of internal forces (herein termed "autostresses"), the elastic limit, as determined in a long length with very delicate micrometers and measured by the intensity of the external forces which produce it, is in nearly all cases very low.

(*b*) The elastic limit, strictly defined, would be of no value as a criterion if determined, and should not be specified.

(*c*) In commercial practice a specified "elastic limit" is understood by both the seller and the buyer to be the point in a commercial test, as ordinarily conducted, properly known as the "yield point."

(*d*) The elasticity of a piece of steel, over a wide range of stress, can be perfected, or seemingly perfected, and then remain perfect or seemingly perfect, as nearly as may be gauged by very delicate micrometers, during long continued static or fluctuating stress. The limitations to this range are the criteria for gauging utilizable capacity in cases of alternate tension and compression, but are not critical, at least for untreated steel,* in cases where the stress is always direct tension or direct compression.

(*e*) The point which is the best criterion of utilizable capacity in a short column or tension member not subject to alternating stress, is the point named by the Society's Special Committee on Steel Columns and Struts

* Steel which has been treated by cold-rolling, cold-drawing, or quenching, is outside the scope of this paper.

the "Useful Limit Point", or "U. L. P.",* beyond which plastic deformation is a dangerous factor and soon becomes either ruinous or seriously objectionable *per se*. As to just what degree of plastic deformation is seriously objectionable *per se* there is room for some difference of opinion, but in most cases the yield, when well started, develops so rapidly that the zone of room for reasonable difference of opinion is limited. The Committee chose and the writer has adopted as the U. L. P. a point where the rate of combined plastic and elastic deformation reaches twice the rate of elastic deformation.

(*f*) The U. L. P. in a short column or a tension member can be fairly well approximated from the U. L. P.'s and tensile strength of representative specimens by a method described near the end of Part 5.

(*g*) As determined in ordinary commercial tests, the U. L. P.'s cannot be inferred from the yield point, but can be directly determined with fair precision in scientifically conducted tests.

(*h*) When used with judgment, the U. L. P.'s of short, centrally loaded columns and tension members are the best criteria of utilizable capacity of such columns and members, but tests of centrally loaded medium and long columns are usually made under conditions less severe than in actual service, and indicate the U. L. P.'s which are not the best criteria of utilizable capacity of members in service.

(*i*) The best criterion of the utilizable capacity of a medium column is sound analysis, based (1) on the U. L. P. of a corresponding short column; (2) on reasonable assumptions as to unintentional eccentricity; and (3) on the closely ascertained and well established modulus of elasticity. The best criterion of the utilizable capacity of a long column is sound analysis based on the maximum deflection consistent with good practice as well as on Conditions (2) and (3). Reasonable assumptions and simple methods are described and explained in Parts 5 and 6.

(*j*) For either direct compression or direct tension combined with intentional flexure, reliance must be placed on sound analysis as there are only a few tests. These few tests, however, corroborate sound analysis.

(*k*) The ordinary theory of flexure is faulty, so that very short beams and girders should have considerably more section than such theory indicates, making greater provision for spreading the load and for ample web section and reinforcement at points of reactions and heavy concentrations of load. This is fully explained in Part 8.

(*l*) In beams and girders supported against lateral deflection and with flanges and webs of sufficient thickness to be amply stiff, the possibilities in the way of shifting the elastic zone and widening its limits under constant and fluctuating, but not alternating, loads, without undue deformation, are greater than for columns or tension members under direct stress.

(*m*) The U. L. P.'s of different pieces of steel of nominally the same grade, purchased under the same specifications, may differ greatly one from another. For instance, the U. L. P. of a short, 8-in., light H-column (web, 0.31 in., and flange, 0.40 in. nominal thickness) was 35 000 lb. per sq. in.,

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1618.

whereas the U. L. P. of a short, 8-in., extra heavy H-column (web, 0.78 in., and flange, 1.212 in. nominal thickness) was only 19 000 lb. per sq. in.

(*n*) While great differences are possible in the U. L. P. of plates, shapes, and bars, and of members built from them, furnished under the same specifications, ordinarily they are all used with the same unit stress.

The paper concludes with the query whether it would not be well for manufacturers, fabricators, physical metallurgists, and structural engineers to investigate the practicability and desirability of so grouping different sizes of plates, shapes, and bars of the same nominal grade that the variation in the U. L. P. within each group would be comparatively small, and of proportioning structural members accordingly.

Part 1.—Constitution, Elasticity, Deformation, Elastic Fatigue, and Permanent Fatigue of Steel and Iron

In general, metals are composed of irregular crystals, termed grains. Both steel and wrought iron are composed of sets or groups of crystalline grains. For either steel or wrought iron, separately considered, these sets have nearly the same modulus of elasticity but different elastic limits.

The deformation of metals is of two kinds: Elastic deformation, from which recovery is complete on release of stress; and plastic deformation, which is permanent. Elastic deformation, within the limitations of delicate measurements, is proportional to stress. Ewing, Rosenhain, and other eminent physical metallurgists have shown that plastic deformation of metals takes place within their grains by the sliding, one over another, of crystalline layers similarly as the cards within a pack slide while its form is being altered. Beilby has shown that thin films, between the sliding crystalline layers of the grains, acquire, by this mechanical movement, the mobility of the liquid state. While this mobility continues, the grains in which it occurs are in a state of elastic fatigue. This state is temporary and is followed either by recovery or permanent fatigue. After the stress that imparts mobility to thin films between crystalline layers of the grains is removed, the films resolidify, and either cement the adjacent layers, thus restoring to the grains their integrity and elasticity, or, if the over-straining has been too severe or long continued, leave the layers separated by cracks. The development of cracks constitutes permanent fatigue.

Short specimens of steel and iron, when tested in the usual way by increasing tension or compression, do not, as a rule, exhibit any plastic deformation discernible by ordinary inspection until a certain zone of comparatively small range is reached within which plastic deformation develops in such a large number of grains that a pronounced yield becomes plainly evident without the aid of a micrometer. The point at which the yield becomes plainly evident is known as the "yield point". In commercial practice, this point generally was, and still frequently is, erroneously termed the "elastic limit".

There are great differences in the recorded observations of the yield point of specimens from the same piece of steel in tests made under different condi-

tions by different observers, as shown in Table 9; but for scientific purposes, a certain point in the yield (hereinafter designated) can be closely defined, and so well determined that it constitutes a reliable criterion.

Part 2.—Originally Imperfect Elastic State of Specimens of Steel and Iron; the Development, by Repeated Cycles of Stress, of Fields of Seemingly Perfect Elasticity of Chosen Range and Position; and the Limitations to Such Development Imposed in Practice by Critical Deformation

Measurements with delicate micrometers on long gauged lengths show that some slight plastic deformation occurs below, and even far below, the yield point in pieces of steel and iron when tested in the condition in which they come from the rolls, forge, or mould. This indicates either that the elastic limits of pieces in such condition are very low or that there are no limits within which they are elastic. Experience and numerous tests show, however, that elastic limits bounding wide ranges of stress can be developed in pieces of steel and iron by repeatedly straining them through cycles of stress. Tests, especially those of Bairstow, also show that the elastic limits which can be developed in a piece of steel or iron are not constant quantities, characteristic of the piece, but are variable, depending on the conditions of straining.

Bairstow's experiments established what Bauschinger's tended strongly to show, that failure under cycles of stress repeated within certain limits is evidence that elastic limits have not been developed, and *vice versa*. This fact renders available, as a means of determining developed elastic limits and the laws governing their development, many published experiments in which failure or non-failure under cycles of stress from external forces has been recorded without stating the deformations.

The center of range of any cycle of stress from external forces is the mean between its extreme intensities. For instance, if the range is between a compression of 10 000 lb. per sq. in. and a tension of 20 000 lb. per sq. in., the center of range is a tension of 5 000 lb. per sq. in.

The maximum range of elastic deformation, with its opposite elastic limits, that can be developed by cycles of stress from external forces, varies with the position of the center of range, as shown in Fig. 1, in which, first, tension is measured upward; second, compression is measured downward; third, the loci of the elastic limits that bound the elastic range are shown for a typical piece of steel and indicate these limits for each elevation of the center of range above zero and each depression of the center of range below zero; and, fourth, each elevation and each depression of the center of range is indicated by an ordinate and an abscissa which are equal. For comparison, the critical deformation points and the maximum tensile strength, as determined in scientifically conducted tensile tests, are also shown in Fig. 1.

The writer has adopted as critical that point in the deformation below which it is predominantly elastic and above which the additional deformation is predominantly plastic. Plastic deformation is useful in adjusting structural members to the service to which they are subjected but, otherwise, the plastic

state is objectionable *per se* while it lasts and the deformation remains an objectionable permanent set. Additional deformation predominantly plastic is seriously detrimental and in many cases is either dangerous or induces destruction under loads only slightly above those causing critical deformation, as discussed more in detail in Part 7. The point adopted as critical is the one designated by the Society's Special Committee on Steel Columns and Struts as the "Useful Limit Point", or "U. L. P." If a member (including its details) is strained beyond its U. L. P. and survives the consequences of such temporary fatigue, its loss or impairment in usefulness is not, ordinarily, due to changes which took place in the structure of the steel, but to the lengthening or shortening, sometimes combined with bending, of the member and its details.

The elevation, even to very high limits, and the moderate depression of the elastic limits shown by the full lines in Fig. 1 are in direct accordance with experiments. The great depression indicated by the dotted lines is inferred, as search has failed to discover any direct experimental evidence.

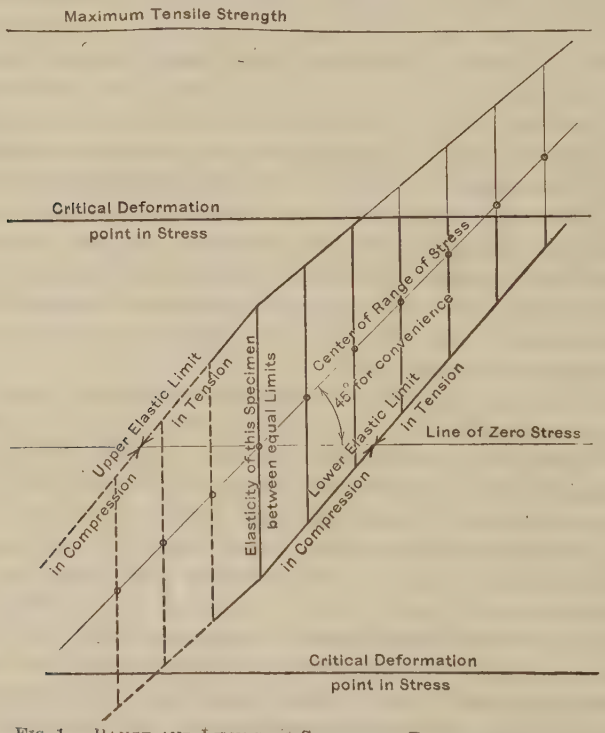

FIG. 1.—RANGE AND LIMITS TO SEEMINGLY PERFECT ELASTICITY DEVELOPED IN DIFFERENT SPECIMENS OF SAME PIECE OF STEEL BY REPEATEDLY STRAINING THEM BETWEEN LIMITS IN DIRECT TENSION, OR COMPRESSION, OR BOTH.

PART 3.—EXPLANATION OF THE PERFECTING OF ELASTICITY WITHIN LIMITS BY THE MODIFICATION OF INITIAL AUTO-STRESSES

As a basis for a satisfactory analysis and explanation of the development of elastic limits in a piece of steel or iron, it is necessary to consider the condi-

tion of the piece as regards auto-stresses and the changes that take place in these auto-stresses when the piece is over-strained and subsequently recovers from the resulting elastic fatigue.

Auto-stresses are the stresses within a body which, considered by themselves, without regard to those from external forces, form a balanced system of internal stresses. They may be present in a piece of steel or iron whether or not, at the same time, it is subjected to stresses from external forces. Auto-stresses are developed in a body while it is cooling from a hot state, and during recovery, or partial recovery, from the elastic fatigue of plastic deformation. They are also developed in structures during and by reason of such mechanical operations as tightening counter rods.

Auto-stresses which originate during the cooling of a body are caused by unequal rates or different periods of cooling of different parts. Every piece of steel or iron as it comes from the mill, forge, or foundry is liable to and probably does contain, in some of the grains of its weakest group, auto-stresses of such great intensity that the addition of even small stresses due to external forces will strain the metal beyond its elastic limit. A grain which has been over-strained may happen to recover from its elastic fatigue at such a point in the cycle of stress that the intensity of the total stress will be just the same as that of the stress from external forces, but the chances are greatly against such a phenomenon.

When the intensity of the total stress in a rehabilitated grain is different from the intensity of the stress from external forces, the difference is a new auto-stress. These new auto-stresses in rehabilitated grains are liable to be of any intensity between zero and the greatest possible, according to the point in the cycle at which recovery from elastic fatigue happens to take place. If this new auto-stress is less than a certain critical limit, and the intensities of the stresses from external forces under succedent cycles do not increase, the grain will not again be over-strained but will remain elastic; but if the new auto-stress is more than the certain critical limit the grain will again be over-strained during the next cycle without, however, destroying the possibility that during the following or some later cycle it will recover from elastic fatigue and thereafter remain elastic. Under continued cycles of stress the fatigued grain will eventually either crack or recover with an auto-stress so low that the combined auto-stress and extreme stress from external forces during subsequent cycles will be within the elastic limits.

By reason of the changes in auto-stresses effected by elastic fatigue and recovery, if the range of stress in a given continuously repeated cycle is within certain limits successive adjustments of the auto-stresses in the various grains of a piece of steel or iron gradually take place through the operation of the law of chance, although in extreme cases a million or more cycles occur before the auto-stress in the last grain is adjusted, the plastic deformation in the meantime growing less and less until no plastic deformation or growth in permanent set under continued cycles of stress can be detected, even with delicate micrometers.

While the adjustment of auto-stresses and the cracking of some of the grains are taking place an improvement occurs in the elasticity of those grains which do not become cracked during recovery from elastic fatigue. This improvement is due to the fact that with the solidification of the thin mobile films new junctures, stronger than the original ones, are formed between the parts of the grains adjacent to these films.

From the foregoing analysis it appears that the results of repeated cycles of stress on pieces of steel and iron are the net sum of various and, to some extent, opposite effects. Analysis by process of reasoning is useful in explaining why and how changes take place, but the phenomena involved are far too complicated to admit of determining by mathematical analysis the limits to the range within which elasticity will be perfected by repeated cycles of stress. Quantitative results of repeated cycles of stress can only be determined by experience and experiments.

Part 4.—Endurance Tests and Their Significance; and the Possibility of Remote Fatigue

Experiments on the endurance of specimens of steel and iron subjected to repeated cycles of direct stress have been made by Wöhler, Bauschinger, Reynolds and Smith, Bairstow, and the Sub-Committee of a Committee of the British Association for the Advancement of Science. The tests by the Sub-Committee were made by repeated tensions of specimens of two lots of steel with tensile strengths of 59 100 and 52 400 lb. per sq. in., respectively. These tests have not been published, but Mr. A. R. Fulton reported* "it was found that:

"1.—After ordinary yield is exceeded and permanent elongation has taken place, the limits of the proportionality of stress and strain are raised. The extent of this elongation for any maximum stress depends on whether the stress has been applied in one stage or with a sufficient number of repetitions at each of several stages.

"2.—The range of stress over which the proportionality is maintained is limited; once established it is independent of the number of cyclical repetitions to which it is subjected.

"3.—The range of stress may be again varied by further elongation, but to this there is a limit.

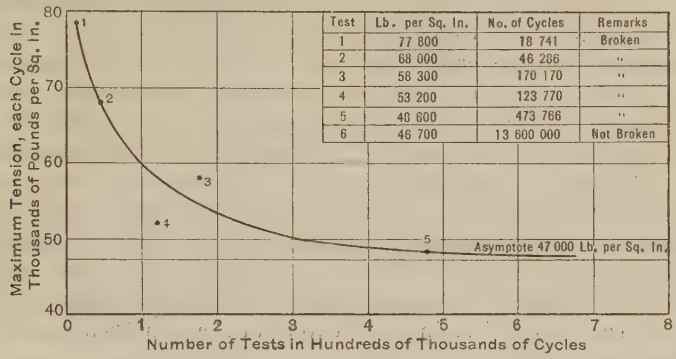
"4.—Failure under repetitions of tensile stress occurs by the movement of the crystals relatively to one another, consequent on the existing range of stress being exceeded, or during the transition period when one range is being changed to another.

"5.—Failure frequently originates by the range of stress, or even the maximum static stress of the material, being exceeded in parts of a section, and is due to mechanical flaws in the material or non-axial loading."

The fourth finding is open to the criticism that the movement occurs within the crystals. In addition to the tests mentioned, Thurston made endurance tests of steel and iron wires by subjecting them to long-continued constant tension. From these various experiments Tables 1, 2, 3, and 4 have been compiled. The data recorded, together with the supplementary data accom-

* Report, British Assoc. for the Advancement of Science, 1919, p. 484.

panying Figs. 2 and 3, and a few additional scattered citations, constitute an epitome of the important information to be gleaned from the published tests under direct stress.



Test	Lb. per Sq. In.	No. of Cycles	Remarks
1	77 800	18 741	Broken
2	68 000	46 266	"
3	58 300	170 170	"
4	53 200	123 770	"
5	40 600	473 766	"
6	46 700	13 600 000	Not Broken

FIG. 2.—WÖHLER'S TESTS OF AXLE STEEL BY REPEATED TENSIONS FROM ZERO, SHOWING THE GRAPHIC DETERMINATION OF LIMITS TO THE CYCLE OF STRESS WHICH SEEMINGLY CAN BE ENDLESSLY REPEATED WITHOUT CAUSING FRACTURE. BY INFERENCE ELASTICITY IS PERFECTED WITHIN THESE LIMITS.

Endurance tests by repeated cycles of transverse loading are comparatively numerous and embrace those of a recent and extensive investigation by the Engineering Experiment Station of the University of Illinois in co-operation with the National Research Council and others.* One set from

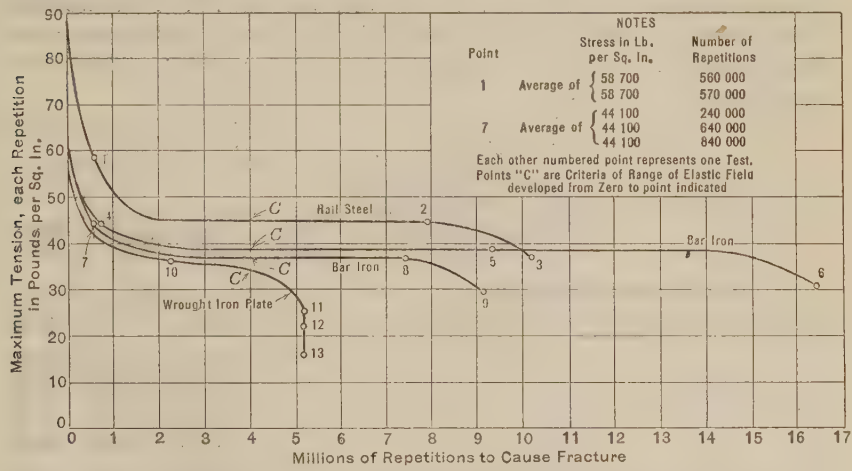


FIG. 3.—BAUSCHINGER'S TESTS BY REPEATED TENSION FROM ZERO. THE REDUCTION IN RESISTANCE UNDER THE EXTREME NUMBER OF REPETITIONS MAY HAVE BEEN CAUSED BY A HYPOTHETICAL "REMOTE FATIGUE", OR BY SOME UNRECORDED VARIATION IN CONDITIONS.

the Watertown Arsenal Reports of ordinary hot rolled steel bars has been chosen for illustration (Table 5). In this set the only important variable in the fundamental conditions was a wide range of carbon in the steel. Auxiliary pulling tests were made. The experiments were well planned and

* *Bulletin No. 124*, Eng. Experiment Station, Univ. of Illinois.

scientifically conducted; and the number of cycles in each case was great and, in some cases, extreme.

Bairstow made the tests recorded in Table 1 for Lots 1, 2, and 3, using the ordinary form of direct tension and compression testing machine with special attachments. His method was to test the specimen between the limits of stress selected for the experiment and to observe the deformation. In those cases in which the range between the limits was too great, the deformation progressively increased until the specimen broke. On the other hand, when the range was not too great, the increments of plastic deformation contributed by successive cycles became smaller and smaller so that eventually the deformation during each cycle seemed to be entirely elastic and no increase in permanent set under thousands of additional cycles could be detected with a measuring device sensitive to 0.00001 in. As long as the metal was to any appreciable extent plastic, the mobile films within the specimen acted as a drag on the elastic metal, delaying its recovery of shape, a phenomenon known as hysteresis.

TABLE 1.—Elastic Limits Developed by Cycles of Direct Stress with Different Centers of Range in Various Kinds of Steel and Wrought Iron.

(Stresses are in terms of tension from external forces (+) and compression from external forces (—). Lots 1, 2, and 3 were tested by Bairstow to determine the development of elastic limits under cycles of stress. The elastic limits given were scaled from his diagrams on p. 51 of *Philosophical Transactions,* Royal Soc. of London, Vol. 210. Lots 8 and 9 were tested by Wöhler. The developed elastic limits are inferred from stresses and endurance.)

Kind of materials.	Lot.	Tensile strength, in pounds per square inch.	Yield point, in pounds per square inch.	Developed Elastic Limits.

* Wöhler's experiments show that these ranges were developed, but do not indicate that they are maxima.

The tests of Lots 1, 2, and 3 recorded in Table 1 were made at the rate of 2 cycles per min. For purposes of comparison some of these tests are again cited in Table 2. The elastic limits and elastic ranges developed in the other tests cited are not directly indicated in the published records but were inferred from the resistance to fracture under the long continued repetitions of stress.

TABLE 2.—Ranges of Stress Between Elastic Limits Developed by Cycles of Alternate Direct Stresses.

(Lots 1, 2, 3, 7, 10, 11, 12, 13, 14, 15, 16, and 17 were tested by Bairstow (See *Philosophical Transactions,* Royal Soc. of London, Vol. 210, and *Minutes of Proceedings,* Inst. C. E., Vol. CLXVI, 1906, Pt. IV). Lots 4, 5, and 6 were tested by Reynolds and Smith (See *Philosophical Transactions,* Royal Soc. of London, Vol. 199, pp. 265-297.)

* Thurston's Table No. 11, *Transactions*, Am. Soc. C. E., Vol. XLI (1899), p. 516. Thurston states that "some of these wires were still unbroken in 1898, after 15 years loading." His records do not mention deformation, but, from the known relation between endurance and elasticity, it can be inferred that each specimen which did not break had developed an elastic limit at and under the load endured.

TABLE 5.—ENDURANCE TESTS OF ROTATING SHAFTS. MATERIAL, HOT-ROLLED BARS OF OPEN-HEARTH STEEL TURNED TO 1.009 INCHES IN DIAMETER, FROM 1.25 INCHES.

(Length between supports, 33 in.; loaded over 4-in. length at middle; speed of rotation, 500 rev. per min. Compiled from Watertown Arsenal Reports for 1903-08.)

Percentages of Chemical Constituents.			Pulling Tests Auxiliary to Endurance Tests. Gauged Length, 4 In.		Endurance Tests of Rotating Shafts.			
					Developed elastic limit or one-half range, in pounds per square inch.	Extreme Tests.

0.82	0.36	0.10	142 250	63 000	44 000	40 000	202 000 000	Not broken.
1.09	0.39	0.11	132 800	76 200	38 000	35 000	175 280 000	Not broken.

* In each case, the U. L. P. was obtained from deformation given in the reports of the Watertown Arsenal, but the term does not appear therein.

† Load fell to 42 000 lb. per sq. in. which is 61.8% of the maximum strength.

‡ Bar ruptured midway between bearings, at a score mark made by the head of the screw which holds up the middle bearing fixture.

The usual method of inferring the greatest resistance of specimens of steel or iron of a given quality, size, and shape to endlessly repeated cycles of stress is to subject different specimens from the same lot or, preferably, from the same long piece, to different ranges of stress in rational series, and to repeat each test until failure occurs or circumstances indicate that the test might be repeated indefinitely without breaking the specimen. The plotted results of a series of such tests indicate by an asymptote the maximum

range within which seemingly the stress can be endlessly repeated without fracture; and within which, by inference, seemingly perfect elasticity has been developed. This is illustrated in Fig. 2. Such tests are commonly called tests of fatigue.

Besides elastic fatigue and permanent fatigue, steel and iron may be liable to what may be called, for want of a better name, remote fatigue. Every change in the temperature or stress to which a specimen of steel or iron is subjected affects it, perhaps permanently, as regards electricity and magnetism. Moreover, some permanent fatigue may be developed at such a slow rate, and be so localized and, for a long time, confined within such narrow limits, that it gives no appreciable indication of its presence in endurance tests carried to what seems to be a sufficient number of cycles. Slow changes are continually taking place in all material things. Even atoms disintegrate, electrons are radiated into space, and planets, suns, and universes come into being, exist for a while, and then pass away. It is not reasonable to expect metals to endure forever no matter how moderate the strain nor how great the protection against corrosion and abrasion.

Bauschinger's experiments on rail steel, bar iron, and wrought-iron plate, cited in Table 3, and in Fig. 3, seem to show that failure from remote fatigue is a reasonable possibility even after seemingly perfect elasticity has been developed within certain limits. The results tabulated may be due, however, to differences in quality of the specimens or, possibly, to unrecorded occurrences during the tests; or it may be that there are some other unexplained circumstances by reason of which these tests are not proper criteria. Reciprocating parts of locomotives, motor vehicles, and stationary engines are sometimes subjected in service to repetitions of stress much greater in number than those noted in Table 3.

Endurance tests by bending stresses are much more numerous than by direct stresses; and the extreme tests are usually carried to a much larger number of cycles, the largest of which the writer has knowledge being 202 000 000, as shown in Table 5. Among the bending tests there are very few failures after elasticity has been seemingly perfected and these few can generally be accounted for by scratches, set screws marks, or other causes incident to testing; in other words, bending tests do not strongly indicate "remote fatigue". Endurance tests by direct stress carried to 50 000 000 cycles or more are much to be desired to disprove or confirm the indications of the extreme tests made by Bauschinger (Fig. 3).

In dealing with machinery, the possibility should be seriously considered of failure from "remote fatigue" after elasticity has been seemingly perfected and no appreciable increase in permanent set has been developed thereafter under millions of cycles of stress; but few if any structures, or parts thereof, will be strained often enough to fail from "remote fatigue" before they fail from other causes or are put out of service. The possibility, if there is a possibility, of the failure of a structure from "remote fatigue" is not an element to be considered in its design, but rather in deciding whether or not an old structure should be condemned.

The development of upper and lower elastic limits, both in tension, is, perhaps, the most astonishing result achieved by straining pieces of ordinary iron and steel by cycles of stress. The occurrence of this phenomenon indicates that a large proportion of the grains either had at the start, or acquired during the test, elastic limits in tension considerably greater than the range of stress between the upper and lower elastic limits of the piece. The stress in the grains that determines the lower elastic limit of the piece is the net result of an "auto-compression," developed in them during the test, and tension from external forces. This auto-compression is so great that when the minimum tension from external forces is reached at the lower elastic limit of the piece the auto-compression in the critical grains exceeds the tension from external forces by an amount equal to the elastic limit of these grains in compression.

It may be inferred that a piece of ordinary iron or steel can have its elastic field lowered by cycles of direct loading to such an extent that both the upper and lower elastic limits will be in compression; but tests to substantiate this are lacking. As shown in Table 2 experiments on pieces of iron and steel under cycles of direct stress indicate that a variation in the rate of from 2 to 800 cycles per min. makes little difference in the range of the elastic field that can be developed. They also indicate that the range is reduced with an increase in the rate above 800 cycles per min.

Some experiments with intervals of hours, days, or even years between successive cycles indicate the development of much greater ranges of elastic stress than with rates of from 2 to 800 cycles per min.; but because of the small number of cycles in these experiments the accumulation of defects and permanent sets may be so minute as to be undetectable with the micrometers used.

Experiments indicate that the elastic limit can be increased by allowing a specimen to remain at rest for a considerable period under strain, provided the strain is not too great. Thurston's experiments in this regard are shown in Table 4. His records do not mention deformation; but from the known relations between endurance and elasticity it can be inferred that each specimen which did not break had developed an elastic limit corresponding to the load.

Part 5.—Interpretation of Tests as Criteria of Utilizable Capacity of Members in Direct Tension or Compression

For members subjected to direct tension only, or if sufficiently stiff, to direct compression only, the criterion of utilizable capacity is either the elastic limit that can be developed or the point of critical deformation, whichever is the lower; and the ratio of this criterion to the computed direct stress in service, is the factor of safety. Unfortunately, this basic criterion can only be determined directly and accurately by endurance tests.

In practice, the utilizable capacity has to be inferred from the results of simple tensile or compressive tests under gradually increasing loads. Some of these results, such as the elongation and reduction in area, are indications of quality. The ultimate tensile strength and the development of the yield, if the

steel is of suitable quality, are fairly reliable criteria of utilizable capacity when jointly considered as hereinafter described.

When, in a tension or fairly rigid compression member under a constant load, any part of the metal is strained beyond its elastic limit by the stress from the load combined with auto-stress, plastic deformation will occur and will continue for a time; but, unless the load is too near the maximum, it will eventually cease and become a permanent set. Slight permanent sets in structural members are unavoidable; large permanent sets are ruinous. Between these conditions are sets which are seriously detrimental without being immediately ruinous. Plastic deformation (which is the original form in which the extension or linear compression constituting a set exists) after it becomes serious, because of the alterations it causes in the lengths of structural members, generally increases with the stress much more rapidly in soft, than in medium, and in medium, than in hard, steel; hence after serious plastic deformation has begun, there is much greater liability to the development of ruinous deformation in soft, than in hard, steel without, in some cases, any increase in load.

It is desirable for purposes of analysis and of definiteness in stating requirements to define precisely a readily ascertainable point in tests which will be regarded as the beginning of serious plastic deformation. In formulating such a rule close approximation to accuracy is the primary consideration and ease of ascertainment secondary.

In the Final Report of the Society's Special Committee on Steel Columns and Struts, it is stated*:

"In the Progress Report of 1917, the Committee mentioned the discussion held by the American Society for Testing Materials at its Annual Meeting, June, 1916, on the relation between proportional limit, elastic limit, and yield point. For the purpose of studying the column tests, the Committee gave careful consideration to this discussion to find whether it was possible to determine some point which, for practical purposes, might be easily located, clearly defined, and at the same time represent the limit where the metal ceases to have structural value. None of the terms defined by the discussions of the American Society for Testing Materials has appealed to the Committee as having these qualities. In searching for a more satisfactory definition, the Committee considered a modification of the suggestion made some years ago by the late J. B. Johnson, M. Am. Soc. C. E. The Committee has defined the critical point as the point which is determined graphically by drawing a line tangent to the envelope of the stress-strain curve, having a slope of one-half that of the last run-up line for its straight, or nearly straight, portion. Fig. 7 [of the Committee's report] illustrates this method of determination. So as not to confuse this with former definitions of yield point or elastic limit, the Committee has adopted a new term, and calls this the Useful Limit Point, or U. L. P.

"* * * It will be noted that the method is applicable to both tension and compression tests."

The normal U. L. P. is the same in compression as in tension for all steel likely to be used in structural members. This is shown in Table 6. It was also shown exhaustively and conclusively by the late Charles A. Marshall,

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1618.

M. Am. Soc. C. E., in his paper entitled "Compressive Strength of Steel and Iron".*

The Special Committee on Steel Columns and Struts precisely defined the most useful point that has yet been selected as the demarcation between characteristically elastic and characteristically plastic deformation. This was in terms of graphics; defined without recourse to graphics, the U. L. P. is that point at which under gradually and slowly increasing stress the rate of combined plastic and elastic deformation becomes twice the rate of elastic deformation. For instance, if the increase in deformation during the yield is measured for each additional 1 000 lb. per sq. in. and the modulus of elasticity, E, is 30 000 000 lb. per sq. in., the U. L. P. will be reached during the first increase of 1 000 lb. per sq. in. in which the increase in deformation reaches $\frac{\text{gauged length}}{15\ 000}$.

TABLE 6.—Comparative Tests in Tension and Compression of Open-Hearth Steel Bars.

(All specimens turned to 1.0092 in. in diameter from 1.25 in. in diameter; tension specimens, gauged length, 30 in.; compression specimens, 12 in. long, with flat ends and a ratio, $\frac{l}{r}$, of 47.6. Tests made at the Watertown Arsenal and given in reports for 1886, pp. 1635-1653; and for 1887, pp. 802-822.)

Note.—The modulus of elasticity of a nickel steel, flat-ended column with a ratio, $\frac{l}{r}$, of 100, a resistance to failure of 48 910 lb. per sq. in., and a U. L. P. of 47 000 lb. per sq. in., computed from compression sets measured at four points, in a gauged length of 50 in., was 29 800 000 lb. per sq. in. The test is reported in Watertown Arsenal Report, 1910, pp. 176-177. The moduli of elasticity, similarly computed except that the gauged length was 80 in., from column tests reported in *Technologic Paper 101*, U. S. Bureau of Standards, are as follows: (p. 48) chrome steel, 29 100 000; (p. 36) silicon steel, 30 400 000; (p. 46) silicon steel, 29 500 000; (p. 32) Mayari steel, 29 000 000; and (p. 42) Mayari steel, 30 300 000. For the chemical analyses, see Table 18.

* In each case, the U. L. P. was obtained from deformation given in the reports of the Watertown Arsenal, but the term does not appear therein.

Precise values of E cannot be observed in a piece of steel after it has been strained to its U. L. P. until the films of metal made mobile by the strain have

* *Transactions*, Am. Soc. C. E., Vol. XVII (1887), p. 53.

resolidified. The value of E for steel of all carbon contents up to and including 0.97% is approximately 30 000 000 as shown in Table 6 and, therefore, it is hardly worth while obtaining values of E (which may be only approximate) for each piece by "run-ups". The value indicated by the last run-up in the columns for which the Special Committee on Steel Columns and Struts submitted graphs varies from 28 000 000 to 30 000 000, with an average of 29 139 000.

The acceptance of the U. L. P. as a criterion of utilizable capacity without serious plastic deformation is qualified by four considerations: First, the rate at which the test is conducted must not be excessive; second, when the U. L. P is greater than the limit to which elasticity can be seemingly perfected by cycles of stress, a suitable deduction should be made in determining the utilizable capacity; third, allowance should be made for the fact that, in testing specimens by gradually increasing the load, the load is liable to drop to a point below the U. L. P. immediately after a yield point is reached; and, fourth, all the U. L. P.'s of the full-sized columns tested by the Column Committee were lower, as far as data were available for comparison, than the weighted average of the U. L. P.'s of the specimen tests.

TABLE 7.—Tests of Wrought Iron to Show the Effect of Slow and Rapid Fractures on Specimens of Varying Length.

No attempt is here made to define what constitutes an excessive rate of speed in testing for the purpose of determining the maximum strength and

the U. L. P. Although published information on the subject is scarce, a search has disclosed the material in Tables 7, 8, and 9. It is reasonably certain that none of the Watertown Arsenal's or of the U. S. Bureau of Standard's tests cited, was made at an excessive rate of speed.

The Special Committee on Steel Columns and Struts states*:

"The ultimate strengths shown on the supplementary specimen tests are very close to the ultimate strengths given for the specimen mill tests, and neither the ultimate strengths from the supplementary tests nor from the mill tests indicate the falling off in strength of the thicker material. It is also evident that the yield point, as recorded by the ordinary commercial tensile specimen tests, even when the machine is run at comparatively slow speeds, as was done in the Pittsburgh Laboratory of the Bureau of Standards, does not give the correct index of the strength of the material."

TABLE 8.—Effect of Variations in Speed of Testing on the Physical Properties of Steel Rivet Rods.

* These data were taken from "The Manufacture and Properties of Iron and Steel", by Harry Huse Campbell, Gen. Mgr., The Pennsylvania Steel Co., 1903, p. 453.

† *Loc. cit.*, p. 457.

In this regard a report of the Committee on Iron and Steel Structures of the American Railway Engineering Association, of tests on columns by the U. S. Bureau of Standards, states:† "The specimen tensile tests on which material is ordered and accepted afford no proper criterion for the strength of a column."

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1612.

† *Proceedings*, Am. Ry. Eng. Assoc., 1918, p. 793.

From Tables 1 and 2 it appears that under alternate direct tension and compression the limits to the range within which elasticity both in tension and compression can be perfected are lower than the yield point and probably lower in all cases than the direct tension and compression U. L. P.'s. It is probably the uncombined soft alpha iron in steel that determines the limits to the range of developed elastic fields. This fact tends to limit the range in steel that has not been cold-drawn or cold-rolled, or heated and quenched,* to what it is in wrought iron or in soft steel (sometimes called ingot iron). The opportunity under direct stress for increasing the elastic range of iron by resolidification of films made mobile by strain is, however, greater in the iron of high carbon steel than in that of medium carbon steel, likewise, greater in the iron of medium carbon steel than in that of soft low carbon steel or wrought iron. On the whole, the advantage is with soft steel and wrought iron over medium and high carbon steel as regards the ratio of the elastic range to the U. L. P. that can be developed by alternate direct tension and compression both of which are within the U. L. P. There is no reasonable chance of developing in service resistance to repeated direct stresses much above the U. L. P. in compression or tension members of structures (except possibly in adjustable rods of Howe trusses), on account of the serious, and in some cases, ruinous deformation that would occur under such stresses. After Wöhler had shown that endurance limits in test pieces can be developed much above the yield point and, therefore, much above the U. L. P., Launhardt published a formula designed to show this endurance limit for different ratios of maximum to minimum stresses, both in tension or both in compression; but, with the possible exception of adjustable rods in Howe trusses, Launhardt's formula has no rational applicability to tension and compression members of structures and machines. The occasion for referring to it is the fact that William Cain, M. Am. Soc. C. E., modified Launhardt's formula empirically "to allow for all the influences of impact", introduced a factor of safety, and recommended the formula thus modified for the design of railroad bridge members. This was forty-eight years ago,† but the modified formula is still extensively used.

As a criterion of utilizable capacity, the U. L. P.'s from specimen tests are too high rather than too low even for direct stress that is static or fluctuating but never reversed. In an extreme case (Test 7934, Table 10), soft steel with a maximum tensile strength of 48 240 lb. per sq. in. seemed in a careful pulling test to be perfectly elastic up to 40 000 lb. per sq. in. and had a U. L. P. of 40 600 lb. per sq. in., or 84.2% of the tensile strength. This U. L. P. is far above any valuation of utilizable capacity justified by endurance tests. Valuable information on this subject was obtained in Bairstow's experiments on an axle steel, with a yield point of 24.9 tons per sq. in., which in repeated loadings from 0 to 23.2 tons per sq. in. showed no lack of elasticity until after 6 000 loadings, when a permanent extension of the order of the yield took place.‡

* Steel which has been cold-drawn or cold-rolled or heated and quenched, is outside the scope of this paper.

† *Van Nostrand's Magazine*, November, 1887, p. 459.

‡ *Philosophical Transactions*, Royal Soc. of London, Vol. 210, p. 35.

Marshall* gives a number of test diagrams in which the elastic limit, as he calls it, is quite close to the U. L. P., and states:

"*First.*—When a load equal to the elastic limit of any of these materials is imposed and allowed to remain for some time, it causes permanent change of length, amounting, it is believed, to much more than has been generally understood, and which is apparently a very definite quantity for each case. *Second.*—This change of length, having begun under a load equal to elastic limit, will continue under a less load.

* As given by J. A. L. Waddell, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXIII (1909), p. 222.

† At yield point and drop of beam.

‡ A permanent set of 0.01 in. was assumed by Waddell to indicate the yield point.

"The plotted tests in tension were all so made as to develop the amount of this stretch; and it is demonstrated in the cases of the 100 000-lb. steel, the 67 000-lb. steel, and the hard iron made from scrap, that the total is obtained equally as well, though requiring greater length of time, with a load 1 000 or 500 lb. less than primitive elastic limit as with a load equal to that limit. This becomes clear from the diagrams, when it is understood that the loads just above the limit were each allowed a minute or more in which to develop stretch."

* * * * * * * *

* "Compressive Strength of Steel and Iron," *Transactions*, Am. Soc. C. E., Vol. XVII (1887), pp. 56–57.

"The amount of stretch at elastic limit as taken from the tension diagrams:

"For the 100 000-lb. steel	0.3	per cent.
" " 80 000 " "	1.4	" "
" " 67 000 " "	1.85	" "
For hard iron	1.3	" "
" soft iron	2.3	" " "

The reduction in the load in the extreme case was about 7 per cent.

From tests conducted at the Watertown Arsenal and published in its reports for the period, 1881-1910, results given in Table 10 have been selected as illustrative of extreme cases of drop in load and as suggestive of its significance. In every one of the tests constituting the first set given in Table 10 the load dropped to either 41 000 or 42 000 lb. per sq. in.; and it is reasonable to infer that the points to which the loads dropped in these ten tests are for them the real criteria of utilizable capacity.

TABLE 10.—Comparison of Tensile Strength, Elastic Limit, U. L. P., and Point to Which Load Dropped.

(Tests 7737-7745, steel bars for comparison of testing machines in Germany; gauged length, 8 in.; comp. from Watertown Arsenal Report, 1903, pp. 455-467. Tests 7934-7936, steel specimens for comparison of testing machine at works of Vicker's Sons and Maxim (Limited), London, England; gauged length, 8 in.; compiled from Watertown Arsenal Report, 1904, pp. 197-199. Up to the elastic limit the elasticity was as nearly perfect as could be gauged by micrometer readings to 0.0001 in. The load dropped immediately after reaching the U. L. P.)

* In each case, the U. L. P. was obtained from deformation given in the reports of the Watertown Arsenal, but the term does not appear therein.

† The elastic limit may have been higher and U. L. P. lower, as no data are given between 55 000 and 58 600 lb. per sq. in.

As a full-sized structural member usually lacks the homogeneity of a specimen, there is little chance, if any, that in a test the load on such a mem-

ber, after reaching its U. L. P., will fall much below it, except during subsequent failure by bending or local crippling. If it ever occurs, it would be most likely in the case of eye-bars. The report of the Watertown Arsenal for 1883 shows tests of six eye-bars; that for 1886, tests of twelve eye-bars; and, that for 1901, the test of one eye-bar. Some of these eye-bars showed pronounced yield points but the load in no case dropped below the U. L. P. previously indicated. In its report the Special Committee on Steel Columns and Struts states*:

"In straining a column, there is a point beyond which its structural value is uncertain, and consequently unsafe to rely upon. This point lies somewhere above the region of perfect elasticity and well below the place where manifest yielding occurs. For the study of column tests, the U. L. P. as above defined seems to fulfill these conditions satisfactorily. Careful observations and plotting of the stress-strain curve locate it without chance for controversy. It will be noted that the method is applicable to both tension and compression tests."

As far as was possible the Committee determined the U. L. P.'s of specimens of the shapes and flats composing the columns, and compared them with the tests of the full-sized members. From these tests, and all the foregoing data (in particular those recorded in Table 10), the writer has concluded that tensile tests of specimens of ordinary size, representative of the steel in a given column, conducted with the care and precision characteristic of the engineers of the U. S. Bureau of Standards and the Watertown Arsenal, are very valuable criteria of the strength of the column; and that they are better criteria than tests by compression of individual shapes and plates representative of those of which the column is composed; and he has devised the following:

Rule for Determining Critical Value.—The critical value of each specimen test in tension, of steel of good quality, as a criterion of the U. L. P. of a full-sized tension or short compression member of a structure, shall be considered as either 87% of its own U. L. P., or 60% of its tensile strength, whichever is the smaller.

As to the use of the specimen tests as criteria, the following is suggested:

Rule for Finding the U. L. P. of Built-Up Members from Specimen Tests.—To gauge the U. L. P. of a full-sized tension or short compression member, from tensile specimen tests, divide the area of its cross-section into representative parts; make specimen tests of each part and find the critical value of each specimen from its U. L. P. or tensile strength according to the foregoing rule; multiply the average of the tests for each part by its area, add the results, and divide their sum by the total area. The final result is the weighted average of the critical values of the specimens and indicates the U. L. P. under simple compression or tension.

This latter rule applies to properly designed, properly fabricated, centrally loaded members, made of steel of good quality, as nearly free from flexure as is practicable in tests of full-sized members. In practice, flexure is rarely confined to these limits.

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1618.

Part 6.—Utilizable Capacity of Compression Members

For convenience, all compression members of structures are herein termed "columns".

Each tension or compression member of a structure has some undesigned eccentricity of its axis with reference to the line of force herein termed "unintentional eccentricity". In addition, there may be intentional eccentricity; but Part 6 deals exclusively with columns to which the load is applied longitudinally and without intentional eccentricity. (For combined compression and flexure, see Part 9.)

In practice even short columns are liable to considerable unintentional eccentricity. The U. L. P. of a column depends partly on the character of the steel of which it is composed and partly on the unintentional eccentricity. The latter in suitable tests of centrally loaded short columns is so small that the U. L. P. may be considered as due to the character of the steel for resistance to force.

In this paper the term, "characteristic U. L. P.", is used to designate—in the steel composing a column—the property of resisting force, measured by the U. L. P., the column, if short, would have in a suitable compression test. In the absence of such tests the characteristic U. L. P. may be inferred from suitable tensile specimen tests.

A comparison of the observed U. L. P.'s of the short full-sized columns tested for the Special Committee on Steel Columns and Struts, with the U. L. P.'s inferred from tensile tests of specimens, as described in Part 5, is given in Table 11.

For the purposes of analysis, columns are classified as short, medium, and long. In the analysis hereinafter given, the utilizable capacities of short, medium, and long columns are determined by different equations corresponding to different conditions which for different ranges of length are critical. The points of intersection of the loci of the different equations define the limits to the ranges of length to which they apply. The divisions between these classes, and the influence of length on the utilizable capacity of medium columns, vary with each different U. L. P.

For the purpose of determining the utilizable capacities of columns both tests and analyses are desirable. When they harmonize the analysis explains the results of the tests and the tests confirm the results of the analysis. Other things being equal, full-sized tests are better criteria than analyses, but where sound analyses based on reasonable assumptions as to the unintentional eccentricity and the end conditions indicate smaller utilizable capacities than tests, analyses are the better criteria for the reason that the conditions which obtain in tests are generally less severe than those to which columns are liable in practice.

Columns are never absolutely straight. It may happen that the crucial eccentricity between the axis and the line of force is due to an initial curve in the axis. If the largest reasonable initial curve in the axis is assumed, it will lead to smaller computed utilizable capacities for medium and long col-

TABLE 11.—USEFUL LIMIT POINTS OF SHORT COLUMNS TESTED BY THE U. S. BUREAU OF STANDARDS FOR THE SPECIAL COMMITTEE ON STEEL COLUMNS AND STRUTS. NOTES.—For each type of column, the maximum, minimum, and average U.L.P. of six columns are given; three with $\frac{l}{r} = 50$, and three with $\frac{l}{r} = 85$, except for Type 1 Extra Heavy for which only three were tested $\left(\text{with } \frac{l}{r} = 85\right)$. Omitting these three from consideration, the U.L.P. of columns with $\frac{l}{r} = 85$ is smaller than for columns with $\frac{l}{r} = 50$ by less than 1 per cent. Where the maximum or minimum U.L.P. is for a column with $\frac{l}{r} = 85$, it is given in bold-face type.

*Comp. from Final Report of Special Committee on Steel Columns and Struts, *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), pp. 1583 *et seq.*
†Weighted average. The other averages of critical values are simple. ‡The critical value of one of the three specimens of Type 5 Light was only 22.3 which is abnormal. §The minimum full-sized test of Type 8 Heavy is abnormal, but is included in the average. ‖Percentage omitted because of abnormality of one of three tests included in average.

umns than those computed from alternative reasonable possibilities. For short columns alternative reasonable possibilities are crucial.

In practice nearly all columns or compression members of structures are connected to adjacent members by full riveted joints, butt joints, or pins; and the joints have sufficient stiffness to transmit flexure between the members, except in the case of pin-ended members under intentional flexure of sufficient magnitude to overcome friction on the pins.

For short columns with butt joints, such as are common in practice, if the abutting faces are not machined to the proper angles a part of the load (sufficient to deform the columns to a point where the faces are in suitable contact) will act with great eccentricity, and the shorter the column the greater will be that part.* Another matter of interest in considering short columns is the fact that even when fairly well designed they are liable in some details to local secondary stresses or reduction in stiffness, which may control their utilizable capacity. In consideration of these facts it is recommended that in practice the utilizable capacity of a short column should be considered as only 90% of the U. L. P. indicated by critical values of specimen tests or by tests of short columns of the same steel and cross-section. Where a large girder or floor-beam, liable to heavy loading, is riveted to a column, the flexure transmitted to the column may be so great that its utilizable capacity to resist direct compression may be reduced to less than 90%; but such cases are special and should receive particular consideration.

Let,

u = the U. L. P. of a tension member or short column, as determined by specimen tests as described in Part 5; or as determined by full-sized tests of tension members or short columns of the same material and cross-section; and

c = the utilizable capacity per unit of cross-sectional area of a column.

For short columns,

$$c = 0.9\,u \qquad (1)$$

The mathematical analyses which follow were made for columns with pivoted or frictionless hinged (but not free) ends, and result in Equation (6) for long columns and Equation (11) for medium columns. Following these analyses, it is shown that it is advisable to apply these equations modified or unmodified, according to conditions, to columns with pin, flat, or riveted ends.

For convenience of analysis and discussion the moments and bending stresses corresponding to the deviation of the line of force from the axis of a structural member before deflection are termed primary moments and stresses, while those corresponding to the deflection (additional deviation) are termed secondary moments and stresses. For further convenience of analysis the curve by which the axis is assumed to deviate initially from the line of force, is assumed to be a sinusoid. Even with this further assumption the analysis is somewhat complicated, and its results are difficult to apply with precision to medium columns; but following the analysis, simple empirical formulas for

* "Imperfect Butt-Joints in Columns, and Stress in Lattice-Bars," *Engineering News*, October 3, 1907, p. 368.

TABLE 12.—Characteristic Useful Limit Points, u, of Columns, Beyond Which Plastic Deformation Is Seriously Detrimental. Limiting Ratios, $\frac{l}{r}$, Between Which Columns Are "Medium"; Below Which They Are "Short"; and Above Which They Are "Long". Utilizable Capacity, c, of Long Columns Beyond Which Elastic Deflection Is Liable to Be Excessive (More Than $\frac{l}{300}$).

medium columns are given as alternatives and shown to be nearly equivalent as regards results. (See Equation (11) and Table 12.)

For the benefit of those who desire to follow the general argument without following the mathematical analyses by which Equation (11) for medium columns and Equation (6) for long columns were derived, it may be noted that all medium and long columns are assumed to have an unintentional eccentricity of $\frac{1}{700}$ of their length between pins or points of contrary flexure and that the utilizable capacities of long columns are limited to the loads which would produce deflections of $\frac{1}{300}$ of such length.

Let,

l = length.
I = moment of inertia.
r = radius of gyration.
p = load per unit of cross-sectional area of column.
e = eccentricity of the line of force relative to the axis of the column at the center before deflection.
Δ = deflection at the center of the column.
f = the intensity of the combined stress from direct compression and bending at the center of the column in the extreme fiber on the concave side.

E = modulus of elasticity $= \dfrac{\text{direct stress intensity}}{\text{proportionate elongation or shortening}}$.

For steel, considering the pound as the unit of stress and the inch as the unit of length, $E = 30\,000\,000$.

Let,

v = the distance from the axis of the column to the extreme fiber on the concave side.

$$q = \frac{\pi^2 E r^2}{l^2}$$

which is Euler's formula.

The curve of the primary bending moment will be a sinusoid. It is a peculiarity of a sinusoidal moment diagram that the deflection corresponding to it will be a sinusoid; hence, the secondary bending moment will likewise be a sinusoid.

From the theory of flexure, when the moment diagram is a sinusoid,

$$\Delta = \frac{\text{Bending moment} \times l^2}{\pi^2 E I} = \frac{p e l^2}{\pi^2 E r^2} + \frac{p \Delta l^2}{\pi^2 E r^2} = \frac{p e}{q - p} \quad \ldots\ldots (2)$$

$$f = p + \frac{p e v}{r^2} + \frac{p e v}{r^2}\left(\frac{p}{q - p}\right) \quad \ldots\ldots (3)$$

Let,

$\frac{l}{x}$ = the unintentional eccentricity.

The utilizable capacity of long columns is limited to the load which can be supported without excessive deflection.

Let,

$\frac{l}{y}$ = the greatest deflection which is not excessive.

Substituting these values in Equation (2),

$$\frac{l}{y} = \frac{p\ \frac{l}{x}}{q - p} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

from which,

$$p = q\ \frac{x}{y + x} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

Assuming that $\frac{l}{x} = \frac{l}{700}$, which seems ample for unintentional eccentricity, and that, for the condition ($p = c$), $\frac{l}{y} = \frac{l}{300}$ (which although great, is not, for a column loaded to its utilizable capacity, an excessive deflection) then, in pounds per square inch,

$$c = 0.7\ q = \frac{207\ 260\ 000}{\left(\frac{l}{r}\right)^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Equation (6) gives the utilizable capacities, in pounds per square inch, of long steel columns of good workmanship with pivoted or frictionless hinged ends. It is independent of u or of any other critical stress and gives values for c which vary solely as the inverse of $\left(\frac{l}{r}\right)^2$. If a column qualifies as a "long" one, its utilizable capacity will in nowise depend on what U. L. P. a short column of similar steel and cross-section would possess.

Medium columns are classified according to the U. L. P.'s that short columns of similar steel and cross-section would possess. In this paper the U. L. P. that determines the series is termed the "characteristic U. L. P.", or "characteristic u".

For medium columns the utilizable capacity, c, may be considered to be the load that will produce a maximum stress intensity, f, equal to the characteristic u. The dividing line between medium and long columns is the $\frac{l}{r}$ at which the load that will cause a deflection, $\frac{l}{300}$, will also cause a stress, u, in the critical extreme fiber. At this line, from Equations (3) and (6), for $e = \frac{l}{700}$ and $\frac{v}{r} = 1.68$,

$$u = c + \frac{1.68\ c\ l}{700\ r} + \frac{1.68\ c\ l}{700\ r} \times \frac{7}{3} = c + \frac{0.008\ c\ l}{r} \quad \ldots\ldots\ldots\ldots (7)$$

Equation (7) determines the characteristic u of the series; it is useful in compiling tables.

For ratios of v to r other than 1.68, Equation (7) is approximate; but the error is not great. In most cases the ratio is less than 1.68 and, there-

fore, the dividing line between short and medium columns occurs at a slightly greater value of $\frac{l}{r}$ than that for a ratio of 1.68.

From Equation (1) the dividing line between short and medium columns is the $\frac{l}{r}$ at which a load of $0.9\,u$ will produce a stress, f, equal to u.

For the conditions, $e = \frac{l}{700}$, $\frac{v}{r} = 1.68$, and $p = 0.9\,u$,

$$\frac{p\,e\,v}{r^2} = \frac{0.9\,u\,e\,v}{r^2} = \frac{0.9\,u\,\frac{l}{700}\,1.68\,r}{r^2} = 0.00216\,u\,\frac{l}{r} \quad \ldots\ldots\ldots (8)$$

$$u = 0.9\,u + 0.00216\,u\,\frac{l}{r} + 0.00216\,u\,\frac{l}{r}\left(\frac{0.9\,u}{q - 0.9\,u}\right) \quad \ldots\ldots\ldots (9)$$

and, solving,

$$\frac{l}{r} = \frac{46.296}{1 + \frac{0.9\,u}{q - 0.9\,u}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

From Equation (10), the $\frac{l}{r}$ that marks the dividing line between short and medium columns of any series can be found; it has to be solved by trial, which is tedious but does not impair its usefulness in compiling tables.

The limits expressed in terms of the $\frac{l}{r}$ within which columns are "medium" are given in Table 12. In compiling these limits, the dividing lines between medium and long columns were chosen, and the characteristic u was determined for each series from Equation (7). The limiting $\frac{l}{r}$ for each series as between medium and short was then determined from Equation (10).

At the limits of the "medium" columns in each series, the utilizable capacity can be found from Equations (1) and (6). For intermediate values of $\frac{l}{r}$ an exact equation can be derived from Equation (3), but it would be far too complicated for ordinary use. However, within the limits of medium columns, the loci of the exact equation can be approximated so closely by an equation of the second degree that the differences between the accurate and approximate loci are of no practical importance. Such an equation has the form:

$$c = u - \left(n_1\frac{l}{r} + n_2\frac{l^2}{r^2}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

in which, n_1 and n_2 are numerical factors the values of which are given in Table 12 for each series. They were determined by reduction after placing Equation (11) equal to Equations (1) and (6) at the respective values of $\frac{l}{r}$ for the dividing points between medium and long columns of each series.

Table 12 gives for medium columns the limiting values of $\frac{l}{r}$ and values of n_1 and n_2 for eighty successive characteristic U. L. P.'s from $u = 19\,505$ lb. per sq. in. to $u = 58\,955$ lb. per sq. in. It also gives the utilizable capacity, c, of long columns from $\frac{l}{r} = 75$ to $\frac{l}{r} = 154$, inclusive.

For the assumed conditions that unintentional eccentricity, e, $= \frac{l}{700}$ and $\frac{v}{r} = 1.68$, the writer has made a considerable number of computations to develop the maximum error involved in using Equation (11) for determining the utilizable capacity, c, in place of determinations by trial from Equation (3). The maximum error discovered was an excess in capacity indicated by Equation (11) of 2% in the case of a column with a u of 20 071 lb. per sq. in. and an $\frac{l}{r}$ of 120. The greatest errors occur in the series having the smallest values of u. All the errors are probably well within 3 per cent.

To summarize: From Table 12 any column with pivoted or frictionless hinged ends can be readily classified as short, medium, or long, when its characteristic U. L. P. is known; if short, its utilizable capacity can be found from Equation (1); if medium, from Equation (11) with suitable values of n_1 and n_2 taken from Table 12; and if long, from Equation (6), or directly from Table 12 if its $\frac{l}{r}$ is any whole number from 75 to 154, inclusive.

The series of tests of columns with flat ends made by the U. S. Bureau of Standards for the Special Committee on Steel Columns and Struts, and the numerous series of tests of centrally loaded pin, flat, spherical, and fixed-ended columns made since 1880 by U. S. Government Engineers at the Watertown Arsenal, developed in all but one series a much smaller reduction in utilizable capacity with increase in length than that indicated by Equations (6) and (11) (as shown in Tables 11 and 13).

In tests of pin-ended columns, the friction between the pins and their bearings restrains the ends and causes the column to act as if it were fixed or flat-ended until the tendency (induced by the primary and secondary bending moments) of the ends to turn on the pins is sufficient to overcome the friction. In all but one case the records of the tests of pin-ended columns cited in Table 13, for which $\frac{l}{r}$ was greater than 96, show that the ends were restrained up to the moment of failure and that the columns then deflected suddenly, thus indicating that the ends suddenly turned on the pins. In the one case, in which the record makes no mention of sudden deflection, the unintentional eccentricity from an initial curve in the axis $\left(\frac{\text{length}}{550}\right)$ was greater than the assumption of $\frac{\text{length}}{700}$, and the deflection at the U. L. P. $\left(\frac{\text{length}}{241}\right)$

exceeded the permissible deflection of $\frac{\text{length}}{300}$, on which Equation (6) is based. The ends in this one case probably turned on the pins before the U. L. P. was reached, and the load at the "permissible deflection" was probably less than the 9 200 lb. per sq. in. indicated by Equation (6).

The additional value of c, if any, which a medium or long column in service possesses over and above the value indicated by Equations (6) or (11), by reason of its having pin, flat, or riveted ends, depends in each case on the conditions.

In laboratory tests the pin and flat ends of columns are restrained by a fairly rigid testing machine, whereas in practice the ends are restrained simply by the stiffness of adjoined more or less flexible members of a deflected structure, the latter, probably, being much less effective. In pin-ended members the ability of adjacent members to stiffen a member is contingent on friction on the pins, which will be overcome if the bending moment is large enough. For long columns and, ordinarily, for medium columns, it is advisable not to place any reliance on friction but to classify as "frictionless pin or hinged-ended" all columns with pin ends and all continuous compression chords of trusses having pin connections to the web members. For long and medium columns with riveted end connections to adjacent members some allowance may be made for the restraining influence of the end connections by letting the l of the equations and of Table 12 represent from three-quarters to two-thirds of the length, according to the conditions, instead of the whole length as in the case of columns with pivoted or frictionless hinged ends. In other words for such columns l represents the distance between points of contrary flexure assumed by judgment. Under ideal conditions, l for columns with fixed ends equals one-half the length, and for columns with one free and one fixed end twice the length; but ideal conditions are not achieved even in the laboratory.

To illustrate the use of Table 12 and Equation (11), a nickel steel column with a characteristic u of 47 700 lb. per sq. in. and an $\frac{l}{r}$ of 100, well connected to adjacent fairly stiff members by riveted joints, might be assumed to have an $\frac{l}{r}$ between points of contrary flexure of 66.7 and, from Table 12, would be a medium column with an n_1 of 53.7 and an n_2 of 2.033 and, from Equation (11), would have a utilizable capacity, c, of 35 100 lb. per sq. in. The test of such a column with flat ends (cited in a footnote to Table 6) showed under laboratory conditions very little variation from perfect elasticity up to 47 000 lb. per sq. in. and a failure load of 48 910 lb. per sq. in.

The equations and Table 12 given in this Part 6 are based on the assumption of no intentional eccentricity between the line of thrust and the axis of the column, whether produced by eccentric application of the longitudinal load or by a combination of longitudinal and transverse loads. Where there is intentional eccentricity, allowance should be made as described in Part 9. The weight of horizontal and inclined columns causes intentional eccentricity.

TABLE 13.—Comparison of Useful Limit Points and Utilizable Capacities, c, in Full-Sized Column Tests.

(Sets 1, 2, 3, and 4 were compiled from Watertown Arsenal Reports for 1908, 1909, 1910, and 1883; Set 5 from *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20).

All U. L. P.'s are in 1 000 lb. per sq. in. All deflections (except one) were less than $\frac{\text{length}}{300}$. In most cases the average is the average U. L. P. of three columns.

For all pin-ended columns (except one) with $\frac{l}{r}$ greater than 96, the reports record sudden lateral springing at maximum load.)

(*a*) Lap-Welded Bessemer Steel Tubing, 5 Inches in Nominal Diameter; 5.02 to 5.36 Square Inches in Sectional Area; Average Characteristic U. L. P. per Square Inch = u = 31 000 Pounds per Square Inch.

* Initial curve in axis, $\frac{\text{length}}{550}$; deflection, $\frac{\text{length}}{241}$; when load was reduced to 1 000 lb. per sq. in., it reduced the deflection to 0.03 in.; on reloading, column failed by deflection; maximum load, 10 100 lb. per sq. in.

It is essential to the applicability of Equations (1), (6), and (11) that the details shall be able to develop the capacity indicated by the equations. For example, tests of forty-two columns by the U. S. Bureau of Standards, for the American Railway Engineering Association's Committee on Steel and Iron Structures, included comparative tests of columns with lacing and columns with batten-plates, and the report of that Committee states:*

"In all cases the columns with batten-plates failed at an ultimate strength of from 6 000 to 9 000 lb. per sq. in. less than the corresponding column with lacing, and, in one case, the heavy section with 120 $\frac{l}{r}$ as much as 15 000 lb. per sq. in. less."

In some cases the details of a column include lattice-bars for one or two open sides. Even under ideal conditions lattice-bars have to possess considerable potential resistance to shear in order to give the column about as much stiffness against deflection from shear as from bending moment. In actual conditions the lattice-bars actually have to resist shear. Lattice-bars also have to take some of the direct compression and should provide some resistance to possible accidental abnormal transverse loads.

Let,

S = the shear when the column is loaded to its utilizable capacity; and
A = the cross-sectional area of column.

The assumption made for short columns that the column is subject to equal eccentricities in the application of the load on opposite sides of the axis at opposite ends sufficient to produce a bending stress of 0.1 u, and the assumption made for short, medium, and long columns that $\frac{v}{r} = 1.68$, together lead to the equation:

$$S = \frac{u\,A}{8.4\,\frac{l}{r}} \qquad (12)$$

The assumption for medium columns that the stress from bending equals $u - c$, and the assumption for both medium and long columns that the column is initially bent in a sinusoidal bow with unintentional eccentricity of $\frac{l}{700}$, together lead to the equation for medium columns:

$$S = \frac{\pi\,(u - c)\,A}{1.68\,\frac{l}{r}} \qquad (13)$$

The assumption for long columns loaded to their utilizable capacity that the deflection is limited to $\frac{l}{300}$, and the assumption for long columns previously cited, together lead to the equation for long columns:

$$S = \frac{\pi\,c\,A}{210} \qquad (14)$$

* *Proceedings*, Am. Ry. Eng. Assoc., Vol. 19, 1919, p. 960.

The following general rule is suggested for proportioning lattice-bars of columns without intentional bending moment: Proportion the lattice-bars of each open side for a stress of $\frac{0.5\,S}{F}$, in which, F is the factor of safety given by the working load used for the column, and S is obtained from the empirical formula:

$$S = 0.02\,u\,A \qquad (15)$$

Equation (15) gives a value of S varying from 2.1 to 4.5 times as great as either of Equations (13) or (14); and from 0 $\left(\text{when } \frac{l}{r} = 6\right)$ to 6.4 $\left(\text{when } \frac{l}{r} = 38.4\right)$ times as great as Equation (12); hence, in all cases except extremely short columns, this rule allows considerable margin, for considerations other than the shear indicated by the assumptions on which Equations (12), (13), and (14) are based.

In 1891, the writer suggested the following:*

"The lattice shall be so spaced that each channel between lattice connections shall be stronger than the column considered as a whole, and their size shall be obtained by treating the column as a lattice girder loaded at the middle with a load equal to 3% of the total compression on the column."

He now modifies this suggestion in conformity with the analysis given to the following:

"The lattice shall be so spaced that each channel between lattice connections shall be stronger than the column considered as a whole; and its size shall be obtained by treating the column as a latticed girder loaded at the middle to the amount of 4% of the total compression that would be allowed on the column if short."

Part 7.—Utilizable Capacity of Tension Members and of Members Subjected to Alternate Stresses; and the Results of Loading Tension and Compression Members Beyond Their Useful Limit Points

Let,

t = the utilizable capacity per unit of net cross-sectional area.

Tension members, like columns, are liable to unintentional eccentricities between their lines of force and their axes, and their connections are of such stiffness that flexure can be transferred to them from the members to which they are connected. Unlike columns, however, they are not liable to eccentricity from imperfect butt joints, and their flexure, instead of being increased by the secondary moments, is decreased. Another important consideration is the fact that ruinous deformation in most cases probably will not cause failure in a short period, with its resultant danger. Logically, this last consideration affects the factor of safety rather than the utilizable capacity, but to avoid complication, the utilizable capacity is considered, instead, as slightly increased and no recommendation made for any reduction in the factor of safety. After weighing all these facts, the writer considers that, except as

* *Lehigh Quarterly*, June, 1891, p. 159.

noted, $t = u$, u being the useful limit point of a full-sized tension or short compression member as described in Part 5.

The exception is the case of a tension member to which a large girder or floor-beam, liable to heavy loading, is riveted; which, similarly as for columns, is a matter in each case for particular consideration.

There are no published results of tests of full-sized tension members other than eye-bars from which U. L. P.'s can be obtained and no published comparisons of the weighted averages of the U. L. P.'s of specimen tests with the U. L. P.'s of tension members. Such tests are desirable. In their absence it is reasonable to infer that the U. L. P.'s of tension members (per unit of net area), made of single symmetrical shapes or built of shapes and plates, are as great as those of short columns of the same cross-section (per unit of gross area), as inferred from specimen tests.

There are no published comparisons between the U. L. P.'s of specimen tests and those of eye-bar tests. For specimen tests to be directly critical as regards U. L. P.'s it would seem that the bars from which specimens are cut should be first annealed, as for eye-bars. In inferring U. L. P.'s of eye-bars from the U. L. P.'s of unannealed specimens allowance should be made for the effect of annealing.

For alternate tension and compression, consider a test piece with a cross-sectional area of 1 sq. in.

Let,

R = the maximum elastic range of stress which can be developed therein.

u = the value of R when the range is from zero to a maximum. For this range, u is the critical value of the specimen.

u' = the greater stress plus x times the lesser stress.....(16)

in which, x is a factor, constant for similar test pieces, but differing for the many grades and kinds of steel.

Let,

y = one-half the stress by which tension exceeds compression or compression exceeds tension, so that,

$$\text{Greater stress} = \frac{R}{2} + y;$$

and

$$\text{Lesser stress} = \frac{R}{2} - y$$

Then,

$$\frac{R}{2} + y + x\left(\frac{R}{2} - y\right) = u'$$

and, solving,

$$R = \frac{2}{1+x}(u' + xy - y) \quad \text{.....(17)}$$

$$x = \frac{2u' - 2y - R}{R - 2y} \quad \text{.....(18)}$$

By careful scrutiny and trial, approximate values of u' and x were inferred from Table 1 for Lots 2 and 3, and the elastic ranges were computed by use of Equation (17) and then compared with Table 1 to test the assumption that x "is constant for similar test pieces," as shown in Table 14.

In considering Table 14 it should be remembered that, in the absence of published figures, the writer obtained the developed elastic limits cited in Table 1 by scaling them from Bairstow's diagrams.

In the latter part of Part 5 it is specified that the critical value of each specimen shall be limited to 60% of its tensile strength and to 87% of its U. L. P. If these limitations govern, the value of u for the specimens of Bessemer steel will be limited to 60 000 lb. per sq. in. and x will not be greater than 62%; and for all the specimens cited in Tables 1 and 2, tested with 800 or less "cycles per minute", having a tensile strength of less than 70 000 lb., the value of x will be well within 50 per cent.

There is a clause in some specifications to the effect that members subject to alternate tension and compression shall be proportioned for both tension and compression separately considered, but that each kind of stress shall be considered as increased by 50% of the lesser stress. If the stresses are those obtaining when members are stressed to their utilizable capacity and the metal is 70 000 lb., or less than 70 000 lb., steel, this specification seems to be ample. It is probably ample for all steel, but for steel of more than 70 000 lb. and up to 100 000 lb. maximum tensile strength the writer considers it best to specify percentages of more than 50 and up to 65 per cent.

TABLE 14.—Comparison of Computed with Actual Ranges of Stress to Show in Cases of Alternate Stresses that x in Equation (17) is Constant for Steel of the Same Kind and Grade; y = One-half the Stress by Which Tension Exceeds Compression or *Vice Versa;* and u = Range from Zero to Maximum Stress.

Unannealed Axle Steel (All Stresses are in Pounds per Square Inch; Tensile Strength, 85 600; u = 48 000; x = 64.4 Per Cent.)			Unannealed Bessemer Steel (All Stresses are in Pounds per Square Inch; Tensile Strength, 99 900; u = 66 500; x = 79.2 Per Cent.)		
y.	Ranges:		y.	Ranges:	
	Computed.	From Table 1.		Computed.	From Table 1.

24 000	48 000	.....	31 500	66 900	67 000
27 500	46 500	47 000	33 250	66 500	.....

To the writer's knowledge all endurance tests of steel whether by repeated direct tension, by repeated direct compression, or by alternate direct tension and direct compression, are of material that has not been treated by cold-rolling, by cold-drawing, or by heating and quenching. As far as this paper is concerned, the important problem of the utilizable capacity of treated steel eye-bars is not considered.

A superficial consideration of the report of the Special Committee on Steel Columns and Struts would give the impression that the U. L. P. adopted is the *Ultima Thule* of the structural value of steel. The writer has used it as the limit to the application of mathematical analysis based on the assumption of elasticity. This "point" does indicate the "limit" within which steel is predominantly elastic, and it is very "useful"; the term, "Useful Limit Point", should be thus interpreted, but it does not necessarily indicate a limit beyond which steel ceases to have structural value.

Tests 4135* of a 5 by 1-in. eye-bar can be considered as typical of the nineteen eye-bars referred to in Part 5 as tested at the Watertown Arsenal. The results of the test of this bar, in a gauged length of 260 in., near its U. L. P. are as shown in Table 15.

As the gauge was set at zero for 1 000 lb., 0.0091 in. (the elastic elongation for 1 000 lb.) has been added to each elongation taken from the report.

A load about 5% greater than the U. L. P. caused a plastic elongation (which would result in permanent set) of about one-third the elastic elongation; and a load 10% greater caused a plastic elongation of more than 500% of the elastic. Under this latter load, the plastic elongation in 25 ft. 8 in. (the length, center to center, of pins) was 2.3 in. Such a phenomenon in a diagonal bar of a bridge panel 18 ft. high by 18 ft. long would permanently distort the panel 4.6 in.; that is, the vertical drop in the lower pin would be 4.6 in. greater than in the upper one. Such distortion would be ruinous.

TABLE 15.—Elastic and Plastic Deformation of a Typical Eye-Bar.

69 330 Maximum load	.....	.....	.....	.....

The eye-bar had a sharp and pronounced yield with a small increase in load just above the U. L. P. Other members the cross-sections of which consist of one piece are liable to sharp and pronounced yields. For instance, an H-section, pin-ended column,† had a U. L. P. of 26 000 lb., a linear compression of 0.0306 in. in 20 in. at 31 000 lb. per sq. in. and of 0.23 in. in 20 in. at 32 000 lb. per sq. in. Built members are usually composed of pieces having different U. L. P.'s and yield points, and are subjected to severe local

* Watertown Arsenal Report, 1886, p. 1574.

† *Loc. cit.*, 1909, p. 755.

strains in fabrication. They rarely if ever have a pronounced yield that is sharply marked until they are near the point of failure.

To show the behavior of columns when loaded beyond their U. L. P.'s Tables 16 and 17 have been compiled. Table 18 gives data referred to in Table 17. The type, section, and other data concerning these columns are given in Tables 3 and 18. (The columns listed in Table 18 are the largest ever tested, are of many varieties of steel, and the data regarding them are very interesting and valuable as criteria.) The forked ends of the columns indicated as Items 5 and 6 in Table 17 were beyond question critical as regards the maximum loads sustained. It appears from these tables that under laboratory conditions short columns with suitable details, to become permanently shortened by an increment of one-third their elastic shortening under the same load, would on an average require loads about 10% greater than at their U. L. P.'s.

TABLE 16.—Small Built Columns, Loaded Beyond Their Useful Limit Points.

R = ratio of plastic to elastic deformation at the U.L P.
L = load which caused plastic deformation equal to one-third the elastic deformation. After removal of load, plastic deformation becomes permanent set.

The question arises whether for short built columns and built tension members a total plastic deformation not to exceed one-third of the total elastic deformation would not be a better limit to adopt for critical deformation than the U. L. P. The writer's opinion is decidedly in favor of the U. L. P. Actual conditions are not those of the laboratory; plastic deformation equal to one-third of the elastic deformation would produce excessive

permanent distortion of structures and would vitiate the results of computations based on the elasticity of steel.

Part 8.—Beams and Plate Girders under Transverse Loads

Simple tension or compression in elastic material has its maximum shearing component in any plane making an angle of 45° with the direction of the force. From the theory of mechanics the intensity of this maximum shearing component is one-half that of the simple tension or compression. The microscope has shown that when the elastic limit is reached in malleable metals under simple tension or compression the yield takes place by the sliding within grains of their crystalline layers one over another; which indicates that the material is really yielding under the shearing component of the simple tension or compression. When, at the elastic limit, iron or steel yields, at an indicated simple tension or compression of, say, 30 000 lb. per sq. in., it actually yields under a shearing component of 15 000 lb. per sq. in. It is a fair inference that under compound stress the elastic limit in iron or steel is reached when the shearing intensity reaches one-half the intensity of simple tension at the elastic limit; and the weight of experimental evidence seems to support this inference. The predominant practice in dealing with beams and plate girders is to permit a shear per unit of gross area of six-tenths the permissible tension per unit of gross area, but the writer prefers five-tenths instead of six-tenths and is confirmed in this preference by the fact that ample webs are advisable for stiffness and reduce somewhat the magnitude of the errors involved in the ordinary theory of flexure. He also considers it best in important cases to compute the maximum shear by the theoretical formula given in textbooks on Mechanics* instead of proportioning for a mean intensity of shear considered as carried exclusively by the web. In rolled I-beams it does not make much difference, but for plate girders the maximum intensity of the shear in the web indicated by theory is ordinarily 10 to 25% greater than the mean indicated by the ordinary method.

That there are "faults in the theory of flexure" has been shown by Bach, Love, Saint Venant, and others, and by the writer in a paper,† thus entitled, and its discussion, to which references are made in this Part 8.

One of these faults is the neglect of the influence of shear on cross-sections, by reason of which originally plane cross-sections do not remain plane during flexure (as ordinarily assumed), but are forced into reversed curves somewhat like a long $\int$ only much less pronounced, as illustrated in Figs. 3 and 4 of the writer's paper previously mentioned.

In consideration of the fact that because of the fault cited the ordinary theory of flexure indicates for the extreme fibers intensities of stress that are too small, an approximate method was devised by the writer‡ and improved

* It is given in the Carnegie Pocket Companion, 1913 Edition, p. 180, and 1923 Edition, p. 151.

† *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), pp. 895–981.

‡ *Loc. cit.*, pp. 896–897.

by J. P. J. Williams, M. Am. Soc. C. E.,* for computing the percentage, P_e, which on account of this fault should, theoretically, be added to the intensity of the stress as computed from the ordinary theory. This method has been adapted to the purposes of this paper.

For steel beams of rectangular cross-section uniformly loaded and simply supported†:

$$P_e = 8.88 \frac{d^2}{x\,(l - x)} \qquad (19)$$

in which, l, is the length; d, the depth between extreme fibers; and x, the distance from the end to the point at which the percentage to be added, P_e, is desired.

TABLE 18.—Tests of Large Steel Columns.

(Made by J. H. Griffith, Associate Engineer Physicist, and J. G. Bragg, Associate Assistant Physicist. Compiled from *Technologic Paper No. 101*, U. S. Bureau of Standards.)

The U. L. P.'s are not stated in *Technologic Paper No. 101*, U. S. Bureau of Standards, but have been taken from the stress-strain diagrams for tests where the diagrams reached this point. The ratios, $\frac{l}{r}$, are different for different axes. The greatest ratio is used. See *Technologic Paper No. 101*, p. 22, for chemical analyses and maximum tensile stress for specimen; pages 20 and 21 for cross-sections; and the pages cited in first column for the remaining data. The columns in each group had nominally identical cross-sections.

* *Technologic Paper No. 101*, U. S. Bureau of Standards.

† Shortening in gauged length not measured at point high enough in stress to indicate the U. L. P.

Substituting C_e, a factor constant for similar cross-sections, in place of 8.88,

$$P_e = C_e \frac{d^2}{x\,(l - x)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

At the center of the beam or girder,

$$P_e = \frac{4\,C_e\,d^2}{l^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

For instance, if $C_e = 10$, $d = 30$ in., and $l = 80$ in., the percentage to be added is 5.625.

When the load instead of being distributed from end to end is confined within and uniformly distributed over a distance, $2a$, at the center, the percentage of increase at the center* is:

$$P_e = \frac{C_e\,d^2}{a\,(l - a)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

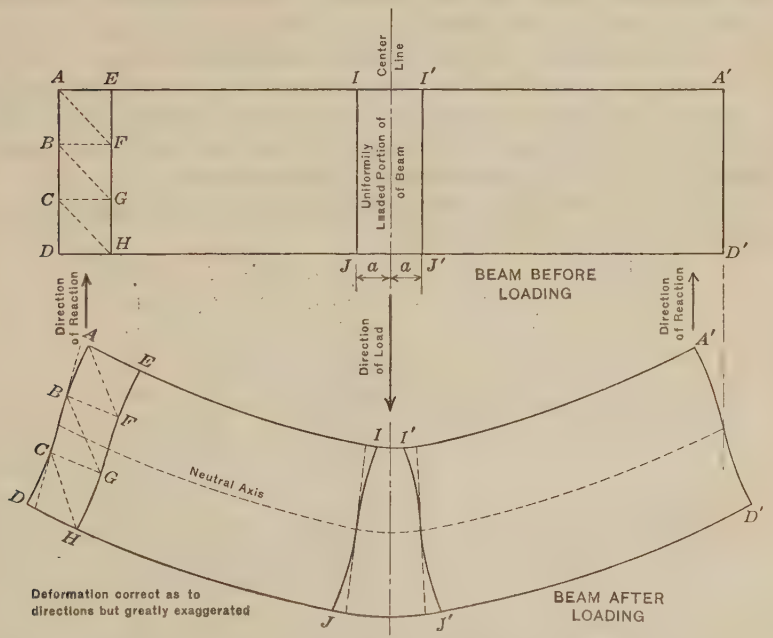

FIG. 4.—DEFORMATION OF BEAM LOADED ON LENGTH $2a$ AT CENTER. SHEAR AND, THEREFORE, DISTORTION IS GREATEST AT NEUTRAL AXIS AND GRADUALLY DECREASES UNTIL IT BECOMES ZERO AT EXTREME TOP AND BOTTOM FIBERS. TO ILLUSTRATE DISTORTION FROM SHEAR, ORIGINALLY STRAIGHT VERTICAL LINES ARE CONCEIVED AS SCRIBED ON BEAM.

C_e has been determined by Williams for rectangular cross-sections as 8.88 (as noted); for a standard 12-in., 31.5-lb. I-beam, as 11.32; and for a 12-in., 28.5-lb. I-beam, as 12.5. From certain determinations by Williams and from others by the writer, the following empirical rules for obtaining the approximate value of C_e for plate girders and I-beams have been devised.

* *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), p. 952.

Let,

"Ratio" = the ratio of web cross-sectional area to total cross-sectional area, considering the web as of full depth.

Then, for I-beams:

$$C_e = \frac{1.96}{\text{Ratio}} + 7.0$$

For plate girders:

With "Ratio" between 0.28 and 0.36.... $C_e = \frac{7.17}{\text{Ratio}} - 4.7$

With "Ratio" between 0.36 and 0.54.... $C_e = \frac{3.32}{\text{Ratio}} + 6.0$

With "Ratio" between 0.54 and 0.71.... $C_e = \frac{5.72}{\text{Ratio}} + 1.6$

In consideration of the initial imperfections and limitations to the elasticity of beams and plate girders and the tendency of steel overstrained in bending to become adjusted to the conditions, as hereinafter discussed, it seems advisable, in the interest of simplicity, not to add any percentage to the computed extreme fiber stresses unless the percentage, P_e, as indicated by Equations (21) and (22) is more than 5, and to avoid values greater than 5, where practicable, either by changing the ratio of the web area to the total area, by spreading the load, or by a combination of these methods.

For simply supported beams and girders uniformly loaded from end to end the percentage, P_e, will be less than 5:

For	lengths	of	more	than	2.67 d	when	C_e =	8.88
"	"	"	"	"	2.83 d	"	C_e =	10
"	"	"	"	"	2.97 d	"	C_e =	11
"	"	"	"	"	3.10 d	"	C_e =	12
"	"	"	"	"	3.23 d	"	C_e =	13
"	"	"	"	"	3.35 d	"	C_e =	14
"	"	"	"	"	3.47 d	"	C_e =	15
"	"	"	"	"	3.58 d	"	C_e =	16
"	"	"	"	"	3.69 d	"	C_e =	17
"	"	"	"	"	3.80 d	"	C_e =	18
"	"	"	"	"	3.90 d	"	C_e =	19
"	"	"	"	"	4.00 d	"	C_e =	20
"	"	"	"	"	4.10 d	"	C_e =	21

If P_e is 5 and 2 a (the distance over which a concentrated uniformly distributed load at the center is spread) is taken as $\frac{d}{n}$, then, as developed from Equation (22):

$$l = \left(0.4\ C_e n + \frac{0.5}{n}\right) d \qquad (23)$$

For simply supported beams and girders, uniformly loaded over a distance or spread of $\frac{d}{n}$, the percentage, P_e, will be less than 5:

For lengths of more than $\left(3.55\ n + \frac{0.5}{n}\right) d$, when $C_e = 8.88$

" " " " " $\left(4.0\ n + \frac{0.5}{n}\right) d$, " $C_e = 10$

" " " " " $\left(4.4\ n + \frac{0.5}{n}\right) d$, " $C_e = 11$

" " " " " $\left(4.8\ n + \frac{0.5}{n}\right) d$, when $C_e = 12$

" " " " " $\left(5.2\ n + \frac{0.5}{n}\right) d$, " $C_e = 13$

" " " " " $\left(5.6\ n + \frac{0.5}{n}\right) d$, " $C_e = 14$

" " " " " $\left(6.0\ n + \frac{0.5}{n}\right) d$, " $C_e = 15$

" " " " " $\left(6.4\ n + \frac{0.5}{n}\right) d$, " $C_e = 16$

" " " " " $\left(6.8\ n + \frac{0.5}{n}\right) d$, " $C_e = 17$

" " " " " $\left(7.2\ n + \frac{0.5}{n}\right) d$, " $C_e = 18$

" " " " " $\left(7.6\ n + \frac{0.5}{n}\right) d$, " $C_e = 19$

" " " " " $\left(8.0\ n + \frac{0.5}{n}\right) d$, " $C_e = 20$

" " " " " $\left(8.4\ n + \frac{0.5}{n}\right) d$, " $C_e = 21$

By care in designing, the deficiency in the computed intensity of the extreme fiber stress can be reduced to less than 5% in all but very short I-beams and girders. For instance, if $C_e = 20$, $d = 24$, and $2\,a = 8$, then, for $P_e = 5$, $n = 3$, and $l = 58$. If l is less than 58, but not too small, P_e can be kept down to 5 or less by increasing either $2\,a$, or the ratio of web area to total area, or by both methods.

The values of P_e given by Equations (20), (21), and (22) are too large. The error increases as the indicated value of P_e increases, but is very slight up to $P_e = 10$; however, when these equations indicate P_e as 50, P_e is probably not more than 35; and when they indicate P_e as 100, P_e is probably not more than 50.

The manner of spreading the load depends on the way it is applied to the beam or girder. If the web has a surplus of cross-section above the requirements of shear and is sufficiently stiff, and if the load is conveyed to it by adequate means, it will spread the load to some extent beyond the limits of the actual contact.

The ordinary theory of flexure is developed on the tacit assumption that the loads and reactions are applied to beams and girders so that each increment

of each horizontal layer, at or vertically in line with each increment of load, receives directly just that share of the load increment necessary to produce the theoretical changes in its shear without any part having been conveyed to it by compression or tension through adjacent layers. This tacit assumption is sometimes approximated, but is never fully realized; consequently, vertical stresses in the web occur at, and inclined stresses in the web originate at, points of loading and reaction, and these inclined stresses have horizontal components, all of which affect the web and flanges although they are neglected in the ordinary theory of flexure. These uncomputed stresses, especially if the load is concentrated, make it advisable to provide web section and web reinforcement in excess of the requirements of ordinary theory, and, in girders with flange cover-plates, to require that cover-plates of the bottom flange extend beyond the nominal theoretical limits when the load is applied at the top and similarly for the top flange when the load is applied at the bottom.

Web section and reinforcement in excess of the requirements of ordinary theory may reasonably be expected to mitigate the effects of concentration much the same as would an increase in the length of direct application.

The theory of flexure is based on ideal material perfectly elastic within limits, but the theory stops at these limits. The effects of the differences between ideal steel and the actual steel of commerce as applied to beams and plate girders under transverse loads require special consideration.

Rolled I-beams are peculiarly liable to auto-stress* and to variations in the elastic resistances of their different parts. The U. L. P.'s in pounds per square inch, as scaled from the diagrams of tests of specimens from the webs, flanges, and roots of certain I-beams tested by the late Edgar Marburg, M. Am. Soc. C. E.†, are given in Table 19.

TABLE 19.—Specimen Tests from Web, Flange, and Root of Large I-Beams.

Beam.	Web, U. L. P., in pounds per square inch.	Flange, U. L. P., in pounds per square inch.	Root, U. L. P., in pounds per square inch.
15-in., 38-lb. I-beam	42 500	.....	26 000
24-in., 72-lb. I-beam	46 000	36 000	38 000
24-in., 80-lb. Standard I-beam	30 500	28 400	25 000
30-in., 120-lb. I-beam	37 000	31 500	30 100
15-in., 73-lb. girder beam	39 000	.....	22 000
24-in., 120-lb. girder beam	36 400	33 300	28 000
30-in., 175-lb. girder beam	34 900	28 000	27 000

Fatigue tests of rotating shafts, of which there have been many (some are cited in Table 5), and fatigue tests by Wöhler and others of presumedly square or rectangular bars loaded alternately in opposite directions, show by inference that fields of seemingly perfect elasticity can be developed by alternate bending in opposite directions; and fatigue tests by Wöhler and others, presumedly on square or rectangular bars, under loads which in each case are in the same

* *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), pp. 913 and 931.

† Reported in "Tests of Standard I-Beams and Bethlehem Special I-Beams, and Girder Beams", *Proceedings*, Am. Soc. for Testing Materials, Vol. IX (1909), p. 378.

direction but repeatedly vary between a given minimum and maximum, show that these fields of seemingly perfect elasticity can be shifted so that the stress in the extreme fiber at the top of the beam varies between computed elastic limits both of which are in compression whereas the stress in the extreme fiber at the bottom of the beam varies between computed elastic limits both of which are in tension.

It has been shown in Parts 5 and 6 that for compression and tension members, loading which would perfect the elasticity to a point much above the U. L. P. is not permissible because there the yield develops so rapidly that a slightly greater load would cause seriously detrimental extension in tension members or shortening in compression members. In beams and plate girders under transverse loads, the plastic deflection develops more gradually than the plastic deformation in tension and compression members; hence if the beams are held against lateral deflection and the metal is not so attenuated as to permit buckling or crippling of the web or flanges, there is greater opportunity for shifting the elastic field. The difference in this respect between the plastic extension of a soft steel eye-bar and the plastic deflection of beams under transverse loads is illustrated by the following comparison:

(*a*).—An eye-bar tested at the Watertown Arsenal* had a U. L. P. of 29 000 lb. per sq. in. The plastic deformation at this point was quite small and of little consequence *per se*, but the rate of extension indicated that a pronounced yield had set in. Between 31 000 and 32 000 lb. per sq. in. there was a definite yield point and at about 20% above the yield point the plastic extension or permanent set became more than sixteen times as great as the computed elastic extension.

(*b*).—Twenty 15-in. I-beams of 21-ft. span and nominally equivalent strength were tested at Ambridge, Pa., loaded at the center†. If in each case these loads had been 36 600 lb. (including one-half the weight of the beam considered as concentrated at the center), and the beams had been perfectly elastic and simply supported, the computed stress in the extreme fiber by the ordinary theory of flexure would have been 39 000 lb. per sq. in., which is about the average yield point indicated by the specimen tests. The actual loads which produced permanent sets of 0.4 in. were all within 7% of their average, which average was 65.7% greater than the load of 36 600 lb. per sq. in., while the permanent set was only a little more than one-fourth the computed elastic deflection. The beams, however, were not "simply supported" as the end connections and supports must have exercised some restraining influence. If this restraining influence amounted to a bending moment at each end of one-third the moment at the center (an exaggerated proportion), the loads which produced the permanent set of 0.4 in. even in that case would have been more than 20% in excess of the 36 600 lb. per sq. in. and the permanent set would not have been much more than one-half the computed elastic deflection.

When I-beams and plate girders, in which the metal is not so attenuated as to permit buckling or crippling of web or flanges, have properly designed

* *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), p. 968.

† *Loc. cit.*, pp. 917–918.

details, are adequately proportioned for shear, are not too short, and have their flanges held against lateral deflection, it seems reasonable from the foregoing analysis to assume that their utilizable capacity in each case will be as great as the load for which the intensity of the stress in the extreme fiber, computed from the ordinary theory of flexure, equals u, u being the useful limit point of the flange similarly as described in the rule in Part 5 (page 1236), for tension and compression members. It is probable, for I-beams at least, that the utilizable capacity is somewhat greater than this when the load varies between a minimum and maximum of reduced range, provided the minimum is not too close to the maximum. If the minimum is too high it does not afford the plastic metal sufficient opportunity to recover from elastic fatigue but causes the plastic deformation to increase gradually until failure results. A very slow increase in plastic deflection of beams may continue for a long time under heavy static loads, as shown in the case of a pair of 15-in., 50-lb. I-beams.*

Part 9.—Combined Compression and Flexure

When in addition to the direct load a column is subjected to intentional flexure, it follows from the assumptions in Part 6 that the utilizable capacity is determined by one of three following limitations, *A*, *B*, or *C*, whichever gives the smallest capacity:

Limitation A.—The utilizable capacity shall not be considered greater than indicated by Equation (1) for columns subjected to direct load without intentional flexure.

Limitation B.—The greatest intensity of stress, f, from direct load, intentional flexure, and unintentional eccentricity $\left(\text{assumed as in Part 6 as } \frac{l}{700}\right.$ in the form of a sinusoidal bow$\left.\right)$ shall not be greater than u.

Let,

f_1 = maximum intensity of intentional primary flexure.

f_2 = maximum intensity of unintentional primary flexure.

$$f_c = f_1 + f_2 \qquad (24)$$

From Equation (3):

$$f = p + f_c + f_c\left(\frac{p}{q - p}\right) \qquad (25)$$

Equation (25) is exact only when the moment diagram is a sinusoid; but it is a close approximation for all cases in which the maximum bending moment occurs at or near the center of the column. For computing f_2, e, as in Part 6, may be taken as $\frac{l}{700}$ and $\frac{v}{r}$ as 1.68. Then, from analysis similar to that by which Equation (8) was developed,

$$f_2 = 0.00240\, p\, \frac{l}{r} \qquad (26)$$

The direct load per unit of area, p, which in combination with f_1 and f_2, will produce a stress intensity, f, equal to u, can be found from Equation (25)

* *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), p. 975.

by first assuming p and then making successive trials, but this tedious process is unnecessary as it can be approximated with sufficient closeness from the following empirical formula:

$$p = c - f_1 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

c having been first found from Equation (11).

To show the approximate accuracy of Equation (27), f has been determined in Table 20 (a) for a large range of cases from Equation (25) using for p the value obtained from Equation (27). If the value obtained for p had been exact, f in all cases would have been the same as u. It differs from u by less than 2% for all cases except those in bold face type.

TABLE 20.—Justification for Empirical Formula, Equation (27).

(For this comparison, columns in which the ratio, $\frac{v}{r} = 1.68$, were chosen. For smaller ratios the error would be less.)

35 105	90	13 781	14 996	9 430	11 247
50 063	70	20 127	23 467	13 206	17 600

* The value of f as indicated in (a) differs from u by less than 2% in all cases except those recorded in bold-face type.

† For these two cases and for these two only, Equation (27) seems to be critical; in all the other cases Equation (31) seems to be critical; actually, Equation (31) is critical in all the cases. The use of Equation (27) for the two cases in which it seems to be critical is conservative, and the error involved on the side of safety is not excessive.

Limitation C.—The deflection under combined intentional and unintentional bending moments shall not exceed $\frac{l}{300}$.

Let,

M_1 = the intentional primary bending moment;
Δ = the deflection;
A = the cross-sectional area; and,
e_1 = the primary intentional eccentricity.

From the theory of flexure:

$$\Delta = \frac{(\text{Bending moment})\ l^2}{C_2\ E\ A\ r^2} \qquad (28)$$

in which, for beams or columns of constant cross-section with frictionless hinged ends, C_2 equals 9.6, for a uniformly distributed transverse load; 12.0 for a single transverse load concentrated at the middle; or 8.0, when the bending moment is constant from end to end; or π^2, when the moment diagram is a sinusoid.

For combined compression and flexure with $\Delta = \frac{l}{300}$, and unintentional eccentricity $= \frac{l}{700}$,

$$\frac{l}{300} = \frac{\frac{\pi^2}{C_2} M_1\ l^2}{\pi^2\ E\ A\ r^2} + \frac{p\ A\ \frac{l}{700}\ l^2}{\pi^2\ E\ A\ r^2} + \frac{p\ A\ \frac{l}{300}\ l^2}{\pi^2\ E\ A\ r^2} \qquad (29)$$

Substituting q (Euler's formula) for its value, as given in Part 6, and reducing,

$$p = 0.7\ q - \frac{210\ \frac{\pi^2}{C_2}\ M_1}{A\ l} \qquad (30)$$

When the primary bending moment is caused by an intentional eccentricity, e_1, constant from end to end, $M_1 = p\ A\ e_1$ and $C_2 = 8$; whence, by substitution in Equation (30),

$$p = \frac{0.7\ q}{1 + \frac{259.1\ e_1}{l}} \qquad (31)$$

In some cases the value of p, as determined from Equation (31), is somewhat greater than indicated by the empirical Equation (27); but notwithstanding this is slightly less than indicated by Equation (25). In such cases, to be precise, Equation (31) should govern, but this fact can only be ascertained by a tedious determination of p by trial from Equation (25). The error involved in using Equation (27) in such cases is not excessive and is on the side of safety, as shown in Table 20 (*b*).

When the maximum possible value of p within the utilizable capacity approaches or is less than one-half u, it indicates that there is liable to be tension in the convex side of the column.

The compression chords of bridges being usually continuous, it may be advisable in important cases when the transverse load is very heavy to treat them rigidly as continuous girders; but ordinarily the only transverse load on a column is its own weight, and for this case, if the column has riveted connections to adjacent members of sufficient stiffness to exercise a fair restraint on its ends, the l of the tables and formulas may be taken as from three-fourths to two-thirds of the length of the column.

In proportioning for combined compression and flexure the only alternative, except for a few particular cases, is to rely on analysis or guesswork, as there are not enough experiments to indicate general empirical formulas; but the Watertown Arsenal Reports record tests of four full-sized, pin-ended, eccentrically loaded, built columns, and one of a pin-ended, steel tube column subjected to longitudinal and transverse loading, which tests give an opportunity for comparing actual and theoretical results. This opportunity has been utilized by compiling Table 21. The best means of comparison is by deflections.

Let,

Δ_p = the deflection from primary bending moment.

This is readily obtained by the theory of flexure (see text following Equation (28)).

$$\Delta = \Delta_p + \frac{p\,A\,\Delta_p\,l^2}{\pi^2\,E\,A\,r} \qquad (32)$$

By substituting q for its value, $\frac{l^2}{\pi^2\,E\,r^2}$, and reducing,

$$\Delta = \Delta_p \left(1 + \frac{p}{q - p}\right) \qquad (33)$$

This use of the factor, π^2, is not rigid analysis, but for equal eccentricity at both ends and to the same side of the axis and for any symmetrical transverse loading its use in Equation (32) gives results for frictionless hinged-ended columns which for all ordinary cases differ from results of rigid analysis by less than one-half of 1 per cent.

Actually columns under combined compression and flexure are subject to friction on their pins, to unintentional eccentricity, and, as failure is approached, to considerable plastic deformation, none of which is allowed for in Equation (32). The effect of friction is to hinder deflection until the bending moment is sufficient to turn the ends of the column on the pin; plastic deformation increases deflection; and unintentional eccentricity, according to its direction, may either increase or decrease deflection. In these circumstances, the tests are not conclusive as to the accuracy of the theory and assumptions used, but, intelligently compared, the tests are strong evidence of the safety and general soundness of the theory.

Part 10.—Combined Tension and Flexure

An analysis of flexure combined with tension is not as important as that of flexure combined with compression for the reason that the bending moment from direct tension reduces the total stress intensity, whereas in the case of direct compression it increases the total stress intensity.

TABLE 21.—Tests of Pin-Ended Columns Eccentrically Loaded; and Pin-Ended Column with Combined Longitudinal and Transverse Loads.

(Compiled from the Watertown Arsenal Reports for 1883, 1884, and 1909.)

Notation: p = longitudinal load per square inch; f = computed extreme fiber compression per square inch on the concave side of the column from longitudinal load and flexure; Δ_c = computed deflection in inches, Equation (33); Δ_a = actual deflection; l = length, in inches; r = radius of gyration, in inches; I = moment of inertia, in inches; v = distance, in inches, from the center of gravity to the extreme fiber on the concave side of the column; u = U. L. P. of material on the concave side of the column, as gauged by full-sized tests of short columns of similar 10-in. channels, 8-in. channels, and 5-in. lap-welded steel pipes.

The columns were subjected during the tests to friction from pins; they were liable to unintentional eccentricity; and, as failure was approached, they underwent some plastic deformation, none of which was considered in making the computations tabulated.

*After reaching this maximum, the load dropped and the deflection increased.

†The amount given in the report as actual area was evidently erroneous.

Let,

p_t = the intensity of the direct tension.

Then, for a tension member with frictionless hinged ends, by analysis analogous to that by which Equations (3) and (25) were developed,

$$f = p_t + f_c - f_c\left(\frac{p}{p-q}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (34)$$

When the tension member is loaded to its utilizable capacity, $f = u$, and,

$$p_t = u - f_c + f_c\left(\frac{p}{p-q}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (35)$$

These equations are strictly accurate only when the primary moment diagram is a sinusoid, but they give close approximations in other cases. They are similar to, or possibly identical with, equations now in use. Equation (35) can be solved only by trial, but in many cases the correction involved is worth the trouble.

In some special instances it may be advisable to treat the tension chords of bridges rigidly as continuous girders and, in other cases of tension members with riveted end connections, to take the l of the formulas and tables as from three-fourths to two-thirds of the length of the members; similarly (as outlined at the end of Part 9) for columns.

Part 11.—Variation of the Characteristic Useful Limit Point Between Different Members of Nominally the Same Grade of Steel

Table 22, listing tests of bars forged down from an open-hearth steel ingot in the direction of its length, shows many variations—in tensile strength between 104 800 and 113 000 lb. per sq. in., in U. L. P.'s between 46 000 and 72 000 lb. per sq. in., and in ratios of U. L. P.'s to tensile strength between 42.4 and 65.5 per cent. In this series the range of the ratio of the U. L. P. to the tensile strength is great but not extreme: For example, Table 7 cites a case where this ratio was 84.2%; the weighted average ratio of U. L. P.'s to tensile strength for twelve specimens representative of the extra heavy H-section columns in Table 11 was only 40.8% (with a ratio in one specimen from the end of the flange of 32.6%); and a specimen from the head of an electric furnace steel rail had a tensile strength of 116 600 lb. per sq. in., a U. L. P. of 47 000 lb. per sq. in., and a ratio of U. L. P. to tensile strength of only 40.3 per cent.*

The chief value of Table 22 is not in the ranges of the properties it shows but in the light it sheds on the fact that the reduction in cross-section and the temperature at which reduced are causes of variation between the U. L. P.'s of different specimens of the same steel. Differences in conditions under which shapes and plates cool after rolling, differences in auto-stresses produced in cooling, and other occurrences during manufacture are, probably, further causes of differences between the U. L. P.'s of different specimens.

The specifications for "Structural Steel for Bridges" (not including eyebars and rivets) of the American Society for Testing Materials and of the

* Watertown Arsenal Report, 1909, Vol. 2, p. 681.

American Society of Civil Engineers* permit a variation in tensile strength of 5 000 lb. either way from 60 000 lb. per sq. in., without any corresponding variation in working stresses. If representative specimens for one member of a structure with the lowest permissible tensile strength (55 000 lb. per sq. in.) have a U. L. P. of 40%, and other specimens of another member in the same structure with the highest permissible tensile strength (65 000 lb. per sq. in.) have a U. L. P. of 60% or more, the characteristic U. L. P.'s for the members

themselves, according to indications given by the rule in Part 5 (page 1236), will vary between 18 700 lb. per sq. in. for the one member and 39 000 lb. per sq. in. for the other; which is quite a wide range for which to use a common unit working stress. The extremes in the characteristic U. L. P.'s of the column, made of 60 000-lb. (desired) steel, tested for the Society's Special Committee on Steel Columns and Struts were 19 000 and 35 000 lb. per sq. in., as shown in Table 11.

* Final Report of the Special Committee on Specifications for Bridge Design and Construction on Specifications for Design and Construction of Steel Railway Bridge Superstructure, *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 487; also Final Report on Specifications for Design and Construction of Steel Highway Bridge Superstructure, *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 1291.

In 1875, the President of the United States appointed a Board for the Testing of Wrought-Iron, Steel, etc., and this Board appointed a Committee, headed by Commander L. A. Beardsley, U. S. N., to investigate wrought-iron chain. The Committee, as a preliminary, investigated the properties of different kinds or makes of wrought iron. It found for iron of the same grade considerable variation in tensile strength and great variation in what it termed "elastic limit" and described as the first perceptible stretch. Its tests in this regard were conducted slowly and with great care and with the aid of a magnifying glass. After experimenting with material and labor, in a rolling mill loaned without charge for the purpose by its proprietor, the Committee succeeded in rolling nine sizes of bars, varying in diameter from 1 in. to 2 in., with nearly uniform tensile strength and "elastic limit". After making these tests and experiments the Committee made a report* an excerpt from which is as follows:

"* * * as important differences exist in the proportionate strength of different-sized bars made of the same material, which are due entirely to differences in the processes by which they are manufactured, and as the elimination or reduction of such differences would necessitate such a great and expensive change in the system by which the bars are produced that it is not probable that it will be often attempted, it is necessary that these differences should be taken into consideration when estimates of the strength of any structure in which rolled wrought iron of different sizes is introduced are made, and in all tables of strength based upon the strength of such bars."

It is more than forty-six years since the Committee made its report. During this time steel has about supplanted wrought iron as a structural material and great changes have been made in rolling mills. The writer does not undertake to discuss what further changes, if any, in mill practice affecting the matter of differences between the U. L. P.'s of specimens of nominally the same grade of steel are possible, practicable, or probable; but inasmuch as wide differences in characteristic U. L. P.'s exist, he believes that they should be taken into consideration in estimating the utilizable capacity of steel members of structures.

Part 12.—Limitation of the Useful Limit Point and Maximum Tensile Strength, as Criteria of Utilizable Capacity, to Steel of Good and Suitable Quality and Workmanship.

The U. L. P. and maximum tensile strength of specimens of steel are criteria of the utilizable capacity of the steel members of structures only when the quality of the steel in other respects is good and suitable and the fabrication into structural members is properly performed.

This paper does not define what constitutes good and suitable quality and proper fabrication (the opinion of engineers has fairly well crystallized on these points and on the tests, analyses, and inspection by which they are gauged); but it does emphasize the importance of good and suitable quality and workmanship.

* Report of U. S. Board for Testing Iron, Steel, etc., 1881, Vol. 1, p. 45.

Part 13.—Factor of Safety

An exact determination of the utilizable capacity of a steel member of a structure, if achieved, would indicate precisely the greatest load that could statically or repeatedly, or the greatest opposite loads that could alternately, be applied during the lifetime of the structure (as determined by other considerations) without causing failure, ruin, or seriously objectionable deformation (plastic, elastic, or combined plastic and elastic). The utilizable capacity can not, of course, be exactly determined, but it can be approximately determined, as outlined in this paper, from representative specimen tests of the steel. The ratio of the utilizable capacity thus determined to the working load on the member is the member's approximate factor of safety; and the smallest factor of safety of any of the critical members of a structure is the approximate factor of safety of the structure as a whole.

Under the present practice of purchasing steel for structures and of designing and fabricating the steel members, the different members may have factors of safety that vary greatly from each other and from what is considered amply sufficient. The factor or margin of safety, instead of being entirely selected by the intelligent judgment of designers, depends largely on circumstances of manufacture of which designers, as a class, are inadequately informed and of which they usually take little heed.

Would it not be well for steel manufacturers, structural fabricators, physical metallurgists, and structural engineers, considered collectively as "makers of steel members of structures", to investigate the question whether or not it is practicable and advisable to classify the various sizes of steel plates, shapes, and bars, of nominally the same grade of steel into such groups that the variations of the U. L. P. within each group would be much less than the present variation within nominally the same grade of steel embracing all sizes of plates, shapes, and bars; and thus to enable engineers to take into account in proportioning members the U. L. P.'s of the different groups according to the sizes used?

DISCUSSION

C. A. P. Turner,* M. Am. Soc. C. E. (by letter).—As a study to discover the fundamental facts regarding the capacity of structural steel members this paper is a failure. It is wanting in a concise statement of vital facts from which definite conclusions may be drawn and it is encumbered with terms of nebulous significance.

Attributing to auto-stresses both the defects and improvements of elasticity will prove more confusing to the average reader than blowing hot and cold with the same breath did to the satyr in the fable. It is recognized that stresses in general may be normal or tangential, positive or negative; one wonders in reading the paper to what gender or classification these auto-stresses may be assigned, what they are, how are they generated, and what is their reaction.

Under tension or compression the position of a piece of steel in the Antimony-Bismuth scale changes in proportion to the stress applied within the elastic range of stress, in one direction for tension and in the opposite direction for compression, so that it is possible to measure dead stress by thermo-electric means. When the elastic range has been exceeded, however, the residual effect as to position is a change characteristic of the opposite kind of external stress to that causing the permanent set. This residual effect has been termed a "permanent strain" by some writers, associating it with the permanent set which accompanies but is not proportional to it. By others this effect has been termed "residual strain" or a strain that is left after exceeding the true elastic limit of the piece and is in equilibrium with, or balanced by, elastic strain.

Having opposite physical characteristics it is natural to expect opposite reactions or changes of shape when the piece is cut so that the elastic and residual strain is thrown out of equilibrium. Take several bars $\frac{3}{8}$ in. square, bent cold in horseshoe form, and measure the out-to-out dimension. Then place one in a vise and cut saw kerfs $\frac{1}{8}$ in. deep at $\frac{1}{2}$-in. intervals on the outside of the bend. Release from the vise and note the inward spring of the ends. Cut another in a similar manner on the inside and again measure the inward spring of the ends. Take a third sample, cut both sides, and measure the outward spring of both ends, then the reaction of elastic strain as opposed to the contrary reaction of the residual strains in the outer fibers in the first and second experiments. Again, take a steel bar as it has passed through the rolls and saw kerfs as before on either top or bottom and, in general, the bar will assume a slight curvature. Cut on the sides and no change results. In like manner, cutting a keyway in a piece of cold-rolled shafting will cause the piece to assume a change in alignment.

A state of permanent strain may be defined as a state of internal stress comprising elastic and residual stress in equilibrium, from which no change in shape results unless this equilibrium is disturbed by forces supplying energy from without. Energy to change the internal state of equilibrium may be introduced as follows: (1) By temperature; (2) by applied forces; and (3) by

* Cons. Engr., Minneapolis, Minn.

cutting away a part of the symmetrically strained body. Such removal or cutting away of symmetrical parts of an over-strained elastic material permits the permanent strains that have been thrown out of equilibrium to re-assert themselves and change the form of the body in a manner comparable to applied external forces.

Gradual recovery from residual strain is sometimes termed elastic afterworking and the lag or slow increase of deformation under stress is called hysteresis. These phenomena are more readily observed by twisting a fine wire suspended from a fixed support and having a small mirror attached to the lower end, the position of which can be observed in the usual way by means of a telescope and scale. If the lower end of the wire is twisted through a moderate angle and then left to itself, the mirror makes oscillations the extent of which may be read on the scale. These oscillations diminish more rapidly than when the only retarding force is the resistance of the air, showing that the force of torsion in the wire must be greater when the twist is increased than when it is diminishing.

According to Maxwell:*

"If we begin by keeping the wire twisted (at not too great or too small an angle) say, for a minute or an hour, and then leave it to itself, we find that the point of temporary equilibrium is displaced in the direction of twisting, and that this displacement is greater the longer the wire has been kept twisted. But this displacement of the point of equilibrium is not of the nature of a permanent set, for the wire, if left to itself, creeps back towards its original position, but always slower and slower. This slow motion has been observed going on for more than a week, and also if the wire was set in vibration the motion of the point of equilibrium was more rapid than when the wire was not in vibration.

"We may produce a very complicated series of motions of the lower end of the wire by previously subjecting the wire to a series of twists. For instance, we may first twist it in the positive direction, and keep it twisted for a day, then in the negative direction for an hour, and then in the positive direction for a minute. When the wire is left to itself, the displacement, at first positive, becomes negative in a few seconds, and this negative displacement increases for some time. It then diminishes and the displacement becomes positive and lasts a longer time till it too finally dies away."

The phenomena here described represent an angle of distortion greater than the true elastic limit but less than the yield point of the metal. Kelvin has treated these phenomena as the "viscosity" of elastic solids. Experiments on the torsional vibration of wires detailed by Kelvin,† indicate elastic fatigue for a considerable range of stress within the limit of elasticity of shape. The experiments were as follows:

About April 26, two equal and similar lead weights or vibrators were hung up by equal and similar copper wires, the upper and lower ends of the two wires being similarly fixed by soldering. Wire No. 2 was kept vibrating as continuously as possible from day to day, and the other kept at rest except when vibrated once a day in an experiment to test the comparative viscosity of the wires, but no exact comparison was made until May 15. Then Wire No. 1 in 97 vibrations subsided from an initial range of 20 to a range of 10, while

* Encyclopedia Britannica, "Constitution of Bodies."

† *Loc. cit.*, "Elasticity."

Wire No. 2 gave the same subsidence in 98 vibrations. During the greater part of May 16 and 17, Wire No. 2 was kept vibrating and Wire No. 1 quiet, and experiments were made with the result that Wire No. 1 subsided from an initial range of 20 to 10 in 98 to 99 vibrations of 2.4 sec. each, while Wire No. 2 gave the same subsidence in from 57 to 60 vibrations of 2.4 sec. each. It was supposed from these experiments that true elastic fatigue occurred for all stresses within the limit of elasticity of shape until a similar and more extensive series of experiments conducted by Tomlinson* showed that no such fatigue of elasticity is felt in steel, iron, or copper, provided the stress does not exceed a certain well-defined limit.

The "micro-flaw" theory of fatigue advanced by Johnson† is untenable because of its failure to account for observed phenomena. Thus, the elastic fatigue in Thompson's experiments depending on the immediately previous molecular condition, whether of quiescence or recurring changes of shape, cannot be accounted for by micro-flaws which are necessarily permanent and not temporary. When a bar of steel is loaded a number of times alternately in tension and compression to a point a little beyond the yield points in tension and compression, these points are thereby both reduced to about six-tenths of their original values (called by Bauschinger the "natural elastic limits" of the material). When the material is repeatedly strained in tension from zero to a value above the natural elastic limit in tension, but within the yield point, the yield point value in tension is raised by such treatment and, in like manner, when similar stresses above these natural elastic limits, but within the yield point values, are applied alternately from tension to compression, the normal yield point in tension is lowered. These phenomena raise the question whether the temporary strain which accounts for the elastic after-working is of the same nature as that produced by a permanent set, and what the limits of its accumulation may be under repeated stress in working of the material, without giving it an opportunity to recover by elastic after-working between consecutive loadings.

These questions would seemingly be more readily investigated by considering the thermal stress curves of the material under load. During elongation soft steel grows uniformly cooler until a stress of about five-eighths the yield point is reached, when the heat of imperfect elastic deformation causes the curve to depart from the straight line. This continues until the yield point is reached when there is a sudden evolution of heat. In like manner, under compression the straight-line relation of temperature increase is maintained until a stress of about five-eighths the yield point is reached, then a similar phenomenon occurs.

The identity of cause (that is, thermal effect), would indicate an identity of result. In other words, for the range of imperfect elasticity within the yield point under repeated working of the material beyond its natural elastic limits, the residual strain accumulates with each repetition of the applied load even if no apparent set or plastic deformation is noticeable. As the apparent yield

* *Philosophical Transactions*, Royal Soc., 1886.
† "Materials of Construction."

point is gradually raised by such treatment, the range of stress may be gradually increased until the ultimate resistance of the material is reached without noticeable plastic deformation. The same piece of steel under a single application of the load would stretch 20% of its length before "necking down" and finally breaking.

The fact that a residual strain is of contrary sign to the internal stress opposing the force which produced it leads at once to the question whether a change in the yield point is a phenomenon of residual strain or of change in structure. Microscopic examination fails to reveal any change in the material that has undergone a sufficient number of repetitions above its natural elastic limits to nearly wear it out or cause it to approach the point of rupture.

The behavior of iron and steel under fluctuating or repeated stresses was the subject of long research by Wöhler and later by Bauschinger. The result of these experiments are claimed to show:

1.—That resistance to fracture under stresses fluctuating within certain limits depends on the difference between the maximum and minimum applied stresses rather than on the maximum stress alone.

2.—That reversed stresses (tensile and compressive), much below the static breaking stress, are sufficient to cause fracture if repeated a great number of times.

Experiments made by the Phœnix Company on axle iron having an ultimate strength in tension of 46 000 lb., with an elongation of about 20%, gave limiting maximum stresses under limited ranges as shown in Table 23.

TABLE 23.—Tests on Axle Iron by Repeated Stress.

Kind of repeated load.	Stress, in Thousands of Pounds per Square Inch.	
	Limiting maximum.	Limiting range.
Completely reversed	15.2	30.4
From maximum to zero	30.56	30.56
From maximum to half load	41.02	About 20

The number of repetitions of stress without breaking, from which these limiting ranges were determined, amounted to millions. The specimens unbroken at an alternating stress of 15 200 lb. per sq. in. were subjected to 132 000 000 repetitions without breaking. This limiting range, which allows nothing for dynamic effect, is nearly six-tenths of the normal yield point of the material; if the dynamic effect of the rapidity of repetition of stress amounts to 10%, the limiting range would be about two-thirds of the normal yield point.

The ultimate strength of the material was 46 000 lb. per sq. in. and its normal yield point was about 24 000 lb. per sq. in. The limiting maximum stress of 42 000 lb. per sq. in. for repetitions of half load in Table 23 is, therefore, at least 18 000 lb. more than the normal yield point, and since whenever the normal yield point is exceeded a large deformation results, the manner in which these repeated stresses were applied is of interest. To avoid the large deformation

produced when the normal yield point is exceeded, the stresses first applied in these experiments were less than the normal yield point; this point was then gradually raised until its ultimate position was above the maximum stress considered in the range noted as the limiting range.

In a practical structure the conditions of loading are not such as to raise the yield point of the material and thus increase its resistance, as was done in these experiments, and failure would result from only a few repetitions beyond the yield point. Consequently, the limiting ranges of intensity of stress which the practical structure can withstand cannot be deduced from experimental results where such artificial assistance to the resistance of the material is given.

As advocates of the fatigue formulas of proportioning agree that, if it be established that Wöhler's results are accounted for by the effects of stress beyond the true limits of elasticity, they have no relation to the logical determination of working stresses, this matter will now be considered from the standpoint of the three determinants of ideal elasticity, to wit:

1.—Proportionality of temperature change to the load applied;
2.—Proportionality of elastic elongation to the applied stress or load; and
3.—The reversible cycle of mechanical work during loading and unloading.

No bar of sound metal has ever been broken by Wöhler's treatment under ranges of stress of one kind or of both kinds, that is, from tension to compression within the limits of thermal proportionality. *Per contra* the range of stress from tension to compression within the natural elastic limits was found by Bauschinger to improve the metal in elasticity, tenacity, and ductility instead of injuring it.

The radical improvement in the strength of cast test bars and the suggestion that they shall not be "rumbled"* (treated in a tumbling barrel for cleaning) if their modulus of rupture be taken to represent the average condition of the casting, is a striking confirmation of the beneficial effect of stress ranging from tension to compression in reducing and eliminating residual states of stress arising from shrinkage in cooling.

The theory of residual strain shows that the range of stress of one kind is not as efficient in eliminating residual strain as range of stress from tension to compression. Where the range is from tension to compression extending equally beyond the natural elastic limits the reaction of the accumulation of residual strain is neutralized because of the opposite signs of its constituents, accompanied by increased internal disturbance and more rapid approach to rupture under repeated stress. Where the limiting range was tension from 20 000 to 42 000 lb. per sq. in., the systematic work on the specimen effected an accumulation of approximately 19 000 lb. of residual strain, which, added to the yield point of 24 000 lb., would give a maximum resistance of 43 000 lb. per sq. in. without plastic deformation. In other words, the effect of a tensile stress of 42 000 lb. per sq. in. on a bar under a state of residual tension of 19 000 lb. or more could not cause plastic deformation in a specimen the yield point

* "A. B. C. of Iron and Steel", Penton Pub. Co.

of which is 24 000 lb., since the algebraic sum of these is only 23 000 lb. and, therefore, less than the yield point of the bar.

The fact that rupture of ductile metal under Wöhler's treatment takes place without plastic elongation has been in the past erroneously regarded as in some way indicating or establishing the fact that all ranges of stress without shock tend to deteriorate or injure sound metal. The law of conservation of energy indicates that the same amount of energy is required to produce rupture whether it is expended in small quantities at different times, or at one time in a single application. When rupture is accompanied by nearly negligible ultimate deformation, as in endurance tests under repeated stresses of intensity lower than the ultimate strength of the material, there appears to be no good reason to suppose that the total energy transformed into heat in small amounts under successive repetitions of the load in endurance tests differs from that when this deformation is as large as in the case of a single load developing the maximum strength of the specimen.

From the foregoing discussion have been drawn the following conclusions:

1.—Steel of good quality has definite limits of elasticity which can be lowered but not raised.

2.—Strain beyond these limits cannot occur without performing work on the metal tending to wear it out.

3.—Strain within these limits tends to improve the metal in elasticity, ductility, and tenacity, by elimination of the residual strains from rolling and cooling.

4.—The limit of possible improvement by repeated stress within the limits of elasticity is readily computed and accords satisfactorily with the investigations of Bauschinger and with his conclusions that, far from being fatigued by repeated stress from tension to compression within the natural elastic limits, sound metal is improved in elasticity, ductility, and tenacity.

5.—In the temporary structure the yield point is the critical limit of stress, for, if the yield point is exceeded under quiescent stress, failure is liable to result from the dynamic effect of the load in motion. The plastic deformation, moreover, may so change the configuration of a truss that failure may result. That bridge structures frequently stand up when counters are over-strained and stretched may be accounted for by the momentary duration of the maximum stress due to the moving load.

From the theorem that volume is a kinetic invarient of elastic strain in an isotropic homogeneous solid,* the moduli, K (of lateral contraction) and F (shear), may be computed as $0.4141e$ and $0.3535E$, respectively (before the temperature changes from the applied stress are dissipated by radiation). Since for over-strain and small set the residual strain will be developed along the curve of greatest displacement and no over-strain takes place along the equipotential curves, F, for small over-strain, will remain numerically constant and only K and E will vary. Hence, the limit of increase in E may approximate 5% by the elimination of residual strains through repetition of stress from tension to compression within the natural limits of elasticity.

* Elasticity and Strength of Materials," Turner, Section 1, p. 75; see, also, Unwin, "Strength of Materials."

The conclusions which should guide in fixing the magnitude of working stresses the writer would summarize as follows:

1.—The working stress for a permanent structure should be kept below the natural limits of elasticity allowing properly for the effect of impact, unsymmetrical distribution of stress across the section due to faulty workmanship, and irregular form.

2.—These working stresses and proper allowances need be no lower for a range of stress from tension to compression than for stress of one kind alone.

3.—It is highly irrational to use higher working stresses for variation of stress of one kind only than for variation of stress of both kinds, because it is impossible in the actual structure for the loads to be applied after the manner of the fatigue experiments of the laboratory by varying the stresses back and forth below the normal yield point until there is temporarily an accumulation of residual strain. This procedure, contrary to any conceivable application of load in the engineering structure, constitutes the hocus-pocus of fatigue formulas; it causes needless waste in the design of bridge members subject to alternating stress, the adoption of unbalanced sections, and a deficiency of strength where the range of stress is small.

Bearing in mind that this natural elastic limit or limit of thermal proportionality hardly exceeds 22 000 lb. per sq. in for soft steel of 55 000 to 60 000 lb. ultimate strength, or 26 000 lb. per sq. in. for medium steel from 65 000 to 75 000 lb. ultimate strength, the desirability of using medium steel rather than soft steel is obvious.

In respect to columns, a fundamental defect of nearly all published column formulas lies in the disregard of twisting. An angle strut* having a ratio of $\frac{l}{r}$ equal to 140 and fitted with ball and socket bearings, is only one-half as strong as a pipe section of the same cross-sectional area and the same radius of gyration. In other words, the ordinary column formula for such a strut is liable to be in error 100% in respect to the strength of these struts if the ratio, $\frac{l}{r}$, is 140 or greater. The inferior showing of steel Z-bar columns as compared with wrought-iron columns in Strobel's tests may be accounted for by the fact that Strobel made one radius of gyration much more than the other, thereby forcing the columns to fail by simple bending instead of by combined bending and twisting as in the U. S. Bureau of Standards tests.

A more careful consideration of the facts determined by test will profit the Engineering Profession, while blind acceptance of ingenious algebraic formulas founded on assumptions which disregard the vital facts of experiment may lead to serious error, lack of economy, and occasional failure.

Mr. Prichard states there are faults in the theory of flexure, and correctly points out that shear strain is disregarded in the ordinary theory of flexure.

* A pipe strut is equally strong whether pin ended or with ball and socket bearing, whereas an angle is 1¾ times as strong with pin as with ball and socket bearing when $\frac{l}{r}$ is greater than 140 although calculated the same by present theory.

This disregard does not increase the maximum fiber stress at the points of greatest deflection as he appears to suppose, nor does the exact theory substantiate the supposition of Marburg that the modulus, E, of Bethlehem beams is any lower for a given grade of steel than that of standard beams. Far from increasing the maximum fiber stress as computed by the ordinary theory of flexure in the restrained beam, the maximum tension is reduced both over and between the supports and a similar reduction holds true for continuous beams. The resistance to external shear may be two to four times as great per inch of section in the restrained beam as in the simply supported beam of the same cross-section. Again, as the neutral plane of the simply supported beam drops downward toward the end of the beam approximately one-tenth of the depth according to the exact theory of flexure, how can this theory be applied to a column, assuming that the neutral plane follows the axis of the piece when it does not in the beam? Moreover, since the principal tensions in the column are at right angles to the axis or cross-wise of the piece until the stage of incipient failure is approached, how can the bending of a column be compared with the bending of a beam, in which the greatest tensions are nearly parallel to the axis of the piece? Is not much of the mathematical discussion of the paper based on assumptions which are unrelated to the facts?

H. F. Moore,* Esq. (by letter).—This interesting paper is a welcome attempt to meet the question "What is an allowable stress for structural steel?" The author recognizes that this is very far from being a simple matter of taking some value from a set of handbook tables and applying it in a standardized formula.

One interesting point of Mr. Prichard's paper is his use of the "Useful Limit Point" (U. L. P.) rather than the yield point, or Johnson's apparent elastic limit (which involves an increase of rate of strain over the initial value amounting to 50 rather than 100 per cent. A more extended statement from Mr. Prichard as to the advantages of the U. L. P. over Johnson's elastic limit would be of value.

In connection with Mr. Prichard's suggestion as to the possibility of "remote fatigue", the writer would like to quote results not conclusive, but interesting, from some tests of I-beams made about 1912 in the laboratories of the University of Illinois. Several I-beams were loaded in flexure with loads which stressed the compression flanges to the yield point. The load was continued for 107 days without causing failure of the beams, and after the first few days there was no further material increase in deformation.

Relative to "remote fatigue", the interrelation of localized stress and corrosion are parts of a subject on which there has been very little investigation. From certain experiences with boilers, the writer believes that this is a very important subject for research by the structural engineer.

In connection with the author's discussion of fatigue tests, the writer would call attention to the results reported† by Mr. Paul L. Irwin, of the Westinghouse Laboratories. Mr. Irwin developed a method of gripping the specimen in a

* Research Prof. of Eng. Materials, Univ. of Illinois, Urbana, Ill.

† *Proceedings*, Am. Soc. of Testing Materials, 1925, p. 53.

repeated stress test under cycles of tension and compression, by which accidental bending action was reduced to a very small value. For all the metals tested thus far, Mr. Irwin finds that the fatigue limits determined by such tension-compression tests and by tests in reversed flexure are almost the same. Previous investigators from Wöhler on (including the writer) have been rather prone to assume that a tension test specimen is under pure tension. As a matter of fact it is very difficult, even under laboratory conditions, to avoid appreciable bending action, especially on a short tension test piece.

G. B. Woodruff,* M. Am. Soc. C. E.—If this paper did no more than call attention to the uncertainties of present knowledge as to the behavior of structural steel specimens and structural members under stress, and the relation of the strength of the member to that of the specimen, it should prove valuable in pointing out the need of further investigations of these matters.

In so far as safe unit stresses are concerned, the problem may be divided into three main phases:

1.—What is the "utilizable capacity" of a structural member?

2.—What requirements may be made of the test specimen that will give the most definite information as to the capacity of the structural member?

3.—What factors may be applied to the results of specimen tests to give the safe load in a structural member?

According to the author's definition, it would be permissible to stress a member to its "utilizable capacity". Evidently this is not his interpretation since he later introduces the "factor of safety," and by this factor apparently destroys his definition. Considered alone, the knowledge of the U. L. P. of a structural member would not seem to be especially valuable. Admitting that the term "proportional limit" is to a certain extent a misnomer, the deviation of the stress-strain curve from a straight line, as generally understood, is so small as to be negligible. Structural theory, especially in the case of indeterminate stresses, is predicated on the proportionality of stress and strain. It would seem that the structural designer is more interested in the proportional limit than in any other characteristic of the behavior of the members. If this proportional limit could be positively predetermined and the design based on the maximum possible combination of loads, no factor of safety would be required.

In the speaker's opinion, therefore, the desired result of the specimen tests is to obtain the best possible index of the proportional limit of the fabricated member. Perhaps the U. L. P. of the specimen will furnish this index, but further investigation of this point is required. That the yield point "as determined in ordinary commercial practice" gives far from satisfactory results is generally admitted. The question here is whether the trouble lies with the yield point as such or with "ordinary commercial practice." The data presented in Table 9 merely indicate errors in the operation or calibration of the testing machines. There seems to be no better indication of the proportional limit of a fabricated member than the ultimate strength of the test specimen.

* Asst. Engr., Modjeski & Moran, New York, N. Y.

The speaker interprets the results of the most careful tests as indications that the proportional limit of fabricated short columns and fabricated tension members approximates 30 and 40%, respectively, of the ultimate strength of the test specimens. He believes it to be conservative when designing for maximum loads to use unit stresses of 25 and 35% of the ultimate strength of the specimens.

The proposal to vary unit stresses with the thickness of the material is a step in the right direction. Quite likely the variable in this case, however, is the amount of working the material receives in the rolling. The thickness is only a partial indication of this variable.

The author's specification for lattice is similar to that in some recent specifications and probably results in as good design as is possible within the limits of present knowledge. Some tests, however, indicate that the reaction from the light lattice in vogue before 1907 has gone too far and that it is possible to use lattice too stiff and with too rigid connections for the maximum strength of the columns.

In conclusion, the speaker would urge that the arguments developed by the author be given full consideration, especially by those urging a revision in working stresses.

R. VON FABRICE,* ASSOC. M. AM. SOC. C. E. (by letter).—An examination of the various tests quoted shows that the yield point is a variable quantity if found from specimens taken from the same plate but tested in different laboratories (see Table 9). Evidently, the true elastic limit can be correctly defined only by means of the closest scientific observations.

Furthermore, Mr. Prichard's references show that the elastic limit is not a constant but a variable quantity and can be changed at will by adopting different conditions of straining. Therefore, it is evident that none of these points should be used as a criterion for the strength of any members.

The author's suggestion of basing practical formulas on the U. L. P. basis, as adopted by the Society's Special Committee on Steel Columns and Struts, must be recognized as a step forward toward the solution of the problems dealing with the strength of structural steel.

The elevation, to higher limits, of the elastic limit shows that steel, as well as other material, will adjust itself to variable conditions and survive severe over-straining by readjustment of the grains or fibers. This behavior of steel may be compared with the characteristics otherwise attributed to the muscular development of an athlete, in whom stiff joints and muscular defects may be compared with the causes underlying auto-stresses in a piece of steel, and with whom careful working and manipulation will cause these defects to disappear as weak fibers or grains in steel recover and remain elastic after being subjected to a certain cycle of stresses. In both instances the elasticity has been raised or increased. If, however, the training or cycle of stresses is beyond the U. L. P., negative results will be obtained and permanent fatigue or failure

* Designing Engr., Public Service Production Co., Newark, N. J.

will be the result in man and material. This behavior of structural steel under loading, adjusting itself to severe loading, accounts for the existence and apparent stability of structures which according to the recognized mathematical calculations should have failed.

Mr. Prichard shows that large variations in elastic limit exist. It would be advisable to determine by tests if a lowering of the lower elastic limit in compression is possible and if it is accompanied by a lowering of the upper elastic limit in tension; in other words, if by a cycle of stresses the elastic limit of the material under compression can be raised thereby losing a part of its resistance against tensile stresses.

The fibers of a piece of metal under tension undoubtedly have a tendency to align themselves in the direction of pull, and thus produce the increased elastic resistance (Fig. 5 (*a*) and Fig. 5 (*b*)).

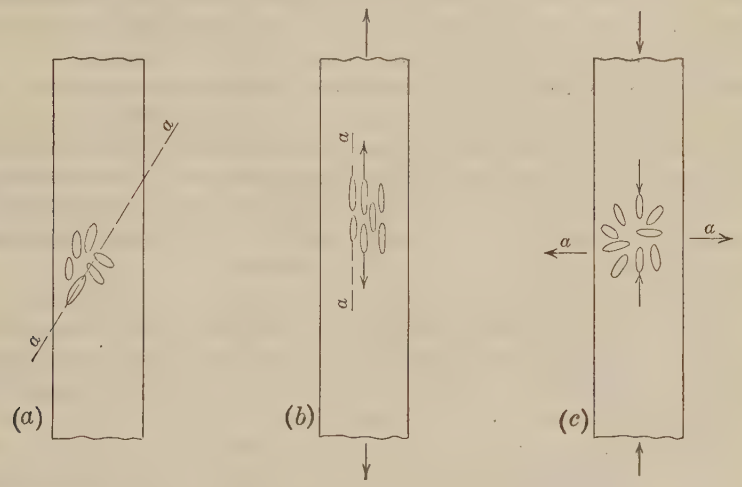

FIG. 5.—ALIGNMENT OF METAL FIBERS UNDER STRESS.

Under compression the fibers tend to flow or squeeze sidewise, which causes transverse shear and consequent buckling of the specimen (Fig. 5 (*c*)). Therefore, it is fair to conclude that under tension all fibers or molecules unite in aiding each other, while under compression they tend to work against each other and squeeze and flow apart. If this conclusion is correct the elastic resistance of steel under compression cannot be increased by a cycle of stresses.

Tables 9 and 19 show great variation in the quality of the material taken from different parts of the plate or I-beam. For example, a 15-in., 38-lb. I-beam gives the U. L. P. for the web as 42 500 lb. per sq. in., while for the root it is 26 000 lb. per sq. in., and, further, the tests for the other beam sections in Table 19 show that the flange has a still different U. L. P. This condition may be due to the process of rolling whereby the web becomes more compacted than the flanges.

The variation in U. L. P. in the various parts of a structural shape leads to the conclusion that not only the elastic resistance, but also the moduli of elasticity of the various parts of any section may vary. Tables and references

show a variation from 28 000 000 to more than 31 000 000 in moduli of elasticity for various compositions of steel; but is it not possible that the modulus of elasticity will vary in the same structural section within these limits?

The theory of flexure is based on ideals, that is, perfectly elastic material with uniform elastic limits throughout the entire member. This condition does not exist in practice. The theory is further based on the erroneous assumption that plane sections remain plane after bending. This is not correct since the influence of the shear (which is usually ignored) prevents the originally plane cross-section from remaining plane. Further, this deformation of the section must become more pronounced if the elastic elongations of the various parts of the section vary in unforeseen and incalculable dimensions.

The rule for finding the U. L. P. of built-up members from specimen tests (page 1236) may give an approximately correct value for tension members and short columns not subjected to flexure. Even tension members may be composed of materials of varying elasticity in such a manner that the resultant of the elastic properties of the different parts does not coincide with the axis of the member. This will result in incalculable auto-stresses since the internal stresses are not balanced around the axis of the section. Mr. Prichard brings this out forcefully in his appeal for an investigation to classify the various sizes of structural shapes into groups having minimum variations in their U. L. P. values. To reduce auto-stresses to the minimum and to manufacture steel uniform in quality and in elastic properties is an ideal which can be hoped for but which probably never will be attained.

To classify the various groups of steel according to the variations of the U. L. P., it is necessary first to establish by a series of tests the variation of auto-stresses, U. L. P.'s and other elastic properties in various rolled shapes and in their different parts, and also to give due consideration to the different rolling processes used by the various steel mills.

From Mr. Prichard's investigations it does not seem possible that built-up members will ever consist of materials of entirely the same class or quality. Fortunately, however, in built-up members the materials with greater elastic resistance seem automatically to go into the extreme fiber; for instance, a Bethlehem H-column or a girder reinforced by two plates will have the more reliable material in the plates. The same holds true for plate girders with cover-plates; Table 9 shows that the edge portions of plates are stronger than the interior ones.

Beams.—To consider the influence of shear, Mr. Prichard recommends adding a percentage, P_c, to the intensity of stress as computed from the ordinary flexure theory and advocates the use of Equations (20), (21), and (22). He then gives the possible error of these equations as up to 50 per cent. It is difficult to understand why the old and approved theory of flexure should be revised for an empirical formula afflicted with 50% factor of error.

As even good steel is not a perfectly elastic medium; as there is the possibility of variable elastic properties of different parts of one and the same shape; and as the designers of steel structures are not assured of the elastic properties of the various parts of built-up members, it is logical to assume

that all these unknown factors probably bring about a greater pronounced warping of plane cross-sections than the hitherto neglected influence of the shear.

Shear.—Of course, for short beams with heavy concentrated loads provision should be made to bring this load safely over the supports without distortion of the local parts. In such cases the flanges should be supported by milled stiffeners. Web sections and reinforcement in excess of ordinary theory should be provided as recommended by Mr. Prichard.

Columns.—Under Paragraph (*m*) of the "Synopsis" it is stated that the U. L. P. of a light H-column was 35 000 lb. per sq. in., while that of an extra heavy H-column of the same material was only 19 000 lb. per sq. in. According to Table 11, twelve tests were made with these extra heavy columns and only three with light ones. The writer does not believe that these tests should be used for final deductions.

All the tension tests of Table 11 show an increase of unit strength for the heavier columns with the exception of tests for No. 5 which show the reverse. It is recommended that light and heavy H-columns be re-tested in order to determine whether the cross-section of the heavier columns was properly proportioned and the stress evenly distributed over the entire area, rather than to arrive at the conclusion that the U. L. P. of a heavy column is only about 60% that of a light column of practically the same shape as shown in Paragraph (*m*) of the "Synopsis".

Heavier sections of the same or nearly the same over-all dimension have a smaller radius of gyration, which confirms the conclusion that an increase of area without an increase of outer dimensions is not an economical solution. Therefore, Mr. Prichard is correct in his statement that heavier columns possess a lower U. L. P. than lighter ones; but the variation from 19 000 to 35 000 lb. per sq. in. seems to be too great in view of the tests recorded in Table 11.

By his research work Mr. Prichard has added most valuable material as to the theory of columns, but his suggestion to classify columns into three divisions—short, medium, and long—does not simplify the already very complex problem of column design. What is needed for designers is simplification, not theoretical refinements and consequent complications as to the selection and classification of columns.

Equations (1), (6), and (11) have been derived assuming frictionless hinges at the ends, a condition which does not exist in practice. For columns restrained at both ends, the recommendation is made to use as l of the equation a value from 0.67 to 0.75 of the actual length. The wide range of this recommendation eliminates all refinements gained in developing Equations (6) and (11).

The author's classification of columns cannot be termed a happy solution since the first two, short and medium, are made dependent on the U. L. P., while the long columns are independent of their U. L. P.'s or of any other critical stress mentioned.

Table 12 cannot be readily understood, nor do the illustrations of its use shed any light on this subject. It would be helpful if the author would add

further discussion of this part to clarify his data and increase the usefulness of the paper.

F. E. SCHMITT,* M. AM. SOC. C. E.—Hitherto, the relation between the ultimate strength and the working strength of structural members has of necessity been a matter of judgment based on structural experience, illuminated and supplemented by the data of tests on parts and entire structures. It remains so to-day, and the art of testing, in spite of its high development, has not yet progressed to the point of allowing the engineer to utilize it for definite verification of his design procedure or selection of his working stresses. In large part, this shortcoming is due to the virtual impossibility of determining service requirements and translating them into quantities commensurate with test values. The line of progress is strongly in the direction of placing safety margins and working stresses on a rational basis, however, and the author's scholarly paper is of value in inviting closer attention to this objective.

Views long abandoned are brought forward anew in the reversion to a fatigue or endurance basis for structural design. It is now commonly accepted that steel structures are free from fatigue action, and no evidence to the contrary has been brought forward. Occasional tests of wrought iron and steel taken from structures long in service have in no case shown recognizable weakening or reduction of ductility of the material. Moreover, the large-scale experiments of recent years on fatigue endurance have established that in steel and other ferrous metals there is no fatigue at stresses lower than a certain limiting amount, the endurance limit, which is not far below the yield point even in case of complete reversal during the repetitive stressing, and probably very near to the yield point for one-directional stress repetition. Stresses permitted in structures are well below these limits, and the evidence is clear that such stresses may be repeated an indefinite number of times without effect on the metal. Thus, it would seem that there is no ground for the reversion to the concept of fatigue in connection with studies of working stress.

Further, some of the data on endurance phenomena contained in the paper are not in harmony with experimental results. The investigations carried out by Messrs. H. F. Moore and his associates, at the University of Illinois, D. J. McAdam, at Annapolis, Md., R. R. Moore, at Dayton, Ohio, and others, give no support to such an anomaly as the terminal drop of the stress-cycle curves in Fig. 3, attributed to Bauschinger.

Certain unusual terms introduced by the author contribute to the difficulty of following an intrinsically complex argument. Such expressions as "remote fatigue" or "auto-stress" are unfamiliar. Even the term used in the title of the paper, "utilizable capacity," is not wholly clear in spite of a carefully phrased definition.

With respect to the latter term, few structural members are subject to only a single kind of loading, and it is, therefore, hardly possible to consider capacity, that is, the limits of service, without at the same time considering the conditions of service. The definition given and the term itself seem to

* Associate Editor, *Engineering News-Record*, New York, N. Y.

have the sole effect of substituting for the concepts of breaking strength and yield point the unaccepted concept of structural endurance limit.

The revival of the term "Useful Limit Point", coined eight or ten years ago by the Society's Special Committee on Steel Columns and Struts, seems unfortunate. The term was the outgrowth, apparently of an attempt to displace the yield point by a compromise between yield point and proportional limit. It differs a little from the "apparent elastic limit" of the late J. B. Johnson, M. Am. Soc. C. E., an ingenious approximation to the proportional limit devised to give a uniform, unambiguous definition of that limit. No good reason has been advanced for modifying the Johnson limit and introducing still another point and name into the already confused terminology of the elastic behavior of structural steel—a material whose yield point is well marked and whose resistance to load is largely dependent on the yield. With respect to structural behavior, the establishment of an arbitrary point some distance below the yield point has no demonstrated justification.

Some interesting considerations suggest themselves in connection with "auto-stress." This new term presumably covers mainly initial and residual stresses. In such parts as gusset-plates and other vital details these stresses may be important even for uniformly ductile steel, especially when the load stresses are compressive. This fact constitutes one reason for estimating stresses in details rather liberally and maintaining a relatively large safety margin, since such concealed stresses are not determinable by analysis or test, but require empirical allowance. On the other hand, similar stresses within the solid body of a member do not appear to be important. In reasonably good fabrication and assembly they are certain to disappear before the strength of the member is overtaxed. This may be deduced consistently from large-scale tests, in which a uniformity of action is displayed that could not be realized if the local constraints arising from rolling, fabrication, and other sources of "auto-stress" were not ironed out by the growing load. It has been held by many authorities that initial stresses constitute one important element of the necessary margin between calculated working stress and testing machine load; with respect to main members, this is open to doubt.

The treatment of reversed-stress members which are also considered by the author, has long been a doubtful point in specifications and structural practice. Increased section is customarily provided for such members, but it is questionable whether there are tests or data from experience to support this rule; it rests rather on tradition. In so far as it seeks to provide resistance against the greater fatigue effect of alternating stress as compared with repeated one-directional stress, it cannot be defended in the light of modern endurance investigation. The loosening effect of reversed stress on connections should have consideration, and, as common rivet loads exceed the lower limit of frictional bond between the connected parts, the provision of excess strength in the end details of reversed-stress members is justified; but the members themselves ought not be penalized on this score.

It may be hoped that the author's study will bring about further attempts to define structural strength more precisely than has yet been done. This

strength, it would seem, cannot be a fixed single quantity, but must be interrelated with service. The view that one point should determine the strength of a member is not in harmony with practical appraisal of service conditions. It is certain that some service resistances are related to the ultimate strength, that is, to the actual point at which a member breaks and other resistances to earlier stages of the elastic behavior of the material.

The understanding of these relations is slowly progressing. Several attempts have been made in recent years to approach the determination of factors of safety or of working stresses rationally, although so far without marked success. There are still too many variables, too many indeterminates, in the problem to permit of full rational analysis. Yet, even to-day, it is possible to set down some general conclusions from known facts and structural experience as a starting point. The following items may be noted, for example:

(1) Under steady, slow, and frequently occurring load, a member is likely to be deformed to destructive degree if the load passes its yield point.

(2) Stress intensification at points of changing section, holes, and flaws does not appear to be significant in ductile steel as long as the mean stress remains below the yield point, but at a higher stress it presents the possibility of failure, so that such stress has an importance greater than that due only to its deforming or crippling effect on the structure.

(3) The small, high-frequency variations or oscillations of stress which are present in all or nearly all steel structures should be considered as a possible tax on fatigue endurance when the main stress is beyond a certain limit. This limit, which is not yet known with certainty but probably is at or somewhat above the yield point, therefore is to be rated as the ultimate strength for some groups of stress.

(4) Plastic readjustment at the yield point acts to redistribute load in most structures to a degree that makes this point not definitely critical, in addition to providing warning of over-stress.

(5) Under single, suddenly applied loading, a member has unimpaired resistance nearly up to its breaking strength.

(6) Stresses set up in elastic distortion, or secondary stresses, are in most (but not all) instances self-limiting in character, tending to disappear by a smoothing out of the inequalities in stress when yield is approached and before they can contribute to failure.

Statements of this kind seem capable of providing a starting point for an approach to the desirable end of rational determination of working stresses and safety factors. For the present, the best that can be said is that the problem is not amenable to mathematical calculation but must be tested by experience of long service, and to this extent the work of the immediate future seems likely to depart from the course outlined by the author.

Henry S. Prichard,* M. Am. Soc. C. E. (by letter).—The writer's reason for introducing the new term, "auto-stresses", is that there is no other term that indicates precisely those stresses and only those stresses within a body

* Analytical Engr., Am. Bridge Co., Pittsburgh, Pa.

which, considered by themselves, without regard to others from external forces, form a balanced system. The term, "initial stresses", is frequently used to designate auto-stresses but is not suitable. Strictly, initial stresses are those which exist in a body before an experiment or before an episode of loading. They include the auto-stresses existing beforehand, but they also include stresses from the body's own weight and those from slight loads applied in advance to take up slack but not considered in comparing measured stress with measured strain. Initial stresses, from the fact that they are initial, cannot include any changes that occur in auto-stresses during an experiment or episode. "Residual" ("remaining after a part has been taken away"), as applied to stresses, does not precisely take the place of "auto". The writer does not know of any other term that has been used or suggested for "auto-stresses".

The writer regrets that he has failed to enlighten Mr. Turner regarding the fundamental facts on which the utilizable capacity of steel members of structures depends. He is confident that to most of the intelligent and thoughtful readers, and hopes that to the average reader, the presentation of the facts regarding auto-stresses will not (using Mr. Turner's phraseology) "prove more confusing * * * than blowing hot and cold with the same breath did to the satyr in the fable". Be this as it may, the facts themselves can not be altered because of confused ideas or preconceived notions; but it may be helpful to quote the previous clear presentation, or rather anticipation, of some of the facts by an eminent engineer and physicist.

In 1848, Professor James Thomson (the elder brother of Lord Kelvin) published* the paper from which the following excerpts were taken. He assumes a case in which a round bar of malleable iron is twisted beyond its elastic resistance and then proceeds:

"* * * and during the progress of this process the outer particles will yield in virtue of their ductility, those toward the interior successively reaching their elastic limits * * *.

"If, after this, all external stress be removed from the bar, it will assume a position of equilibrium, in which the outer particles will be strained in the direction opposite to that in which it was twisted, and the inner ones in the same direction as that of the twisting, the two sets of opposite couples thus produced among the particles of the bar balancing one another. * * * Principles quite similar to the foregoing, are applicable in regard to beams subjected to cross strain * * *.

"When malleable iron has received its final conformation by the process termed *cold swaging,* that is, by hammering it till it is cold, the outer particles exist in a state of extreme compression and the inner ones in a state of extreme tension. The same seems to be the case in cast iron when it is taken from the mould in which it has been cast. The outer portions have cooled first, and have therefore contracted, while the inner ones still continued expanded by heat. The inner ones then contract as they subsequently cool, and thus they, as it were, pull the outer ones together. That is, in the end the outer ones are in a state of compression and the inner ones are in the opposite condition.

"The foregoing principles may serve to explain the true cause of an important fact observed by Mr. Eaton Hodgkinson in his valuable researches in regard to the strength of cast iron (Report of the British Association for 1837,

* *Cambridge and Dublin Mathematical Journal.*

p. 362). He found that contrary to what had been previously supposed, a strain, however small in comparison to that which would produce rupture, was sufficient to produce a set, or permanent change of form, in the beams on which he experimented. * * *

"It appears to me that the defects which he (Hodgkinson) has shown to occur even with very slight strains, exist only when the strain is applied for the first time, or, in other words, that if a beam has already been subjected to a considerable strain, it may again be subject to any smaller strain in the same direction without taking a permanent set."

This remarkable prediction has been supported by the subsequent experiments of Wöhler, Bauschinger, Bairstow, Moore, and others, except that it was found that while the first subjection "to a considerable strain", within limits, causes a great improvement in elasticity, it requires a cycle of such applications to perfect it. Professor Thomson proceeds by a pure effort of scientific reasoning, and without any tests on the subject to guide him:

"The considerations adduced seem to me to show clearly that there really exist *two elastic limits* for any material, between which the displacements or deflexions, or what may in general be termed the changes of form, must be confined, if we wish to avoid giving the material a set, or, in the case of variable strains, if we wish to avoid giving it a continuous succession of sets which would gradually bring about its destruction: that these two elastic limits are usually situated one on the one side and the other on the opposite side of the position which the material assumes when subject to no external strain, though they may be both on the same side of this position of relaxation; and that they may therefore with propriety be called the *superior* and the *inferior limit* of the change of form of the material for the particular arrangement which has been given to its particles; that these two limits are not fixed for any given material, but that, if the change of form be continued beyond either limit, two new limits will, by means of an alteration in the arrangement of the particles of the material, be given to it in place of those which it previously possessed."

Lord Kelvin thought so highly of his brother's paper that he incorporated it in its entirety in his own notable discussion on "Elasticity".*

Ewing, Bairstow, Staunton, Rosenhain, Beilby, Howard, and other eminent physicists and physical metallurgists (none of whom is mentioned by Mr. Turner) having the advantage of the previous investigations of Maxwell, Kelvin, Tomlinson, Wöhler, and Bauschinger (all of whom are mentioned by Mr. Turner), advanced the science of physical metallurgy considerably beyond the point reached by the earlier investigators. Some of Mr. Turner's statements regarding fatigue and the effects of strain are far from orthodox. Experiments by the foregoing eminent investigators will refute his views; some of their results, already quoted by the writer in a previous paper,† prove their contentions.

Mr. Turner states "that rupture of ductile metal under Wöhler's treatment takes place without plastic elongation". In cases of rupture under alternate compression and tension in bending, like that described previously by Ewing, rupture occurs with very little plastic deformation, but where a bar is ruptured

* In Encyclopædia Britannica, 9th Edition, Vol. VII, pp. 798–800.

† From writings of Bairstow, *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1512; of Rosenhain, *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1520. See, also, explanation of Ewing, Encyclopædia Britannica, 11th Edition, Vol. XXV, p. 1019.

by cycles of stress in tension there often is considerable plastic deformation. For instance, in Mr. Bairstow's valuable paper* on the range of the elastic limits, "experiments on an axle steel with a yield point of 24.9 tons per sq. in. showed that in repeated loadings from 0 to 23.2 tons per sq. in. no sign of want of elasticity occurred until after 6 000 loadings when a permanent extension in the order of a yield took place."

The writer wishes to go on record emphatically against Mr. Turner's statement that "these working stresses and proper allowances need be no lower for a range of stress from tension to compression than for one kind only." Intensity of stress that could be repeated indefinitely in tension without causing either rupture or undue permanent set is likely to cause rupture if it occurs frequently in alternate tension and compression. Moreover, alternate stresses are especially severe on end connections. The writer has seen pinholes that have been enlarged ¼ in. in members subjected to alternate stresses. The matter of alternate stresses should be considered in connection with possible increase in the live loads that produce them.

Mr. Turner is correct in his contention that columns are liable to twisting. The writer has seen a column that was perceptibly twisted by reason of its load; but for centrally loaded columns Mr. Turner attaches too much importance to this consideration. Columns should be designed with forms and proportions of cross-section that offer considerable resistance to torsion; but beyond this point tests do not seem to indicate that superior resistance to torsion appreciably adds to the resistance to direct compression for equal ratios of length to radius of gyration. The writer is pleased that "form of section" is included as a sub-division of the subject of "steel column research" outlined in the Progress Report of the Special Committee on this subject.†

The last paragraph of Mr. Turner's discussion, the one in which he discusses faults in the theory of flexure, contains the amazing statement that the writer appears to suppose that the disregard of shear strain increases the maximum fiber stress at points of greatest deflection. In dealing with faults in the theory of flexure the writer did not mention or refer directly or indirectly or by implication to a point or points of greatest deflection.

The supposition, imagined to be the writer's, appeared to Mr. Turner and he combatted it with ideas regarding constrained and continuous beams; and when he had disposed of it to his satisfaction, he inquired, "Is not much of the mathematical discussion of the paper based on assumptions which are unrelated to the facts?" The writer's analysis was confined to beams simply supported and uniformly loaded either over the entire length or over any shorter distance symmetrical with respect to the center line; and for such beams both the maximum fiber stress and the maximum deflection occur at the center and by correct theory both are greater than indicated by the ordinary theory.

No attempt was made in the paper to analyze the true theory of flexure of restrained or continuous beams. The reactions indicated by the true theory

* *Philosophical Transactions*, Royal Soc., Vol. 210, p. 35; see, also, discussion by Mr. T. E. Stanton, *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1482.

† *Transactions*, Am. Soc. C. E., Vol. 89 (1926), see Contents.

would differ somewhat from the reactions indicated by the ordinary theory and in some cases of restrained and continuous beams this would tend to reduce the bending moment.

Mr. von Fabrice discusses "Beams" in a paragraph in which he states: "It is difficult to understand why the old and approved theory of flexure should be revised for an empirical formula afflicted with 50% factor of error."

The ordinary theory of flexure obviously neglects the influence of shear on cross-sections. An analysis of beams and girders simply supported was made to ascertain whether, in consequence of this neglect, the ordinary theory was in any such cases seriously in error and, if so, in what cases.

Believing such an analysis and its results would be of interest to engineers it was published. The method of analysis was to determine approximately the percentage, P_e, which theoretically should be added to the intensity of the stress, as computed from the ordinary theory, to make it correct. Equations (20), (21) and (22) give approximately the value of P_e, for all well-designed beams and girders except very short ones.

The writer's attitude regarding P_e, as applied to very short beams, is stated in the paper. That a theory has long been approved and has stood the test of long experience is a good and strong argument for continuing to use it; but, as regards concentrated loads and short beams, the ordinary theory has not been approved, and as regards these points, it is theory supplemented by good practice which has stood the test of experience. In this regard Mr. von Fabrice has himself provided the answer to his criticism in his discussion of "Shear."

With respect to that part of Mr. von Fabrice's discussion which has to do with his Fig. 5 (*a*), (*b*), and (*c*), the writer refers those interested (and all engineers should be interested) to a discussion* of a paper entitled "Effects of Straining Steel and Wrought Iron." This discussion contains descriptions of some instructive microscopic examinations of strained iron. It was shown that plastic elongation took place almost entirely by successive diagonal slippages over one another, to right and to left, of the layers within the crystalline grains, of which the metal is composed, without appreciably altering the inclination of the grains. There is no reason why such slippages should not similarly take place in plastic shortening under compression, and there is good reason to suppose that they do similarly take place; in other words, the physical phenomenon of plastic deformation under compression is in all probability similar to that under tension, except that each grain becomes shorter and wider under compression instead of becoming longer and narrower, as under tension.

Professor Moore, after pointing out that Johnson's apparent elastic limit involves an increase in rate of strain over the initial value amounting to 50 rather than the 100% of the U. L. P., suggests that, "a more extended statement from Mr. Prichard as to the advantages of the U. L. P. over Johnson's elastic limit would be of value." Mr. Woodruff inquires, "What is the 'utilizable capacity' of a structural member?" and he adds, "according to the author's definition, it would be permissible to stress a member to its 'utilizable

* *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), pp. 1503–1522, especially p. 1522.

capacity'." As a basis for discussing these points, suppose that a steel works which rolls shapes and plates and is known as "the Mill", retains a consulting engineer to design a sample column, of a given length, the purpose being to build a considerable number for testing and, if the tests are satisfactory, to build a large number, all like the sample, for a customer.

The Mill desires that when the columns are loaded with (*a*) a gradually increasing load of twice the working load; or (*b*) an oft-repeated load from zero to twice the working load; or (*c*) a long-continued static load of twice the working load; it will not (1) fail; or (2) acquire an undue permanent set; or (3) be seriously injured; or (4) deflect unduly. The Mill also desires that the columns shall have as little excess section as practical.

The consulting engineer is free to select all the material required from which to make specimen tests, and he is afforded every opportunity for making the specimen tests in any way he chooses. Doubtless he would make a number of specimen tests and a few tentative designs before finally deciding on the design from which the test columns will be built, and he would doubtless adopt or originate a method of procedure.

If in testing the full-sized columns, twice the working loads are applied under Conditions (*a*), (*b*), and (*c*) with the eccentricities to which they are liable in service and if they stand the tests as regards all the Requirements (1), (2), (3), and (4); and if they are again tested under slightly increased loads and fail to meet one or more of the Requirements (1), (2), (3), and (4), the consulting engineer will have accomplished his purpose, and the Mill will supply its customer with columns that, as nearly as can be foreseen, have a factor of safety of two.

The attention of engineers in general, and Mr. Woodruff in particular, is called to the fact that a factor of safety is necessary (although it may not be the factor of two used for illustrative purposes in the assumed case) for the reasons that in spite of the best intentions, the actual loading may exceed the assumed working loading, and in spite of the consulting engineer's precautions, his determinations may be deficient.

The writer's reasons for preferring the U. L. P. to Johnson's apparent elastic limit, in determining utilizable capacity, are that he considers that the additional load permitted by the U. L. P. (as qualified in the paper) will not cause failure or serious injury and that the additional permanent set permitted is not undue.

In general, the consulting engineer's most difficult problem will be to determine the eccentricity of application of the loads (restraint of the ends being considered in terms of eccentric application), as it is a problem which, ordinarily, does not admit of close mathematical determination. Such being the case, it does seem to be somewhat irrational, as Mr. von Fabrice points out, to specify precise formulas for the influence of length on utilizable capacity or on permissible loading; but every engineer who writes specifications for the design of structures gives a formula or formulas for columns, and if he distinguishes between steels with different characteristic U. L. P.'s he should make the formulas consistent one with another. In a paper like the writer's, how-

ever, attention should be called to the fact (as it has been) that in determining, as nearly as may be, the utilizable capacity, such formulas should be used with judgment.

The writer considers that Table 12, used with judgment, should be quite useful in determining the utilizable capacities of columns, and he hopes that engineers will find it useful in devising formulas for alloy and other steels with high U. L. P.'s (assuming that they will for a time continue the present practice of specifying the same formula for all steel of the same grade and chemical composition); but he realizes the justice of Mr. von Fabrice's criticism that "Table 12 cannot be readily understood"; hence he has supplemented the table with a diagram, Fig. 6, which he trusts will make it easier to understand.

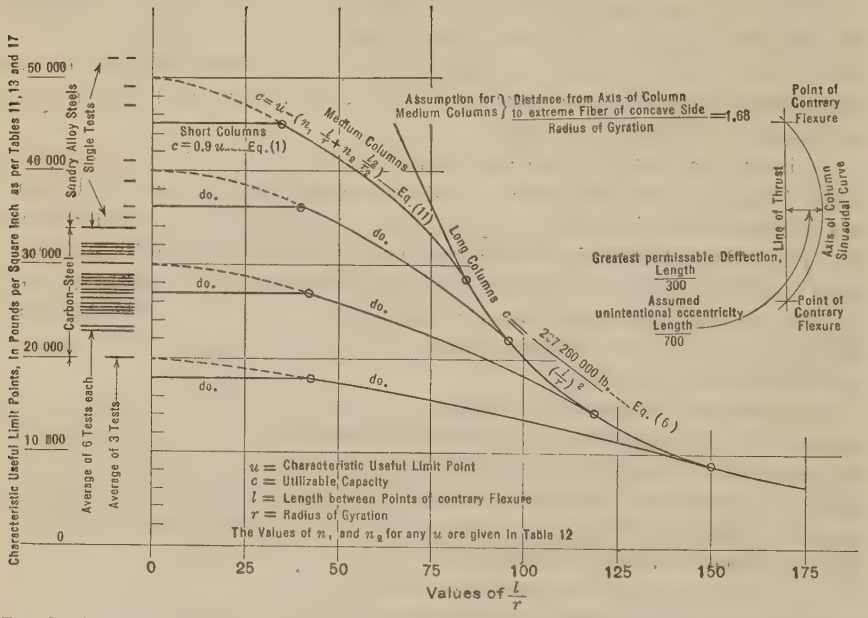

FIG. 6.—THE RELATIONSHIP OF LENGTH OF COLUMN, CHARACTERISTIC USEFUL LIMIT POINT, AND UTILIZABLE CAPACITY.

After carefully considering Mr. Schmitt's discussion it seems best to explain some matters in and regarding the paper. The first four parts were originally written as a monograph on the subject, "Perfecting of Elasticity of Steel Bodies by Modification of Auto-Stresses, and the Development, by Repeated Cycles of Stress, of Fields of Seemingly Perfect Elasticity of Chosen Range and Position". It was the original intention to present the monograph to the Society as a contribution to pure science without regard to its application to engineering practice. Its incorporation as a part of a paper on "Utilizable Capacity of Steel Members of Structures" was an afterthought. Tables 1, 2, 3, 4, and 5 therein give a collection of the results of experiments by others, and show for various cases the limits within which elasticity has been perfected. The explanation of the perfecting of elasticity by modification

of auto-stresses is the writer's adjustment of the ideas, previously referred to, of James Thomson to the discoveries of Beilby, Ewing, Rosenhain, and others as to the nature of plastic deformation of metals.

Fig. 1 illustrates the various ranges of seemingly perfect elasticity which can be developed in different specimens from the same piece of steel by repeatedly straining them in direct tension or compression through extreme ranges of stress with different upper and lower elastic limits. If the ranges were any greater and the upper limits any higher the specimens would eventually break. The terms and expressions used in the first four parts of the paper were chosen with reference to close reasoning and definite meaning.

Among the experiments of Bauschinger, as given by Professor Unwin,* there were some, numbered 3, 6, 9, 11, 12, and 13 on Fig. 3, which indicate a strange anomaly in the diagram in the way of a decided terminal drop after seemingly perfect elasticity had been indicated through millions of repetitions. This is not in accord with the general indications of the other tests in the tables nor with the writer's explanation of the perfecting of elasticity. He considers it highly probable that there were special circumstances which caused this anomaly but he could not find information to confirm this view, so he included the tests in the paper, with qualifications as described therein. He was in hopes that some reader could contribute information regarding them. To distinguish the superficial indications of this anomaly from permanent fatigue, as previously defined, he used the term "remote fatigue".

After it was decided to incorporate the first four parts in a paper on utilizable capacity, the lines termed, "Critical Deformation Point in Stress", were added to Fig. 1. This critical deformation point occurs somewhere in the zone of the yield which extends from the point, where the strain ceases to be closely proportional to the stress, to the yield point, when there is one. Sometimes the zone of yield is of zero length. Sometimes the yield shown in pulling tests is deceptive. In an extreme case (Test 7934, Table 10) soft steel with a maximum tensile strength of 48 240 lb. per sq. in. seemed, in a careful pulling test, to be perfectly elastic up to 40 000 lb. per sq. in. and had a U. L. P. of 40 600 lb. per sq. in., or 84.2% of the tensile strength; and then the load dropped to 30 000 lb. per sq. in. Valuable information on this subject was obtained in one of Bairstow's experiments on axle steel, with a yield point of 49 800 lb. per sq. in., which in repeated loadings from 0 to 46 400 lb. per sq. in., showed no lack of elasticity until after 6 000 loadings, when a permanent extension of the order of the yield took place. The first yield point observed was not a true criterion as the yield point under repeated stress was 3 800 lb. per sq. in. lower.

Some engineers consider the limit to approximate proportionality to be the critical deformation point, others consider the yield point as the critical point in deformation, whereas the Society's former Special Committee on Steel Columns and Struts adopted the U. L. P. (the point where the plastic deformation just equals the elastic deformation) as critical. For specimens used as criteria for full-sized members the writer adopted 87% of the U. L. P., or 60% of the tensile strength, whichever is the smaller.

* "Testing of Materials of Construction."

After Wöhler's experiments were published Launhardt and others developed formulas to indicate the loci of the upper elastic limit, under cycles of stress, beyond which failure would take place. In the past many engineers used these formulas as criteria on which to base working stresses, and some continue to use Professor Cain's modified Launhardt's formula. The writer for many years has consistently opposed such a practice and has advocated the use of the critical deformation point as the criterion, and this paper is in harmony with his record in this regard, but, in the light of experience, he now places the position of the point somewhat lower than formerly. If the critical deformation point is chosen somewhat too high a member under repeated one-directional stress from zero to the point chosen may fail from permanent fatigue, while stress from a minimum tension or compression of appreciable intensity, to the point chosen as critical, may cause undue deformation. By adopting his method of selecting the critical deformation point, the writer considers it likely that he has escaped both these possibilities.

In the tests recorded in Table 2, it did not seem to make much difference whether the speed was 2 cycles per min., or 800. Above 800 the range and upper elastic limit were reduced. Regarding repetitions of stress to capacity under the conditions of actual service, it is conjectural whether the range and upper elastic limit would differ from those recorded, but unless the range would be less, it would not affect the criteria advocated in the paper for members subjected to compression only or tension only.

For alternate stresses attention is invited to the well-known specification:

"Members subject to alternate tension and compression shall be proportioned for both kinds of stress separately considered, but each kind shall be considered as increased by x per cent. of the lesser stress."

Suppose that, for purposes of analysis, the factor of safety is discarded; and that unit stresses for the various kinds of steel and iron termed Lots 1, 2, and 3 in Table 1 are chosen as follows: For charcoal iron, 32 500 lb. (it cannot be the 40 000 lb. indicated in the table, as that is greater than the yield point, which is 32 500 lb.); for unannealed axle steel, 48 000 lb.; and for unannealed Bessemer steel, 66 500 lb.; and that a different value of x is chosen for each kind of metal, as indicated in Table 24; and suppose further that the bars are proportioned for total stresses just equal to the stresses per square inch shown in Table 1; the tension per square inch plus the compression per square inch, which is the "range", will then be in each case up to, or nearly up to, the greatest range which can be indefinitely repeated without causing failure or exceeding the limits within which elasticity can be perfected as shown in Table 24. It should be noted that the analysis of the experiments recorded in Table 1, indicates, for every case of alternate stresses, (*a*) that an addition has to be made to the greater stress before the proper cross-sectional can be determined; (*b*) that the percentage of the lesser stress to be added varies in some way with the tensile strength; and (*c*) that, with the percentages of increase determined by experiments, the "well known specification" seems to be well supported by the experiments. The writer does not know who originated the "well known specification" or how he derived it, but it is shown in Table

24 that there are tests to support it. It is generally recognized that reversed stresses are severe on end connections of members. It seems reasonable to infer that they are also severe on the connections between the crystalline layers of the grains of the steel.

TABLE 24.

Lot.	x, in percentage.	Tensile strength, in pounds per square inch.	Yield point, in pounds per square inch.	Specified unit stress allowing no factor of safety, in pounds per square inch. Greatest possible range, tension plus compression, from Table 1, in pounds per square inch.
					Tension, in pounds.	Compression, in pounds.				
1	38.8	43.900	32.500	32.500	22.000	20.600	30.000	1.00	42.600	42.600
2	64.0	85.000	55.800	48.000	30.000	28.000	47.900	1.00	58.000	58.000
2	64.0	85.000	55.800	48.000	39.000	15.000	48.600	1.01	53.400	54.000
3	79.2	99.900	71.700	66.500	38.200	35.700	66.500	1.00	73.900	73.900
3	79.2	99.900	71.700	66.500	58.000	11.000	66.700	1.00	73.900	73.900
3	79.2	99.900	71.700	66.500	65.000	2.000	66.600	1.00	67.000	67.000

The writer is aware of the tendency to provide no additional cross-section to tension and compression members on account of reversed stress. When many engineers very properly discarded Launhardt's and similar formulas, some of them also discarded (as the writer considers, without good reason) the "well known specification" cited.

The writer does not know of any modern endurance investigation that explains away the tests by direct stresses recorded in Table 1. Most if not all modern endurance tests are by bending, for which stress strain diagrams are very different from those of tests by direct stresses. Bending tests are so affected by auto-stresses developed in testing that inferences from them as to the behavior of members under direct stresses carry little weight as compared with tests by direct stresses. Such of the pertinent bending tests as the writer has analyzed, however, tend to support the conclusions reached, notably the extensive series of fine tests given in Table 5.

The writer would emphasize the fact that utilizable capacity can not be gauged from one "point in stress". The U. L. P. is sometimes so high that it can not be regarded as critical and some percentage of tensile strength should be substituted; the liability of failure from permanent fatigue is critical as regards members subjected to direct alternate stresses, but the liability to undue deformation is the consideration which limits the capacity of members subjected to stresses in only one direction. In some cases the degree of stiffness limits capacity. Details are supposed to be stronger than the member as a whole, but eternal vigilance is advisable in this regard. Some allowance is made for inevitable defects in workmanship, but good practice and intelligent inspection are highly important. Of course, long endurance is dependent on protection of structural members from corrosion.

Paper No. 1593

THE HEXAGONAL SLAB DESIGN OF CONCRETE PAVEMENT*

By Lewis A. Perry,† Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. E. G. Hooper, S. Herbert Hare, Jacob Feld, H. O. Root, Wesley Vandercook, and Lewis A. Perry.

Synopsis

This paper records the results of experiments conducted by the writer to learn what relation the shape of a pavement slab has on its strength.

Although these experiments were made in a laboratory with miniature specimens, the condition of moment, stress, and manner of loading was such that the results may be assumed to be representative of the behavior of pavement slabs in actual use. The uniform behavior of the test specimens lends weight to this assumption.

With the record of these experiments, a study of moments, as developed in various shaped slabs, is reported. This study is confirmed by the results of the experiments and presents some pertinent facts apparently hitherto unrecognized or considered unimportant.

The paper also discusses current practice in the light of information gained from these studies. Pavements of correct slab shape, as determined from these studies, are illustrated and described. Finally, the writer has attempted to define the limitations and essential features of an economic design.

Corner Weakness of Four-Sided Slabs.—A general failure of a concrete pavement is invariably a progressive destruction following corner fractures developed under flexural stress. Such corners may be right-angled corners

* Published in November, 1925, *Proceedings*.

† Constr. Engr., The Longview Co., Longview, Wash.

at the intersection of joints, or joint with edge, or may be corners formed at the intersection of temperature cracks in an over-sized slab.

Proof that the 90° corner is susceptible to fracture under loading that is safe for the mid-portion of the slab is found in a study of Fig. 1 (*a*), (*b*), and (*c*), which shows a stress analysis of a slab, 16 ft. square and 6 in. thick. The section, *Y-Y*, is arbitrarily fixed at about 1 ft. less than the breadth of the section. The depth of 6 in. has also been arbitrarily chosen. The section modulus then established defines the moment, using 300 lb. per sq. in. as the allowable fiber stress. Knowing L and the moment, the loads, W and W', are found, which, of course, are much less than the actual safe loads because the sub-grade offers substantial resistance to flexure. The diagram, however, is still proportional and representative. The computed sections at x for each foot along L result in the curved figure the area of which outside the square is shaded.

The equation defining the moment at any section is:

$$M = W x \left(\frac{1}{2} - \frac{2 x^2}{31^2}\right) \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

As the section modulus is $\frac{b d^2}{6}$, and $d = 6$, the section, $A B$, is defined by Equation (2):

$$A B = \frac{M}{6 f} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

$$= W x \frac{\left(\frac{1}{2} - \frac{2 x^2}{31^2}\right)}{6 \times 300} = 10\,000 \frac{6\left(\frac{1}{2} - \frac{2 x^2}{31^2}\right)}{6 \times 300}$$

$$= \frac{(60\,000)\,(0.4532)}{1\,800} = 15.1 \text{ ft.}$$

Thus, it is determined that 15.1 ft. of section is needed at AB and the right-angled corner is only 12 ft. at this point, or only 80% efficient.

In his paper entitled "Highway Research in Illinois",* Clifford Older, M. Am. Soc. C. E., emphasized this weakness by stating that corner failures could be prevented by proportioning the thickness of the edge to the thickness at mid-slab as $\sqrt{\frac{3\,W}{S}}$ is to $\sqrt{\frac{W}{S}}$. When W is 8 000 lb. and S is 300 lb., the respective thicknesses should be 8.9 in. and 5.2 in.

Tests of Laboratory Specimens.—In order to determine the relative strength of small specimen slabs, a simple apparatus shown in Fig. 2 was constructed. Square and hexagonal-shaped laboratory specimens, ¾ in. thick, 144 in. in area, and of 1 : 3 sand mortar were made and tested after having been cured 7 days and 5 months, respectively, in open air.

As shown in Fig. 2, the specimens were tested on a bed of dry fine sand, the loads being applied at two points, each 1 in. inside the actual corner, and on

* *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 1180.

a line joining opposite corners. The loads were applied in units of 5 lb. until the specimens were fractured, the time of each test to failure occupying about 10 min.

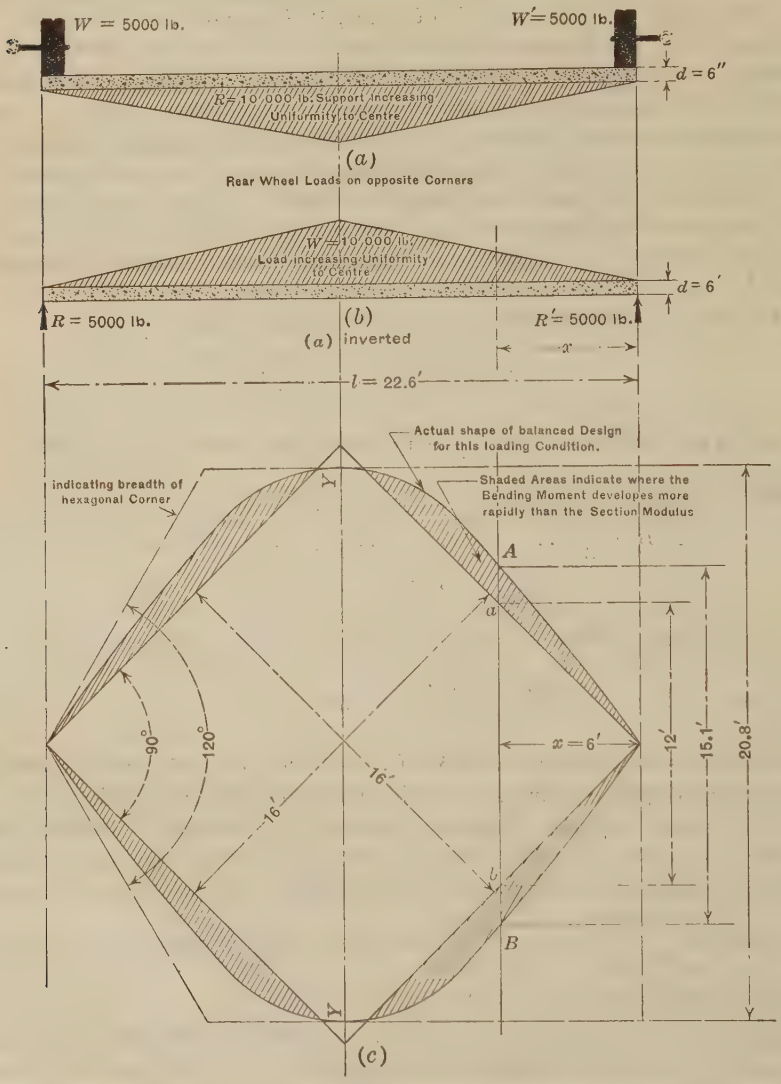

FIG. 1.

Table 1 records the results of the tests on specimens that had been aged 7 days, of secondary tests on the fragments of the 7-day specimens, and the loadings necessary to produce primary fractures on the 5-month specimens.

The broken specimens and the relative breaking loads under primary and secondary loading are shown in Figs. 3 and 4. The compound fracture of

Hexagon No. 4 (Fig. 3) was caused by splinters from broken specimens that had become hidden in the sand bed. The compound fractures of Hexagons Nos. 6 and 9 (Fig. 4) were caused by the falling of the bar after primary fracture had occurred. It will be noted from Fig. 3 that all square specimens fractured at the corners and that the hexagonal specimens under primary loading (see Table 1) broke into figures of uniform shape and size.

Present Methods of Compensating Corner Weakness.—The practice of using a center joint in highway and street pavements is logical provision against the development of longitudinal cracks. Such joints, or cracks, form right-angled corners at their intersection with transverse joints, or cracks. To preclude fracture of these right-angled corners without the use of shear bars, or other such compensation, the thickness at the edge must be greater than that required at the mid-portion of the slab. This means that a uniform thickness is either insufficient at the corners or extravagant at mid-slab. The additional concrete required to deepen the edge along the center joint is an important item of cost.

The shear-bar connection is probably the most widely used provision against corner breakage along the center joint, but it is far from ideal for several reasons. Neither shear bars that are placed at their closest effective spacing, nor the so-called tongue-and-groove type of joint, can entirely compensate corner weakness because diagonal shear of concrete is the limiting factor.

Under adverse conditions, such as unstable subgrades and frost heaving, where the slabs vary seriously in coincidence, spawling of the concrete destroys the bond of the shear bar. The bar is then rendered ineffective, and the slab has suffered a reduction in section at what may be a critical point.

In time, corrosion at the exposed part, and the crystallization caused by vibration, must disqualify the shear bar as an agency of support, and shorten the life of the pavement, which otherwise would be limited only by wear. Corrosion increases the volume of steel about 90 per cent. This increase in volume produces pressure, and a shear bar in a relatively thin pavement may be expected to spawl off a part of the slab, thereby weakening it.

The cost of shear bars, or metal tongue-and-groove joints, although not the governing consideration, is nevertheless important.

Structural Advantages of Hexagonal Slabs.—In view of the foregoing it would seem that an arrangement of plain concrete slabs, the interior corners of which were of sufficient breadth to preclude corner breakage without costly compensation, would be a logical design. This may be accomplished by arranging a plurality of hexagonal or fractional hexagonal slabs, the interior corners of which are substantially 120°, the 90° corners occurring along the outer edge being compensated by additional thickness of concrete. Such an arrangement is illustrated in Figs. 5 and 6.

Fig. 5 shows part of a pavement, of which each slab is a true hexagon, 314 sq. ft. in area and 6 in. in thickness. This pavement is in use continuously for heavy traffic and storage and has shown no evidence of failure. Fig. 6

shows an adaption of hexagonal slabs for street pavement. As shown by Figs. 3 and 4, the corner was the pronounced place of weakness in the four-sided laboratory specimens, which is likewise true of four-sided roadway slabs.

TABLE 1.—Test Data on Square and Hexagonal Shapes of Equal Area and Thickness—Loading, in Pounds, to Produce Failure.

A study of Figs. 7 and 8 will reveal the marked structural advantages of the hexagonal slab. It will be noted that the areas of these two slabs are practically equal, yet the greatest diagonal length of the hexagon is only nine-tenths that of the square. This reduces the bending moments to a gratifying extent. It is also found that the hexagonal corner develops 1.732 times the section width of the square corner, as shown by comparing the line, *a-b*, in Fig. 7, with the line, *A-B*, in Fig. 8. It will be noted that the perimeter of the hexagon is 4 ft. less than that of the square. In localities where extremes of temperature occur and prepared expansion joint material is used in generous thickness, this saving may amount to as much as 3 cents per sq. yd.

An important virtue of the hexagonal slab pavement is that the greater breadth of corner accumulates the greatest possible area of support near the

point of application of the load. In Fig. 9, which is a panel design of a highway or narrow street pavement, the hexagon or fractional hexagon most closely

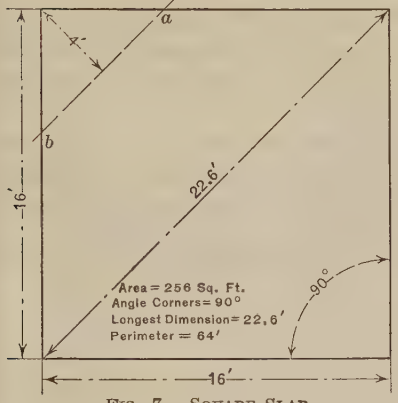

FIG. 7.—SQUARE SLAB.

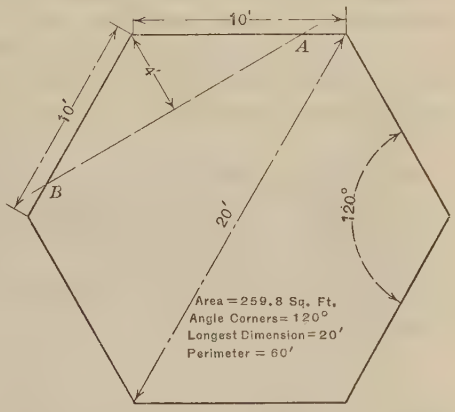

FIG. 8.—HEXAGONAL SLAB.

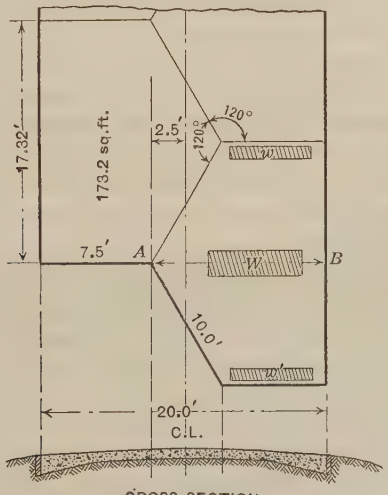
approaches the circle, or semi-circle, of any figure that can be grouped with similar figures. The circle is the most efficient slab shape by reason of the absence of projecting corners. All sections through it are maximum sections. The hexagonal slab, therefore, offers the maximum resistance to fracture under flexure.



CROSS SECTION

FIG. 9.—PANEL DESIGN OF HIGHWAY OR NARROW STREET PAVEMENT.

Of importance, second only to corner protection, is the virtue of the fractional hexagonal slab, as illustrated in Fig. 9, in which the maximum transverse bending occurs on the line, *A-B*. This is true regardless of whether the loading is at *w*, *w'*, or *W*. Assuming the width of the pavement to be 20 ft. and

the staggered joints at the center to be 10 ft., the distance, *A-B*, then becomes 12.5 ft., or 25% greater than the width of a slab with a straight center joint.

Some idea of the greater strength of the hexagonal slab may be obtained from a study of Table 1, and Figs. 3 and 4.

It will be seen from Fig. 1 (*c*) that although the 90° corner provides only 12 ft. of section along the line, *a-b*, and the actual requirement is 15.1 ft., the hexagonal corner would have a breadth of 20.8 ft., or nearly 38% greater than required.

As the section modulus of any member is a correct measure of its strength, the economic possibilities of the hexagonal design are shown by comparing a square slab corner, 7 in. thick, with a hexagonal slab corner, 6 in. thick.

Referring to Fig. 1 (*c*); when x is 3 ft., the section modulus, $\left(\frac{b\,d^2}{6}\right)$, at this section becomes,

$$\frac{(72)\ (49)}{6} = 588$$

Compare this section with that of a hexagonal corner 6 in. thick, the section modulus of which is:

$$\frac{(124.56)\ (36)}{6} = 747$$

it is seen that the hexagonal slab 6 in. thick has a strength 27% greater at that point than the square slab 7 in. thick.

Another fact deserving mention is that the quality of the concrete itself is likely to be better in the hexagonal corner than in the square corner owing to its better placement in a wider space.

Adaptability of Hexagonal Design to Concrete Pavement.—Before the construction of the work illustrated, the writer discussed with contractors and fellow engineers, a pavement design involving the principle of the hexagonal, or fractional hexagonal, slab. The majority of critics commended the theory of this design, but doubted its practical application with reasonable labor costs. Rarely did one meet with the opinion that the additional cost of constructing such a design could be neglected, yet this is true.

As applied to street and highway pavement, the methods of construction and use of tools employed in the laying of the hexagonal slab design are typical of construction of any design incorporating a plurality of units of uniform area. The fact that the center joint is staggered rather than straight is immaterial to the workman. The total length of transverse and center joints is less than it would be with a straight center joint.

All joint strips were left flush with, or beneath, the surface of the pavement to allow unrestricted use of the rod, roller, limber float, and hand floats. The division boards supporting the joint strips were pulled immediately after the rodding. The test straight-edge and all finishing tools were used continuously over the unbroken surface of the concrete, regardless of the location of slab joints, as shown in Fig. 10, which is a view of hexagonal slab pavement being placed at a street intersection. The joints are embedded ½ in., which allows unrestricted use of finishing tools. In this manner the continuity of true contour and the coincidence of adjacent slabs was assured.

Fig. 10.—Hexagonal Design in Street Intersection. Joints Embedded ½ Inch, Allowing Unrestricted Use of Finishing Tools.

Fig. 11.—Edging Slabs After Joint Material Has Been Pulled.

Before final edging and marking (see Fig. 11), and while the concrete was still plastic, the joint strips were pulled with flat-billed tongs. This pull was perpendicular and was intended to raise the top of the joint strip ¼ to ½ in. above the surface of the pavement.

The construction of the pavement illustrated in Fig. 5 required a somewhat different procedure. A false form system was used for alternate tiers of slabs, the filler tiers being rodded and finished from the existing concrete and with no forms other than division boards. In both these types of improvement it was found that familiarity of workmen with the particular design was not as important as good organization by the contractor. It was also found that the skilled workman will adapt himself to any logical design and go the designer "one better" in developing practical methods of construction.

The writer has designed and supervised the construction of about 376 000 sq. yd. of hexagonal slab pavement during 1924 and 1925 in Longview, Wash. The question of excessive labor costs due to the irregularity of design is answered by the fact that better progress has been consistently made with this work than with the square panel design constructed during 1923. This comparison was made with equal depths of pavement, and it is worthy of note that the finish and riding quality of the hexagonal slab pavement is, if different, superior to that of the old design.

Credit is due H. O. Root, Principal Assistant, for valuable assistance in design and field supervision of the work illustrated in this paper. Henry G. Niblett, President of Olympic Construction Company, who directed the construction of this work, is deserving of compliment for his co-operation in successfully adapting the design to practice.

Conclusions.—It is incorrect to compensate a pronounced weakness in design, when that weakness may be eliminated.

The right-angled corner is a pronounced weakness and has no rightful place in a concrete pavement, except where it must occur along the outer edge.

The cost to compensate such weak corners successfully is not justified in the light of a more economic design.

Harmful temperature cracks which intersect and form corners in an oversized slab may be avoided by a reasonable reduction of the slab area.

The necessity of forming reasonably small slabs to avoid these cracks may be met without the formation of interior right-angled corners.

The writer believes that the economical design is a grouping of slab units of plain concrete, each unit sized so as to prohibit temperature cracks and excessive bending moments, and entirely independent of, and disconnected with, adjacent slabs, which prevents injury to any one slab by reason of the displacement or failure of its neighbor, and, further, that each slab be cast in the ideal shape—the hexagon.

In this grouping the corner ceases to be a weakness and the general design is logical and economical, with a uniform thickness, except where right-angled corners occur of necessity. This reasoning is presented as the writer's interpretation of simple, natural laws.

DISCUSSION

E. G. Hooper,* Assoc. M. Am. Soc. C. E. (by letter).—The problem of pavement design has pre-empted the thought of many practicing and research engineers ever since the automobile became such an important economic factor. Many novel ideas have been developed and presented as the solution of that problem, but as yet none has proved more than partly satisfactory in meeting demands under widely different and varying conditions. A full appreciation of the limitations of the several more generally adopted plans, together with a thorough knowledge of the loads, structural material, and soil conditions in a given locality, makes it feasible to select a reasonably satisfactory type. The outstanding factor militating against a satisfactory general design is a widely varying undependable supporting sub-grade. Until some means is found to reduce materially the number of different critical conditions that can develop under a pavement no satisfactory structural study can be made, as that requires an established maximum loading, a knowledge of the behavior of structural material and type of structure, and a certainty of permanency in the nature and positions of the supporting reactions. The only thing the writer can imagine that will obviate this fundamental difficulty is to provide supports that will carry the reactions to a soil level below that subject to disturbance. A design has been evolved along this line that is practical, the cost of which is not materially above that of present pavements. This discussion, however, will be confined to points of agreement and disagreement in Mr. Perry's paper.

The writer's comment, elaborated subsequently, may be summed up briefly, as follows: It is agreed that (1) corners of pavement slabs are the seats of greatest weakness; (2) corners of hexagonal slabs are stronger than those of rectangular slabs; and (3) improperly planned doweling across joints may produce serious spalling. On the other hand, it is objected that (1) increase in the number of corners by use of hexagonal slabs may offset to a degree the advantage of individual corner strength; (2) the position of corners with reference to traffic lines in the hexagonal slab arrangement proposed subjects these weak places to unusual punishment; (3) the regular zigzag line or joint making an angle of 30° with the center line of the road is a possible source of confusion to drivers; (4) temperature curling at corners that are coming continuously and suddenly under load is likely to aggravate conditions beyond normal; (5) absence of shear connections with adjoining units permits at times relative movement, or displacement of a permanent nature, at joints so that impact, otherwise negligible, may become a formidable factor; and (6) on soil which very little water can reach and from which that little is quickly drawn, as in built-up and sewered communities, the weaknesses of any of the slab designs would not develop to any great degree.

As Mr. Perry states in his excellent presentation the common rectangular slab construction develops its greatest weakness at the corners. The importance of strengthening these corners is definitely recognized, more particu-

* Asst. Prof., Civ. Eng., New York Univ., New York, N. Y.

larly since the publication of results of, and conclusions from, the "Bates" and the "Pittsburg" road tests. Various means have been adopted for making, directly or indirectly, such points as strong as the remainder of the unit. Mr. Perry approves of thickening the edges as he has incorporated that idea where he, of necessity, has right angles; but he objects to the use of dowels or tongue-and-groove joints for transferring some of the load to adjoining members.

Objection to dowels may be partly justified. An insufficient number and size of bar together with an open joint will inevitably produce spalling which may eventually nullify the expected benefits from the steel. However, as such spalling is due to excessive bending of bars across an open joint, or is caused by closure of the joint by temperature, where a dowel is bent or out of alignment it may be corrected by use of bars of proper size and number, to make the bending negligible and the face-bearing area adequate. The writer believes expansion from corrosion is negligible because air and moisture must have access to the embedded metal; even the sliding ends of bars are usually wound with an adequate protective covering.

Tongue-and-groove joints are effective in transferring shear or load from one unit to another and the percentage thus transmitted is a function of the relative deformation of the adjoining units. Exact calculations cannot be made because of the ever-present bugaboo—variable and indeterminate soil resistance—which renders it impossible to predict slab deformation. Numerous service tests have given favorable impressions of carefully designed and made joints of this kind, and until other acceptable tests prove otherwise they may logically be accepted as satisfactory.

It is readily acknowledged that full hexagonal slabs are stronger at the corners than rectangular ones, nevertheless those corners remain a weakness. The use of half hexagons for pavements, as recommended by Mr. Perry, of necessity, retain two of the taboo right angles at critical points. In place of two other right angles along the center line, he substitutes three 120° angles, all three of which are situated so that the left-hand wheels of every vehicle traveling the right-hand side of the road will traverse the ones on that side, and in such a manner as to apply a force comparable with a critical load in case of heavy trucks. Vehicles traveling down the center will likewise traverse the corners, so that the weakest points of the pavement are suffering punishment all the time, a condition not duplicated in the usual rectangular construction. It is conceivable, therefore, that, in spite of the apparently greater strength, the hexagonal slab would break down under as light or lighter traffic than the rectangular slab.

The ordinary "geology-topography-climate" combination for any particular locality produces such a great variation in the supporting value for the same soil that a number of critical design conditions develop. Unless all these critical conditions have been reproduced or approximated for the given case no set of tests can be said to prove the fitness of a design, even for the one case, much less for general use. Mr. Perry's tests show the comparative strength of

hexagons and rectangles with the conditions of load and support shown and described in his paper. As pointed out before, in practice few loads will pass over rectangle corners as compared with those of hexagons in the plan proposed. The test results, therefore, may not be taken as fairly indicative of relative service values.

Absence of ties between the pavement units makes a collection of free slabs, which, at the worst, where soil conditions are very unsatisfactory, is comparable with a field of floating ice cakes. As already stated the best sub-grades serve equally well for any of the better slab types; it is the poorer sub-grades that require the special treatment so many engineers are trying to develop. The action of a soft soil under pressure is to an extent comparable with water. To develop the illustration, if we step on one corner of a floating ice cake that point will go down and the opposite side will rise; in other words, it will tip. The amount of tip, the amount of depression of the corner, is greater for the smaller cakes. If we step from one cake to the next, the one tends to come back as that next cake tips. There is a difference in level between adjoining units during transit of loads, a condition that would produce impact with a rolling load. In the case of pavement units similar vertical movement is bound to occur, its magnitude depending on the stability of the particular sub-grade, the size of the slab, and the number of load repetitions. Although such movement may be insignificant, repetition may develop permanent difference in level. Moreover, the impact developed as a horizontal component against an elevated edge will most probably work the slabs apart laterally even if reasonably good shoulders are maintained. For these reasons the writer considers independent action of slabs highly undesirable.

Another point of minor importance is the comparative amount of joint filler for the two types of pavement. For a given area the perimeter or joint length of a hexagon is the less, and the same may be said of the half hexagon. Were the usual transverse joint spacings the same as those required in the "hex" design, it would be correct to claim a saving in joint material. As a matter of fact, however, there are enough fewer such joints in the usual rectangular design to eliminate any such saving. This is another instance where comparisons under different conditions modify or change conclusions.

An advantage of the small units, offsetting to a degree the disadvantage, is greater freedom from cracks developed in the early stages of setting when volume changes occur due to moisture variation and temperature. As such small cracks are fruitful sources or beginnings from which develop the large disruptive breaks, it is obviously very desirable to reduce them to a minimum.

In discussing at such length the practicability of hexagonal slab design for highway pavements, the writer has had in mind that he should make his viewpoint clear. Although many of the premises, or conclusions, or both, may not be approved, he believes that a consideration of them all will be helpful in the final analysis.

S. Herbert Hare,* Esq. (by letter).—The writer has had an opportunity to watch the development of this type of slab under Mr. Perry's supervision in

* Kansas City, Mo.

street paving at Longview, Wash., and has been much interested in the results. His interest, however, is not primarily in the strength, economy, or efficiency of this type of slab, which points are so ably discussed in the paper and which are so vital to the engineer, but in the appearance of the paving as laid on the streets. Any longitudinal joint, whether continuous or broken, appears very conspicuous in the perspective view as one drives down the street. The hexagonal joints, having no sides parallel to the curb, soon lose themselves from view. In most cases they cannot be seen farther than 150 to 200 ft. away. Beyond that the pavement appears as one unbroken slab.

Although often secondary from the point of view of the engineer, the esthetic effect of any paving is quite important to those who use the street, especially when such paving is used on boulevards and parked roads, as in Longview.

JACOB FELD,* ASSOC. M. AM. SOC. C. E. (by letter).—The author plainly states his thesis and proves it. The right-angled corner is a pronounced weakness in a pavement. Both experimentally and theoretically, he shows why right angles should find no rightful place in a pavement design. Then, as a solution to the problem, he recommends the use of hexagonal units, noting as special advantages the decreased danger from temperature changes and the elimination of the right-angled corners. However, as is plainly seen in Fig. 6, the proposed type does not eliminate the right-angled corners along the outer edges of the pavement. It is along these edges that the greatest stresses occur and to allow for these, Mr. Perry recommends greater thickness of the slab along the edges—the same remedy as is used in present-day construction.

There is no special advantage in having the intersections of the joints with the edges staggered; nor is the elimination of the square joints from the center line of great importance. The advantage gained from the use of smaller units can be just as easily obtained by increasing the number of expansion joints in the square arrangement. The elimination of the straight center joint takes away the common traffic line, separating the streams of travel. There is no doubt that hexagonal slabs are of special value in paving large areas, as shown in Fig. 5, and should be used in such cases, especially since their cost is no more than that of square slabs.

A useful application of the hexagonal idea for soil bearing is for column footings. A hexagonal footing contains the same volume of concrete as an equivalent square footing, with somewhat less steel reinforcement and a smaller area of forms. The cost is practically the same. Hexagonal footings are used only where space limitations govern, or for extremely large loads as, for example, high stacks.

The author has brought out a novel idea and has proven its advantages; but the writer cannot see where its use can be justified in the ordinary type of pavement.

H. O. ROOT,† ESQ. (by letter).—The theory of the hexagonal design of concrete pavement is simple and has been ably handled in this original paper. There may be, however, some question in the minds of many engineers as to

* Cons. Engr., New York, N. Y.

† Los Angeles, Calif.

its practicability. The writer, having had two years of field experience in laying the hexagonal design, feels that a detailed description of field methods would be a fitting contribution to this discussion.

Narrow Streets and Highways.—When the street or highway is of such width that it can be screeded successfully from edge to edge and the design is a single staggered center joint, the placing of the interior joints is very simple.

The start is a matter of special plan in each case, and, if made from an existing straight pavement edge, will result in one smaller and one larger slab, the end of the first length of center joint being brought to a point off center the required distance at the end of the first transverse joint.

Assume, for illustration, that the pavement is to be 24 ft. wide and that the design calls for a single staggered center joint of 10-ft. lengths. These will form 120° angles with intersections 2.5 ft. off center, and the transverse joints from these points to the edge will be 9.5 ft. in length.

The contractor provides metal "saws", or strips, in both the 9.5 and 10-ft. lengths. One end of a 10-ft. saw is secured to the first fixed angle point established, its free end is brought to an intersection with a 9.5-ft. saw and the latter adjusted to be at right angles with the edge. The location of each 10-ft. center length is, therefore, automatically established by bringing it to meet the end of the next 9.5-ft. transverse joint. The transverse joints can be kept square with the edge by eye and should fall at intervals of 17.32 ft. on each edge.

Intersections of streets must be carefully planned in advance, and it may be necessary to shorten or lengthen two or three panels at the end of a block so as to join in correctly with the intersection plan. Thin boards are used instead of metal saws where odd lengths are required. When panel plans of both block and intersection are supplied to the field engineer and the inspector, there need be no delay to the mixer while constructing irregular layouts.

The fact that the intersection of the center joint with the transverse joint falls off center gives the joint setter more freedom of action, for he is not required to work directly under the boom of the mixer, and the to-and-fro movement of the bucket does not interrupt him, nor does his work in any way interfere with the rapid deposit of concrete by the mixer operator.

Experience proved that it was more efficient to move the mixer and pull up the power sub-grade drag only far enough to allow one length of center joint and one transverse joint to be set at a time. These short moves can be made without loss of mixing time and tend to simplify the organization of the work on the sub-grade and joints between the mixer and the line of deposit.

Actual experience covering two seasons' work and a yardage of more than 400 000 seems to warrant this assertion, that the hexagonal design actually makes for higher efficiency and, therefore, for better progress and lower costs than is usually attained with the standard rectangular design.

Wide Streets.—When the improvement is of such width that it cannot be laid completely at one trip, it is necessary to set one straight form outside the

line of hexagon points to be laid in the first operation. The sub-grade may then be brought to correct crown and grade by a template drag riding on this false form and the curb, or edge, form.

The contractor provides a supply of 3-in. form lumber, of a width equal to the thickness of the pavement. These pieces are cut so that the ends have a bevel of 60°, the two bevel cuts being parallel, and the face length equal to the designed length of the joints. The straight false form is marked off in panel-length intervals and the extreme ends of two beveled pieces are brought to these marks; their adjacent ends are then brought together on the grade and secured by staking. The setting of these forms in pairs to the marks on the false form is a simple operation and increases only slightly the whole cost of form-setting.

The concrete is then struck off, tamped, and finished, all from the false form; the beveled forms are merely trued up to the rod as it passes over them. Longitudinal expansion joint material is placed with the first strip, flush with the form, and secured to the concrete by small nails driven through flat tin flashers, adequately spaced and located near the top of the pavement. This holds the material firmly against the concrete and prevents loosening and flopping after the forms are removed.

A long straight-edge should be used on the projecting points of concrete during the finishing process. It is important that these areas be reasonably true as to surface contour, for they must fit the crown of the tamping rod as it idles over them during the laying of the adjacent strip.

The beveled forms may be removed and used elsewhere the following day, but the false form should be left in place. The remainder of the sub-grade, or such part of it as will be required for the next run, may be brought to its true crown by means of the template drag sliding on this form. The open triangles between the form and the old concrete must be smoothed up by hand. After the sub-grade has been struck off and before the concrete is placed, this false form should be removed and all tamping and finishing done from the hardened surface of the old concrete.

Here, again, it is important that the long straight-edge be used carefully where the triangles of new concrete mesh in with the old. A series of humps or hollows, even if slight, occurring as they do at regular intervals, will seriously affect the riding qualities of the pavement. As the difference in cost between a smooth finish and a rough one is probably less than 1 cent per sq. yd., it is the writer's opinion that the public would gladly pay this difference and secure the better riding quality.

Wide Areas.—Alternate tiers of hexagons may be laid between false forms as described previously, the filler tiers being screeded and finished to the surface of the old tiers, with no forms other than division boards.

General.—Complete separation of the slabs from one another is important. Careful edging and complete separation will prevent spalling and the subsequent raveling at corners and along joints. The longitudinal joint material

may be run continuous through the three-way intersection and all splices made to occur at least 2 ft. from the angle. The concrete deposited in the angle of the continuous joint tends to keep it butted firmly against the end of the transverse joint. It is possible that some metal clip device could be used to hold the end of the transverse joint in true position.

Where manholes occurred on or near the line of joints, the joints were broken and turned to intersect them squarely. An extra thickness of concrete was put in to compensate for any section reduction caused by manholes, inlets, or other features.

An instrument crew can be kept steadily employed with each paving mixer, staking and checking forms, laying out intersections, and checking crowns on both sub-grade and finished concrete. Close co-ordination in this respect is reflected in the progress, quality, appearance, and cost of the finished work.

Conclusions.—The laying of hexagonal slabs is not as difficult as appears at first glance. The radical change in design is not confusing to workmen and even ceases to be a novelty after the first few panels have been laid. The design permits of a highly efficient organization of the labor, which, in turn, results in rapid progress and low costs for the contractor. The item of increased cost soon disappears under the pressure of competitive bidding.

The methods here detailed will no doubt be improved by other engineers and contractors when the use of the hexagonal design becomes more general. It is with this thought in mind that the writer presents this discussion, more as a basis for further refinement in practice than as a set of hard and fast rules.

WESLEY VANDERCOOK,* ESQ. (by letter).—The fact that such widely different views are held concerning the essentials of concrete pavement design should promote research of the character reported in Mr. Perry's paper. Even if no definite refinement of design resulted from this work, the subsequent investigations on a larger scale (which, unfortunately, are not reported in the paper) and the better acquaintance with the causes and character of typical failures in pavement slabs have completely justified the effort made.

It seems necessary to the intelligent discussion of the paper to note that the designer of this type of pavement is among those who believe in segregating a pavement into certain definite slab units and eliminating cracking by meeting Nature "half way". To this school of thought the paper should be of interest, if not of value. There still are, however, adherents to the custom of constructing pavement in slabs of full width and in excessive or indefinite lengths, who rely on Nature to use her best judgment about cutting them up into smaller units.

Serious consideration of the paper pre-supposes that the former group of designers is thinking rightly, which leads to the question of slab sizes. Since the structural effect is of prime importance, probably the soundest argument for moderate slab sizes is the fact that the expansion of over-sized slabs, with insufficient expansion provision, sets up compressive stresses which express

* Chf. Engr., The Long-Bell Lumber Co., Longview, Wash.

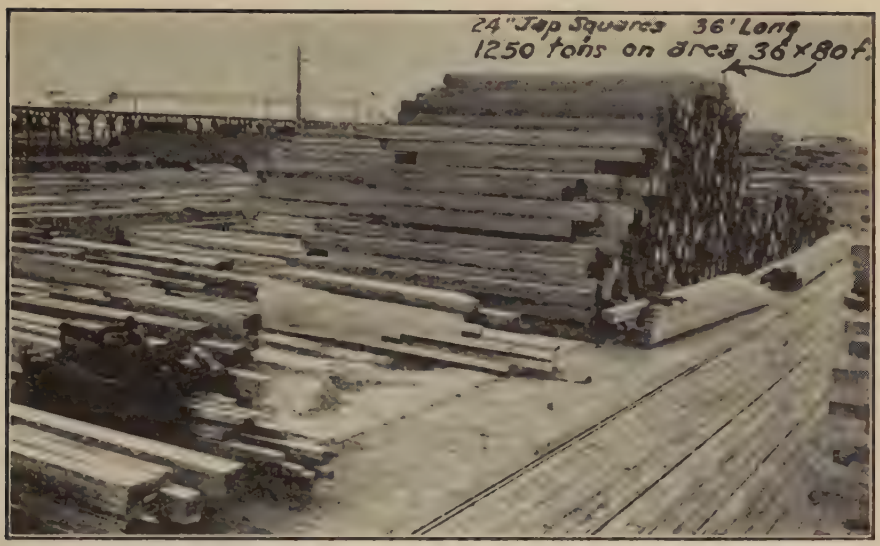


FIG. 12.—VIEW OF HEAVY STORAGE OF LUMBER ON HEXAGONAL SLAB PAVEMENT, LONG-BELL LUMBER COMPANY, LONGVIEW, WASH.

FIG. 13.—VIEW OF LOADING AND TRAFFIC ON HEXAGONAL SLAB PAVEMENT. SAME CONSTRUCTION AS SHOWN ON AUTHOR'S FIG. 5 AND IN FIG. 12.

themselves in transverse flexure. This becomes harmful when sympathetic transverse loading is applied and probably accounts for much pavement breakage. Random transverse cracks often follow local lines of least resistance and frequently terminate at the edge with an acute corner, which suffers under cantilever loading even more heavily than the right-angled corner. In the case of city streets, of course, this is not as serious as on highways, where the traffic is concentrated along the edge.

Probably the best argument in favor of the relatively long slab is the apparent saving in first cost of expansion joint material. The writer, however, questions whether within a few years, this saving, and more, has not been lost in the "hot pot" by the maintenance crew. Certainly the appearance of pavements, especially of city streets, is highly important, even if secondary to utility, and, in the writer's mind, cracks in a pavement, whether raw and raveled or treated with asphalt, are decidedly unsightly. It is unfortunate that the logical asphalt treatment serves to accentuate these flaws.

The writer, therefore, endorses the practice of segregating pavements into slabs, sized as nearly as may be to the ideal unit. Probably the size will vary with conditions, in fact, all the conditions having a bearing on the correct slab size may not be known as yet. Some of these conditions are range of temperature, character of subsoil, width of roadway, position of loading concentrations (if defined), and the correlated consideration of slab shape, which the paper discusses.

Of these conditions perhaps the most important is temperature. A survey of existing pavements in Longview, Wash., indicates that the maximum slab area may be fixed by the formula:

$$A = d\,y$$

in which,

A = the area of the slab, in square feet;

d = the depth of the pavement, in inches; and

$$y = 100 - \left(\frac{\text{temperature range, in degrees Fahrenheit}}{2}\right)$$

For a local temperature range of 100° this would set the maximum size of a 7-in. pavement slab at 350 sq. ft., and for a range of 140° at 210 sq. ft. Subgrade conditions in any given locality, of course, enter into this determination. The foregoing values seem logical for the local conditions, and this rule should be followed only when the slab is compact in shape, preferably hexagonal. In Longview the minimum slab area is fixed by a minimum weight of 7 000 lb. It is not to be expected that these empirical rules will hold good for any or all localities, but they may suggest a logical measure of safe dimensioning whereby slabs may be intelligently designed rather than merely jointed according to some custom that may have been established under dissimilar conditions.

Professor Hooper probably would not have considered his objections to this type applicable or important had he had an opportunity to watch closely its development, and the apparently highly successful performance of the resulting improvement. His comment seems to be directed chiefly at this design as

applied to narrow street or highway pavements, as shown in Fig. 6, and has apparently missed the importance of the increased transverse section at mid-slab. Professor Hooper does not comment on the advantages of this principle for a street three, four, or five panels in width. Certainly, the wider the street the greater will be the number of corners and the greater the value of the design.

Fig. 5 was taken immediately after construction; Figs. 12 and 13 show the normal heavy traffic and storage on this pavement. It is 6 in. thick and was built on a hydraulic sand fill of from 6 to 35 ft. in depth. The slabs are slightly in excess of the allowable area as determined by the formula, being 314 sq. ft. Since this improvement shows no signs of structural defect after twenty months of this usage, it is considered reasonable proof of the fitness of the design. The writer doubts whether any other type of pavement at the same, or nearly the same, cost would have proven as satisfactory.

The author compares the 6-in. hexagonal corner with the 7-in. rectangular corner, which no doubt is correct reasoning. The writer, however, cannot agree with the implication that it is good practice to minimize the thickness of pavement of hexagonal design in the interest of first cost economy. It is thought that, except in rare cases where maximum loading is fixed for all time, it is better practice to maintain depths heretofore considered standard and enjoy the increased value of the improvement by reason of the design, rather than to hold to capacities of existing standards at reduced cost. In this connection it may be remembered that the structural value of the slab itself increases with the square of the depth, whereas the cost does not quite vary directly with the depth.

The hexagonal design has passed the experimental stage, has proved to have structural merit peculiar to its shape, and is of considerable economic value. The 120° corner has been found approximately 50% stronger than the 90° corner under cantilever loading on sub-grades. It is doubtful whether this value can be ignored by engineers. While it is questionable whether this type will find immediate acceptance by designers, because conservatism in the engineer is a virtue, the writer ventures the prediction that this principle will find favor when it has been investigated in theory and practice as thoroughly as it has been by Mr. Perry.

Lewis A. Perry,* Assoc. M. Am. Soc. C. E. (by letter).—A review of the discussion indicates that the writer has wrongly made the paper too brief, assuming the reader's understanding of facts and theories implied, rather than presenting them.

Fig. 14 will serve to illustrate the reference to the added breadth at mid-slab of the fractional hexagonal slab, shown in Fig. 6. It is surprising that this point has been missed or considered unimportant by some members. Slab (*a*), 10 by 20 ft., is typical of the design of the excellent pavements built by the Highway Department of the State of Washington; Slab (*b*) is identical with those shown in Fig. 6. In the design of the theoretical slab, indicated

* Constr. Engr., The Longview Co., Longview, Wash.

by the upper diagrams of Fig. 14, end concentrated loading was assumed, the slabs then being inverted and computed as simple beams. In both cases the sub-grade is assumed to be uniform, and resistance to flexure is not considered. There is also a fallacy of compensating bearing values at the ends, but as these conditions are common to both slabs, and as the loading and depths are equal, the resulting wide difference in the failure areas is a true indication of the superior value of Slab (*b*). This value, of course, will be realized first when "curling" occurs, and contact with the sub-grade at the ends of the slab is lost. The fact that the distance between the loads is not identical has no bearing as the distance between concentrations varies in actual practice. It should be borne in mind that these loads are not actually maximum safe loads, but are theoretical values used to compute moments. The actual safe load of Slab (*b*) is probably four times the load used here. In these computations plain concrete is assumed to be stressed to 300 lb. per sq. in. To simplify computations deepened outer edges are omitted, although in practice both designs include this feature; also, shear bar connections along the inner edge of Slab (*a*) are not considered because they do not serve the companion slabs when both are similarly loaded, and, further, because the effective life of shear bars, under these conditions, is limited.

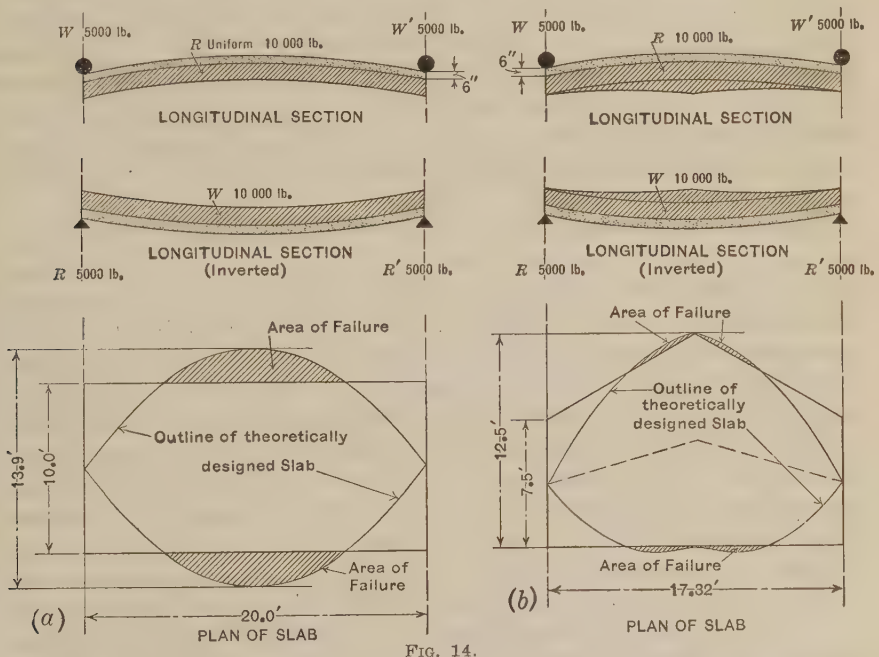

FIG. 14.

It should be noted that the dimensions of Slab (*b*) might be varied to benefit the slab structure. It is a good rule, within reasonable limits, to make the length of the diagonal center joint 1 ft. less than one-half the roadway width. In this case these joints would become 9 ft. instead of 10 ft. The writer has constructed some 20-ft. pavement by each method but as practi-

cally no cracking or breakage has occurred in either it is not possible to state which will show the better behavior. The shorter slab, with "dummy joints," is preferred by the writer.

The lengths of joint filler in these two designs are:

Slab (*a*).....0.900 lin. ft. per sq. yd.
Slab (*b*).....0.909 lin. ft. per sq. yd.

Thus, Professor Hooper's objection concerning the quantities of joint filler is correct only to this extent.

The question of the advisability of a grouping of free slabs has been discussed at considerable length by Professor Hooper, and the writer values his opinion, except that in his illustration buoyancy of water has been used to illustrate sub-grade fluidity or elasticity. This comparison does not seem fitting.

The writer believes that something more satisfactory than either the steel bar tie, or absolute slab freedom, exists in the "dummy joint" developed by Messrs. W. H. Tiedeman and H. F. Faulkner, Assistant City Engineer and Engineer of Tests of the City of Seattle, Wash., respectively. This "dummy," which is a narrow strip of joint filler, is inserted, with the aid of a T-bar template, into the plastic concrete after finishing, and penetrates about one-third of the depth of the slab; subsequent cracking is then controlled and does not show on the surface, and there is a frictional connection between slabs that the writer considers very valuable. Complete joints are placed at regular intervals to provide for expansion. This type of joint may be finished easily and is excellent in appearance; the writer is now using it in connection with the hexagonal design.

Professor Hooper has evidently meant by his reference to the "geology-topography-climate combination," that, in his opinion, the tests reported do not define the fitness of the slab design, because these tests were not correlated with sub-grade studies. The writer cannot think of anything that would have detracted more seriously from the value of the paper than to have confused slab structure with soil mechanics. The latter subject is a comprehensive study in itself, which is being investigated by some of the ablest engineers. It is to be hoped that they will arrive at something more definite and scientific than reliance on human judgment. The writer is, as yet, unversed in the science of soil mechanics, and the assumption that this ignorance condones illogical slab sizes and shapes would be evidence of unfitness for the tasks before the engineer. The questions of slab design and soil mechanics are equally important. A good slab will fail on a poor sub-grade; a poor slab will fail on a good sub-grade; and a properly designed slab has a much better chance, on any sub-grade, than one of illogical shape, depth, and size.

Professor Hooper believes:

"It is conceivable, therefore, that, in spite of the apparently greater strength, the hexagonal slab would break down under as light or lighter traffic than the rectangular slab."

Except in the rare cases where street widths, and other conditions defining traffic lanes, are fixed for all time, load concentrations must be considered to be generally distributed as to transverse location; and that even if traffic is temporarily localized ("traffic" is generally understood to mean standard motor vehicles up to 12 tons, which, however frequent, should have no effect on a well-designed and well-built concrete pavement*), the great majority of initial failures are caused by the movement of occasional excessive loads, such as heavy construction equipment. These initial failures then progressively expand and become increasingly evident under standard motorized traffic so that the layman and sometimes the engineer fails to fix the responsibility on the right kind of "traffic". The point is that such occasional excessive loads do not necessarily follow, but, in fact, frequently avoid, traffic lanes, and if the improvement is designed with assumptions regarding locality of traffic—even admitting that a Utopia exists where the American motorist even temporarily drives where he is wanted, and the power shovel goes somewhere else, which is to be desired—the designer's plans have seriously miscarried.

The writer has in mind an instance that may be illustrative. In July, 1924, a 12-ton, gasoline-propelled road roller was moved three city blocks along 21st Avenue, Longview, Wash. This pavement was 24 ft. wide and 6 in. thick, having straight longitudinal joints, the slabs being 12 by 20-ft. (rectangular) and the concrete about 12 months old. Cars were parked next to the curbs in places, which forced the movement to the center line and brought concentrations on slab corners. Thirty-six corner fractures developed, which under subsequent standard traffic suffered to the extent that repairs were necessary. Later, the same load was moved over an adjacent fractional hexagonal slab pavement, also 24 ft. wide, but only 5 in. thick, and about 3 months old. The same conditions of loading occurred and the subgrades on the two streets were identical In the latter case no fractures of any character have resulted, either from this loading or the subsequent standard traffic. Since that time many such instances, permitting comparisons of the two types, have occurred, which fix in mind three facts, namely: First, the occasional excessive loads that amount to probably only 1% of the traffic tonnage and 0.1% of the traffic count cannot be relied on to follow fixed traffic lanes; second, that such loads do probably 95% of the damage, which in most cases is initiated by simple corner fractures; and, third, that the substitution of the 120° corner for the common 90° corner materially reduces, if not practically eliminates, this breakage.

* The writer has determined to his own satisfaction, from experiment, that a 6-in. hexagonal pavement slab will fail at about 12 tons cantilever loading on each corner, or 24 tons total restrained load.

Conditions bearing upon this determination are:

Sub-Grade.—Uniform and sandy and not less than 1 500 lb. per sq. ft. bearing value, without deflection.

Concrete.—5 U. S. gal. per sack of cement (about 4 400 lb. per sq. in. compression).

Curing.—10 days under water, 18 days drying in air. Average daily temperature 60° Fahr.

Size of Slab.—16 ft. across opposite corners.

By stressing concrete one-third its ultimate strength this type of improvement is eminently fitted for 8 000-lb. wheel loads, but the writer would recommend heavier slabs under abusive traffic conditions and, under all conditions, careful sub-grade treatment.

It may be true that State or city laws should be enforced to prohibit abuses. On the other hand it is also true that the building of cities requires the use of certain heavy tools, which must go from one task to another, and while it is manifestly unjust to build with public funds improvements suitable for 0.1% of the traffic, it is also improper to disregard design refinements which materially increase loading capacities without additional cost.

Figs. 15 and 16 illustrate how unwise it would be for the designer to make assumptions concerning the transverse location of traffic on a wide street. The situation changes with parking restrictions, density of traffic, crown of street, and future widenings. It is correct, therefore, to assume that any weak spot between curbs will be found and punished; and to try to eliminate those weaknesses in design rather than to repair them later at considerable cost, and with sacrifice of street appearance. Fig. 15 also illustrates that, under the conditions shown, a rectangular slab pavement frequently comes under the objections raised by Professor Hooper to hexagonal slabs, namely, that the corners are generally in the path of traffic.

A pointed illustration of the fallacy of Professor Hooper's objection to the number of corners of hexagonal slabs would be to consider a circular slab (which is admittedly an ideal shape) the radius of which is, say, 8 ft. and the perimeter of which is cut into 1-ft. chords. It remains essentially a circle, with all its virtues, but with about fifty corners. If, however, a limited number of corners were desired, and the designer went to extremes, he might make slabs of equilateral triangles, having only three, instead of fifty, corners. A slab of this type, and of an area equal to the circle, would have sides about 21.6 ft. long, the corners of which develop less than 16% of the breadth of the corners of the former shape, yet this shape would use 27% more joint material. It is seen, therefore, that the number of corners and their locations are immaterial as long as each corner is structurally fit, and it is well to remember that breadth as well as depth of members fix their section moduli.

Professor Hooper has referred to the "regular zigzag line or joint" as "a possible source of confusion to drivers." It is to be assumed that this observation was made without due consideration. It has been necessary to photograph the slab layout from a great height to show the joints.

The question regarding curling at corners due to temperature raised by Professor Hooper, but left "up in the air" by him, is important. The curl is proportional to the slab length. The "aggravated condition" is roughly proportional to the curl, and inasmuch as, for the hexagonal slab, the extreme cross-corner length is about 90% that of a square slab of equal area, it follows that the hexagonal slab suffers less than 90% of the "aggravated condition" of the square slab.

The question of appearances raised by Mr. Hare is, as he states, "secondary" to that of utility, but is still important. In perspective, from the driver's eye, this design takes on a suggestion of uniform texture from curb to curb that is quite pleasing, and not possible with straight center points. On highways, and elsewhere, where lines for traffic division are desirable,

FIG. 15.—VANDERCOOK WAY, LONGVIEW, WASH., EXAMPLE OF 8-INCH RECTANGULAR SLAB PAVEMENT.

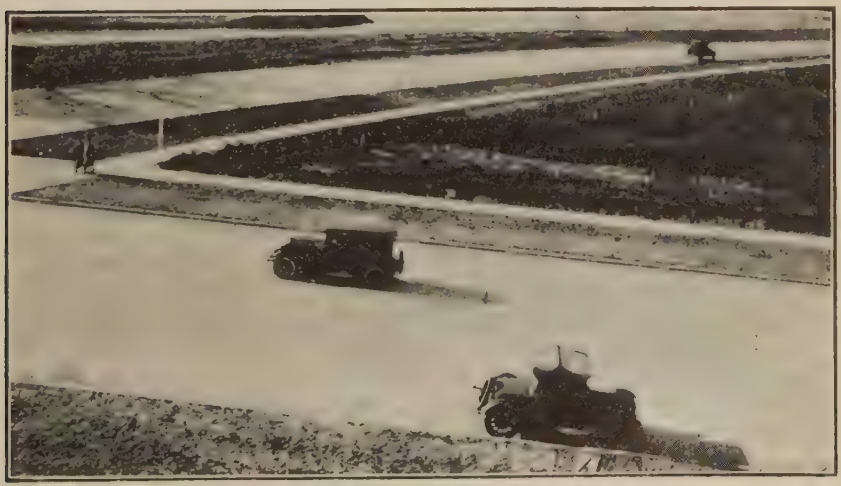

FIG. 16.—WASHINGTON WAY AND KESSLER BOULEVARD, LONGVIEW, WASH., EXAMPLE OF 6-INCH HEXAGONAL SLAB PAVEMENT.

they must be frequently re-painted for clearness, which is also true of the hexagonal design.

The writer thinks that Mr. Feld might revise his statement that "there is no special advantage in having the intersections of the joints with the edges staggered," after careful consideration of Fig. 14; and that he intended the statement, "nor is the elimination of the square joints from the center line of great importance," to apply to highways or narrow streets. Even with this qualification the writer cannot agree. It is thought that each street width presents a new application of the principles, all of which have not been considered by Mr. Feld. The writer regrets that Figs. 14, 15, and 16 were not submitted with the paper for the better information of members in discussion.

Mr. Feld has referred to the "ordinary type of pavement" meaning probably highway pavements, and his approval of the hexagonal design for "large areas" leaves the writer wondering what his judgment would be of widths "in between," such as a street pavement from 30 to 100 ft. in width. Surely all common widths are "ordinary," and many are what the writer would call "large areas."

Mr. Root's discussion has fittingly been a description of construction methods. This should be of great importance to engineers, especially since, in the construction of the work illustrated in the paper, some enviable progress records have been made, and the general consistent weekly averages have exceeded any others known to the writer.

It is thought that Mr. Root's reference to "complete separation" is meant to imply approval of moderate slab size without steel bar connection. The writer believes that the "dummy joint" will fulfill Mr. Root's requirement of complete separation. Certainly, the existence of joint filler for the top 2 in. of the slab will serve to "prevent spalling and the subsequent raveling" of the surface. It is not probable that the bottom of the controlled crack will spall; in the event this did occur, no harm will be done.

Mr. Vandercook has a geographical advantage over some other discussors, in that he has been in intimate contact with the work described, from its first consideration, and in that the same and many other objections and questionings that have been raised in the discussions, were carefully considered by Mr. Vandercook before he sanctioned the writer's extensive use of the new design.

Mr. Vandercook's reference to the inadvisability of reducing the thickness, by reason of the hexagonal design, is the expression of a valuable opinion. This is a question of economic policy, to be determined by the local conditions, such as community finances, the traffic anticipated, and the nature of the sub-grades; and it is probable that the general trend in pavement construction will be toward higher safety factors, because in few cases can it be said that loading limits are fixed, or even anticipated, "for all time."

The "subsequent investigation" referred to by Mr. Vandercook was a series of tests of square and hexagonal pavement slabs under cantilever loading of corners.* Briefly, the average results may be reported, as follows: (*a*) 5-in.

* *Engineering News-Record*, October 8, 1925.

hexagonal slabs bore 23% greater loading than 6-in. square slabs of equal area; and (*b*) 5-in. hexagonal slabs bore 48% greater loading than 5-in. square slabs of equal area. The slabs were cast *in situ* on a water-settled sand subgrade. The individual breaks were remarkably uniform.

The purpose of the paper has been to draw attention to the possibility of enhancing the value of this logical type of road surface by intelligent consideration of the slab shapes. It pleases the writer to think that, in a measure, this has been done; and to thank those engineers whose discussions have furthered this purpose.

A REVIEW OF THE WORK OF THE UNITED STATES PUBLIC HEALTH SERVICE IN INVESTIGATIONS OF STREAM POLLUTION

By W. H. Frost,* M. D.

In March, 1901, Congress provided for the erection of a laboratory by the United States Public Health Service, "for the investigation of infectious and contagious diseases and matters pertaining to the public health," and in the same year a Division of Scientific Research was organized in the Bureau of the Public Health Service. Therefore, the year 1901 may be said to mark the establishment of systematic and continued scientific investigation as a recognized function of the Public Health Service. Considering the rôle which sewage-polluted drinking water was playing at that time in the spread of typhoid fever and other infectious diseases, and recalling that the membership of the Hygienic Laboratory Advisory Board included the great leader in sanitary science, Professor William T. Sedgwick, it was inevitable that attention should have been directed at once to the importance of comprehensive studies of stream pollution in relation to disease. That this was true is evidenced by frequently recurring references in the Annual Reports of the Director of the Hygienic Laboratory during its early years; but the number of other urgent problems was so great and the resources of the Laboratory so limited, that, for several years, work in this field was of necessity limited to occasional studies of local water supplies, undertaken usually in connection with investigations into the causes of the epidemic or endemic prevalence of typhoid fever in various localities.

In 1910, the first systematic investigation of the status and effects of sewage pollution in any large area was begun by the assignment of A. J. McLaughlin, Surgeon, U. S. Public Health Service, to make a survey of cities in the Great Lakes region, with instructions to investigate the extent of the pollution of their water supplies and its relation to the prevalence of typhoid fever and other water-borne diseases, and to examine State and municipal ordinances relating to its control. Upon the completion of these surveys and of the reports thereon, which were published as *Bulletins* of the Hygienic Laboratory, Dr. McLaughlin was assigned, by request of the health authorities of States bordering on the Missouri River, to make a survey of the sewage pollution of that stream. In this work, which was carried out during the summer of 1912, Dr. McLaughlin for the first time had the assistance of another officer of the Service and was enabled, through the co-operation of the health authorities of the States concerned and of certain cities on the river, to establish several laboratories and make a rather extensive series of bacteriological examinations.

* Surgeon, U. S. Public Health Service, in Chg. of Stream Pollution Investigations, Baltimore, Md.

By the time this work had been brought to a close, the International Joint Commission, established under the treaty between the United States and the Dominion of Canada, had taken up the question of regulating the pollution of international boundary waters; and on request of the Commission, Dr. McLaughlin was granted leave of absence from the Service to accept appointment as Chief Sanitary Expert and Director of field work in investigations undertaken by the Commission. These studies, although undertaken independently by the International Joint Commission, may, in a certain sense, be considered as an extension and continuation of the survey of Great Lakes cities previously undertaken by Dr. McLaughlin for the Public Health Service.

In the meantime, by an Act approved August 14, 1912, Congress had extended the function of the Public Health Service to include, among other added duties, that of investigating "the diseases of man and conditions influencing the propagation and spread thereof, including sanitation and sewage and the pollution, either directly or indirectly, of the navigable streams and lakes of the United States"; and in 1913 made a special appropriation, which has since been continued annually, for carrying out these provisions. The Public Health Service was thus enabled for the first time, in 1913, to establish field laboratories at such points in the United States as might be most suitable for special purposes and to employ a scientific personnel especially qualified to conduct investigations in various fields of research.

It was under this extended authority that, in the summer of 1913, a group of sanitary engineers, chemists, biologists, and bacteriologists was assembled and a beginning made on a concerted plan of investigations relative to stream pollution. As originally organized, the work undertaken comprised the following main divisions.

1.—Studies of the bio-chemistry of sewage and industrial wastes were undertaken at the Hygienic Laboratory under the direction of Mr. Earle B. Phelps, who was appointed in that year as Chief of the Division of Chemistry in the Laboratory. These studies were devoted especially to testing and developing the application of biological oxygen demand determinations to the measurement of the potential polluting effect of sewage and the capacity of streams for its oxidation, a field of research to which Mr. Phelps had already made notable contributions.

2.—Intimately connected with these was a series of studies, likewise under the direction of Mr. Phelps, but carried on for the most part at various points outside Washington, D. C., attempting, by means of experimental installations, to devise better methods for the treatment of various important industrial wastes, for which economical and effective processes had not previously been evolved.

3.—Under the direction of H. S. Cumming, Surgeon, U. S. Public Health Service, the present Surgeon-General of the Service, a study of the pollution and natural purification of the Potomac River was undertaken. The Potomac was selected as a type of tidal stream and special attention was

paid, in this study, to the effect of sewage from the City of Washington on the waters near the mouth of the river where important shellfish beds are situated. This investigation, which was completed in the summer of 1914, was then extended and continued as a survey of the sewage pollution of various coastal waters, with special reference to the contamination of shellfish.

4.—At the same time, in the summer of 1913, work was begun on a study of the pollution and natural purification of the Ohio River, which was selected as a typical large inland stream, receiving sewage, usually without treatment, from all cities on its water-shed, and, at the same time, being used by many of these cities as their source of water supply. Headquarters for this work were established in Cincinnati, Ohio, with subsidiary temporary laboratories at five other points along the river.

These several studies, although conducted by working parties organized into separate units, were closely knit together by being all under the direction of the Division of Scientific Research in the Bureau of the Public Health Service and by the intimate relations which were maintained between those in charge of the several organizations. In fact, they were considered and pursued, not as separate studies, but as interdependent parts of a common and general plan. They were all continued, substantially as originally organized in 1913, until 1917 when it was necessary to discontinue them in order to utilize their personnel in various other more urgent duties during the period of the World War.

By the latter part of 1919, when it was possible to resume the investigations, the original personnel had become much dispersed by necessary assignments to other duties and by resignations. Likewise, the funds available for these investigations, although not actually reduced to any great extent, were relatively diminished by the material increase in all scales of cost, so that in the re-organization it was necessary to discontinue the investigations of coastal waters, which had been brought to a fairly definite conclusion, and to re-establish the other work at a single base in Cincinnati, which has since served as central headquarters for experimental studies of stream pollution and as the base from which parties have been sent out for work in the field.

Shortly after this re-organization, the Surgeon General, recognizing the need for authoritative advice in the planning and conduct of these investigations, requested Dr. Stephen A. Forbes, Professor Emeritus of Biology at the University of Illinois, and Director of the Illinois State Natural History Survey; Dr. Edwin O. Jordan, Professor of Hygiene and Bacteriology at the University of Illinois; Langdon Pearse, M. Am. Soc. C. E., Sanitary Engineer of the Sanitary District of Chicago; and Earle B. Phelps, Consulting Sanitary Engineer, of New York, N. Y., to serve as consultants in studies of stream pollution. These consultants, meeting once or twice each year with the staff engaged in the investigations, and keeping in close touch with the progress made, have rendered generous and valuable assistance in shaping plans, devising methods, and interpreting results. Subsequently, Joseph W.

Ellms, M. Am. Soc. C. E., consented to serve as special consultant in studies of water purification processes and has had an active share in the development of investigations along this line.

Since 1919, the principal field investigations undertaken from this base have been:

1.—A study of the pollution and natural purification of the Illinois River, undertaken chiefly to check and extend observations previously made on the Potomac and the Ohio Rivers relative to the laws governing natural purification in streams.

2.—A survey of representative municipal sewage disposal plants in various parts of the United States, to collect information as to their efficiency and cost in actual operation.

3.—A collective study of municipal water purification plants, chiefly rapid sand filters, as operated in a number of cities on the Ohio River and elsewhere, with a special view to ascertaining more precisely the relations between pollution of the raw water and quality of the effluent under varying processes and conditions of operation.

Along with these field studies, experimental investigations have been consistently pursued in the Cincinnati Laboratory, chiefly along the following lines:

(*a*).—An attempt has been, and is being made, so far without notable success, to reproduce on a small scale, adapted for intensive experimental study, the phenomena of bacterial purification which are now known to take place in natural streams. This has included as a necessary item rather extensive research into the biology of various plankton forms in relation to bacterial purification.

(*b*).—Studies of the biological oxygen demand of sewage, industrial wastes, and polluted river waters have been continued in the endeavor to establish more definitely the laws governing the natural processes of oxidation in streams and to check and improve the precision of methods for making the determinations required.

(*c*).—As an extension of the collective study of municipal filter plants which was completed in 1924, experimental studies are now being made of the relation of the pollution of raw water to the quality of effluent obtainable by rapid sand filtration and chlorination, utilizing an experimental plant on the laboratory grounds which is designed so that the conditions of loading and of operation can be varied at will through a wide range.

In addition to these studies, which have been pursued at Cincinnati, work has been going on for several years at the Hygienic Laboratory, under the direction of Dr. William Mansfield Clark, in a study of the physical chemistry of coagulation, with special reference to applications in water purification.

It would be impossible within a brief space and is, moreover, not pertinent to this paper to relate in more detail the history of the various undertakings which have been outlined, nor will any discussion of the results be attempted. As far as they have matured, they have already been made generally available

in a considerable number of publications,* and some of them with the addition of some more recent data, have been discussed in the papers by Messrs. Theriault, Streeter, and Hoskins, which follow.

In conclusion, it will be more appropriate to review briefly the broad general considerations which have determined the scope and direction of such studies as the Public Health Service has undertaken in this field since it has been in a position to make and pursue any general plan, that is, since 1913.

The first consideration, of course, has been the limitation of available resources, which have sufficed in most years for the maintenance of a staff not exceeding six to twelve workers in the higher grades, enough to form a compact group for consistent work on definite lines, but obviously not sufficient to permit of any wide dispersion. The governing considerations in deciding on the use to be made of these resources have been: The existing status and trend of conditions with respect to sewage pollution in the waterways of this country; the status of sanitary science as applied to devising the remedial measures necessary to meet present and future conditions; and the facilities available through State and municipal organizations, independent institutions for research, and the Engineering Profession at large, for conducting such further investigations as may be required.

With respect to sewage pollution, the status in the United States was, in 1913, and is to-day, that the greater part of the sewage from cities, probably not less than 85 to 90% of it, is discharged without treatment into the most convenient stream. Where the dilution is insufficient for prompt oxidation and removal of the sewage, the result is the establishment of a gross nuisance in the immediate vicinity, offensive to the sense of decency and frequently injurious to the financial interests of the community responsible for the pollution. The remedy for this, however, is at hand, as the ingenuity of sanitary engineers, chemists, and biologists has already devised effective means for the treatment of sewage at reasonable cost, and self-interest may be relied upon to impel cities which suffer nuisance from their own sewage to avail themselves of this remedy. The abatement of such gross nuisance is usually a local matter, requiring no broad plan of concerted action between widely separated communities; and as the principles of the required treatment are already well established, such special investigation as is required is usually a matter of detail, to ascertain the particular process or combination of processes which will serve most economically and effectively in the particular case. Obviously, such investigations are the business of the State and local authorities and of the practicing engineers retained by them rather than of a Federal agency.

The more usual and more serious result, where dilution and current are sufficient to prevent immediate gross nuisance from the discharge of untreated sewage, is to contaminate the water supplies of other cities taken from the same river system at down-stream points, or, in the case of tidal waters, to dangerously contaminate waters from which shellfish are taken. In

* A list of the more important of these publications is given in the Bibliography appended.

the case of public water supplies necessarily taken from such polluted sources, the immediate remedy is artificial purification of the supply. For this, again, sanitary science has already provided the means in various processes of treatment, economically practicable and of such efficiency that they may be relied upon to give safe effluents from water which is highly but not indefinitely polluted. In 1913 there were, to be sure, a number of cities using dangerously polluted water supplies, but in every instance the remedy—installation of adequate water-purification works—was obvious, and such investigations as were required were not general, to ascertain the practicability of a remedy, but local and special, to decide upon the details of the installation best adapted to apply established principles to the problem at hand. It is clear that these local investigations, like those required for local sewage treatment installations, are not the function of the Public Health Service.

In general, the situation has been that, notwithstanding the customary practice of discharging raw sewage into streams, those cities which have had to take their water supplies from the rivers thus polluted have almost invariably been able, by applying established processes of artificial water purification, to secure water supplies of good, safe quality. This has been true because the volume of the larger rivers is such as to afford great dilution, even for the sewage of the larger cities, and because the distances between the sewer outlets of these cities and the water-supply intakes of other cities down stream are such as to permit of great reduction in pollution by the natural agencies of purification. Similarly, in coastal waters, although they are grossly polluted in the immediate vicinity of cities discharging sewage, there are still great areas sufficiently free from dangerous contamination to be suitable for shellfish culture. Consequently, local measures, namely, the installation of water-purification plants for safeguarding water supplies and the condemnation or local protection of the relatively small areas unfit for shellfish culture, have sufficed for immediate protection against the dangers of sewage pollution. The protection has not been perfect, but it has tended to become progressively better in recent years, as evidenced by the enormous decrease in prevalence of sewage-borne diseases.

Looking to the future, the conditions foreseen and the remedies which must eventually be applied, become more complex. With the growth of urban population, which still continues at a rapid rate, the sewage pollution of streams and coastal waterways must increase; and sooner or later, in the absence of anticipatory control, it seems inevitable that eventually the pollution will become such that water-purification plants of the highest attainable efficiency will not be able to deliver consistently safe effluents. To guard against this condition it will be necessary, perhaps in the near future, to limit the pollution of such inland streams as are necessary sources of water supply by such measure of sewage treatment as will suffice to keep the pollution at water-works intakes within definite bounds.

This, however, is an extraordinarily complex matter, not only from the administrative point of view, with which this presentation is not concerned, but equally from the scientific viewpoint. It implies a concerted plan of

control applied to an entire river system as a unit, a plan in which, presumably, each community will be required to limit its contribution of sewage pollution, not in the interests of its own citizens, but for the protection of other communities down stream, usually including cities in several States. Safety demands that the measure of control exercised be adequate; justice demands that it be distributed among the communities on some definite and equitable principle, and economy demands that it be not more rigid than is actually necessary to insure the requisite protection to health.

The data needed for laying out any such comprehensive plan for controlling the pollution of an entire river system, with due regard for the considerations of safety, equitable distribution of the burden of control, and economy, are as follows:

First.—It is necessary to have established some quite definite and objective criterion of the quality which is to be maintained in the water supplies taken from the river, as they are delivered to the consumers after artificial purification. This criterion or standard must be in terms of measurable characteristics, determinable by quantitative bacteriological or chemical examinations. It must be rigid enough to insure safety beyond any reasonable question, but not much more rigid than is actually necessary, lest it impose an excessive burden of costs.

Second.—It is necessary to have a fairly precise knowledge of the reliability and efficiency of such purification processes as can be applied at a reasonable cost to purification of the raw water available at the best practicable intake, for it is this efficiency, taken in connection with the standards set for the final effluent, that determines the upper limits of the pollution which may be tolerated at the intake.

Third.—It is necessary to know what proportionate part each of the sewered communities, situated at varying distances up stream, contributes to the pollution existing at any given intake, for otherwise it is impossible to estimate what effect elimination or reduction of the pollution from any single community will have in reducing the pollution in the intake zone. This, in turn, implies a fairly precise quantitative knowledge of the laws governing the processes of natural purification, and of how they may vary in different types of streams in relation to various climatic, seasonal, and hydrographic conditions, for it is only through such knowledge that these great protective processes which Nature has provided may be used most effectively; and not to use them is to waste a natural resource of enormous economic importance.

Unfortunately, sanitary science has not furnished such full and precise knowledge as will be required on any of these points, especially in regard to the natural agencies which tend so greatly and rapidly to reduce bacterial contamination and which constitute one of the main reliances for protection of health. Moreover, it seems unlikely that it will be possible to borrow this knowledge from the experience of other more densely populated countries, as the writer knows of no other country having similar problems in the control of stream pollution on a comparable scale and for a similar

purpose, that will probably have to be studied successfully before a solution becomes necessary for some of the great river systems in the United States.

It is with these considerations in view that the Public Health Service, with the advice of its consultants, has consistently directed its investigations of stream pollution along the lines described, devoting a large part of its effort to such undertakings as the attempt to improve technical methods for laboratory determinations, to evaluate the efficiency of filtration plants under the adverse conditions of loading which may be anticipated in the future, and to add something to the present scanty knowledge of the laws of natural purification. Information of this kind, even if it may seem at this time to be more or less academic, will be essential to sound sanitary engineering practice in the future. Moreover, it appears to be pre-eminently the kind of information that a Federal agency should collect, because it is of general, not local, application, and because it involves such long-continued and laborious investigations as are not likely to be undertaken by private agencies, or even by State and municipal organizations, busy as they are with more immediate administrative work, and with the necessary local studies incident to it.

However, while the Public Health Service is confident that this general policy is sound, it can not, of course, feel equally confident that the sequence which is being followed in the development of these studies is the best possible or that the methods which are being applied are always the most effective. For guidance in such matters the Service relies primarily on its special consultants, but, in addition, it always has sought and sincerely desires the criticism and constructive advice of the entire Sanitary Engineering Profession.

APPENDIX

BRIEF BIBLIOGRAPHY RELATING TO STUDIES OF STREAM POLLUTION, SEWAGE, AND WATER SUPPLIES.

The following is a list of the publications of the U. S. Public Health Service, relating to studies of stream pollution, sewage, and water supplies. The list includes only publications containing original data, omitting numerous articles which present general discussions of various topics.*

Sewage Pollution of Interstate and International Waters, with Special Reference to the Spread of Typhoid Fever: I, Lake Erie and the Niagara River.
A. J. McLaughlin. (*H. L. B. No.* 77 (1912); 169 pp.)

Sewage Pollution of Interstate and International Waters, etc.: II, Lake Superior and St. Marys River; III, Lake Michigan and the Straits of Mackinac; IV, Lake Huron, St. Clair River, Lake St. Clair, and the Detroit River; V, Lake Ontario and the St. Lawrence River.
A. J. McLaughlin. (*H. L. B. No. 83* (1912); 296 pp.)

* The abbreviations used in the Bibliography are as follows: "H. L. B.", *Bulletin*, Hygienic Laboratory, U. S. Public Health Service; "P. H. B.", *Public Health Bulletin*, U. S. Public Health Service; and "P. H. R.," Weekly Public Health Reports, U. S. Public Health Service. The reprint number is given where article has been reprinted separately. All these publications are issued from the Government Printing Office, Washington, D. C.

Sewage Pollution of Interstate and International Waters, etc.: VI, The Missouri River from Sioux City to Its Mouth.
A. J. McLaughlin. (*H. L. B. No. 89* (1913); 84 pp.)

Investigation of the Pollution and Sanitary Condition of the Potomac Watershed, with Special Reference to Self-Purification and the Contamination of Shellfish in the Lower Potomac River.
Hugh S. Cumming, with Contributions by W. C. Purdy and Homer C. Ritter. (*H. L. B. No. 104* (1916); 231 pp.)

Investigation of the Pollution of Tidal Waters of Maryland and Virginia, with Special Reference to Shellfish-Bearing Areas.
Hugh S. Cumming. (*H. L. B. No. 74* (1916); 199 pp.)

Artificial Purification of Oysters.
William F. Wells. (P. H. R., July 14, 1916; Reprint No. 351; 4 pp.)

Investigation of the Pollution of Certain Tidal Waters of New Jersey, New York, and Delaware.
Hugh S. Cumming. (*P. H. B. No. 86* (1917); 147 pp.)

Stream Pollution: A Digest of Judicial Decisions and a Compilation of Legislation on the Subject.
Stanley D. Montgomery and Earle B. Phelps. (*P. H. B. No. 87* (1917); 408 pp.)

Treatment and Disposal of Creamery Wastes.
Earle B. Phelps. (P. H. R., December 6, 1918; Reprint No. 496; 5 pp.)

Studies on the Treatment and Disposal of Industrial Wastes: I, The Treatment and Disposal of Strawboard Waste, by Harry B. Hommon; II, The Determination of Biochemical Oxygen Demand of Industrial Wastes and Sewage, by Emery J. Theriault and Harry B. Hommon. (*P. H. B. No. 97* (1918); 56 pp.)

Studies on the Treatment and Disposal of Industrial Wastes: III, The Purification of Tannery Wastes.
Harry B. Hommon. (*P. H. B. No. 100* (1919); 133 pp.)

Studies of Methods for the Treatment and Disposal of Sewage: Treatment of Sewage from Single Houses and Small Communities.
Leslie C. Frank and C. P. Rhynus. (*P. H. B. No. 101* (1919); 117 pp.)

A Further Study of the Excess Oxygen Method for the Determination of the Biochemical Oxygen Demand of Sewage and Industrial Wastes.
Emery J. Theriault. (P. H. R., May 7, 1921; Reprint No. 594; 11 pp.)

Studies on the Treatment and Disposal of Industrial Wastes: IV, The Purification of Creamery Wastes.
Harry B. Hommon. (*P. H. B. No. 109* (1921); 87 pp.)

Studies on the Treatment and Disposal of Industrial Wastes: V, The Purification of Tomato-Canning Wastes.
Harry B. Hommon. (*P. H. B. No. 118* (1921); 58 pp.)

Hypochlorite Process of Oyster Purification (Experimental).
F. A. Carmelia. (P. H. R., April 22, 1921; Reprint No. 652; 10 pp.)

The Loading of Filter Plants.
H. W. Streeter. (P. H. R., March 24, 1922; Reprint No. 737; 13 pp.)

A Study of the Pollution and Natural Purification of the Ohio River: I, The Plankton and Related Organisms.
W. C. Purdy. (*P. H. B. No. 131* (1923); 78 pp.)

Sewage Treatment in the United States: Report on the Study of Fifteen Representative Sewage Treatment Plants.
H. H. Wagenhals, E. J. Theriault, and H. B. Hommon. (*P. H. B. No. 132* (1923); 260 pp.)

An Experimental Study of the Relation of Hydrogenion Concentrations to the Formation of Floc in Alum Solutions.
Emery J. Theriault and William Mansfield Clark. (P. H. R., February 2, 1923; Reprint No. 813; 20 pp.)

Indicators for p^H Control of Alum Dosage.
Barnett Cohen. (P. H. R., April 6, 1923; Reprint No. 828; 2 pp.)

On the Composition of the Precipitate from Partially Alkalinized Alum Solutions.
Lewis B. Miller. (P. H. R., August 31, 1923; Reprint No. 862; 10 pp.)

A Study of the Pollution and Natural Purification of the Ohio River: II, Report on Surveys and Laboratory Studies.
W. H. Frost, H. W. Streeter, J. K. Hoskins, and R. E. Tarbett. (*P. H. B. No. 143* (1924); 343 pp.)

Adsorption of Aluminium Hydrate Considered as a Solid Solution Phenomenon.
Lewis B. Miller. (P. H. R., June 20, 1924; Reprint No. 932; 14 pp.)

A Study of the Pollution and Natural Purification of the Ohio River: III, Factors Concerned in the Phenomena of Oxidation and Re-aeration.
H. W. Streeter and Earle B. Phelps. (*P. H. B. No. 146* (1925); 75 pp.)

The Determination of Dissolved Oxygen by the Winkler Method.
Emery J. Theriault. (*P. H. B. No. 151* (1925); 43 pp.)

Some Preliminary Observations from a Study of Water Purification Plants Along the Ohio River.
H. W. Streeter. (P. H. R., January 30, 1925.)

A Study of the Effects of Anions Upon the Properties of "Alum Floc".
Lewis B. Miller. (P. H. R., February 20, 1925.)

THE RATE OF DEOXYGENATION OF POLLUTED WATERS

By Emery J. Theriault,* Esq.

The biochemical oxygen demand test to be discussed in this paper, although at present it enjoys a certain measure of renewed interest, is by no means new. The earliest record of such a procedure is probably to be found in a report published in 1870 by a British Rivers Pollution Commission. In France, oxygen demand determinations were made as long ago as 1885 in a study of the pollution of the Seine. In Germany, extensive series of experiments were conducted on the test from 1900 to 1911. In the United States, a modified procedure appears to have been used in the early experiments at the Lawrence Experiment Station, although it is only since 1915 that the method now in use has been more or less generally adopted.

It is significant both of the intrinsic merit of the biochemical oxygen demand test and, it must be admitted, of the numerous difficulties which arise in its practical application, that, in a recent bibliographical review, no less than 150 references were found which dealt directly with the subject. The consensus of opinion appears to be that the test is valuable. In fact, for the purposes of stream pollution studies, it is frequently the only chemical procedure which can be used to advantage. As a measure of the relative strength of various organic wastes and as a guide in estimating the efficiency of particular methods of treatment, the test also appears to possess decided advantages over the usual chemical procedures.

General Considerations

As regards the theory underlying the test, it is a well established fact that a polluted water containing bacteria, if exposed to air, tends to become completely purified. It has been repeatedly demonstrated that definite quantities of dissolved oxygen are absorbed during this self-purification process. It follows that the quantity of oxygen required for the complete stabilization of a polluted water may be taken as a measure of its organic matter content. In the simplest case, two glass-stoppered bottles are completely filled with the sample under examination. The initial dissolved oxygen content is found by analyzing one of these sub-samples at the beginning of the test. The other sub-sample is placed in a constant temperature chamber at 20° cent. After an arbitrarily selected time, preferably five days, the sample is removed from the incubator and its oxygen content is re-determined. If bacteria and organic matter were present, a decrease in the oxygen content is invariably observed. This decrease is then reported as the 5-day oxygen demand of the sample at 20° cent.

A limitation of this test as outlined lies in the fact that the saturation value for the dissolved oxygen content of water at 20° cent. is only 9 parts

* Associate Chemist, U. S. Public Health Service, Cincinnati, Ohio.

per million, corresponding to the 5-day oxygen demand of a highly purified effluent or a highly polluted water. With sewage effluents of average quality, a 5-day oxygen demand value of about 20 parts per million may be expected. Before the test can be applied, it is necessary, therefore, to dilute such effluents with five or ten volumes of fully aerated distilled water or tap-water of good quality. For raw sewages, the 5-day oxygen demand is generally greater than 100 parts per million, so that the samples must be diluted about fifty times in order to provide a sufficient supply of oxygen throughout the course of the test. Tannery and abattoir wastes possess oxygen demand values which range from 1 000 to 10 000 parts per million. With unusual trade wastes, 5-day oxygen demand values of 50 000 parts per million have been obtained. At the other extreme, the 5-day oxygen demand of good tap-water is about 0.5 part per million.

Various other methods of procedure have been proposed for determining the oxygen requirements of heavily polluted waters without resorting to dilution. The "excess-oxygen" method just described, inasmuch as it depends on the volumetric determination of dissolved oxygen, using ordinary glass-stoppered bottles, possesses the merit of extreme simplicity. Extensive series of experiments conducted at the Cincinnati Laboratory of the U. S. Public Health Service have amply demonstrated that the precision attainable leaves little to be desired even if it is necessary to dilute the samples before conducting the test. With suitable laboratory facilities, the dilution technique is simple.

A more serious limitation, and a limitation which is inherent in any method of procedure, is the necessity for interpreting the results in the light of time and temperature relationships. Owing to the fact that the rate of absorption of oxygen by a polluted water is exceedingly slow, it is generally desirable to extend the incubation period over several days. Again, as the reaction is purely biochemical, the temperature at which the test is conducted must be carefully controlled. In order to correlate the laboratory results with the ever-changing time of flow and temperature conditions of a stream, it is necessary, therefore, to obtain reasonably accurate formulas by which the oxygen demand of a sample after any interval of time at any specified temperature may be calculated from the values obtained under standardized conditions.

The experiments herein described, were undertaken, primarily, for the purpose of confirming the validity of the various time and temperature correction formulas which have thus far been proposed. The discussion will be limited to the formulas developed in the course of the Ohio River investigation.* These experiments have also demonstrated that factors other than time and temperature must be considered before a valid interpretation of the highly consistent results obtained with the "excess-oxygen" method can be made. In particular, the condition of a sample with respect to its state of oxidation and, possibly, the nature of the micro-organisms present, both exert a marked influence on the magnitude of the observed oxygen demand values.

* H. W. Streeter and E. B. Phelps, U. S. Public Health *Bulletin No. 146.*

Experimental Procedure

For the purpose of securing representative samples, a large vessel was first filled with Ohio River water or, in some instances, with sewage suitably diluted. After the sample had been thoroughly mixed, it was siphoned into bottles with capacities of 350 cu. cm. The initial oxygen content was then determined and the remaining sub-samples were incubated at 9°, 20°, or 30° cent. In the course of experiments which have extended somewhat more than a year, twelve separate series of observations have been made. In most cases, the course of the deoxygenation was followed for at least one month. As a rule the experiments were conducted in duplicate and, in several instances, comparative data were obtained at three different temperatures.

Precision of Base Data

The agreement between duplicate samples was excellent even when the incubation period extended over several months. In one series of experiments in which a large number of sub-samples were titrated after an incubation period of 96 days at 20° cent., the average deviation from the mean was found to be less than 0.2 part per million. The findings in this respect are of considerable analytical interest.

General Course of Deoxygenation Curve

Given the precision of the base data, the next step has been to plot the observed average oxygen demand values against the period of incubation. The type of curve obtained in a typical series of observations is illustrated by Fig. 1. The data plotted in this chart are probably unique in so far as they all refer to the same sample incubated at different temperatures over prolonged periods. It is also to be noted that the oxygen demand determinations were made at relatively short intervals, so that the general course of the deoxygenation curve is reasonably well defined. At 9° cent. (lower curve), there was a slight lag in the establishment of bacterial equilibrium. In other respects, however, there is a striking parallelism between the results obtained at different temperatures.

Considering only the results obtained at 20° cent. (middle curve), it is evident that the rate of deoxygenation decreased very uniformly during the first nine or ten days. Relatively small quantities of oxygen were absorbed during the next five or six days. After the sixteenth day, the rate of deoxygenation suffered a marked acceleration. It is also noteworthy that, contrary to a generally accepted notion, appreciable quantities of dissolved oxygen continued to be absorbed even after the twentieth day. As the same phenomenon has been observed with fully aerated samples, this secondary increase in the rate of deoxygenation can hardly be ascribed to the approaching exhaustion of dissolved oxygen. In fact, within wide limits, the rate of deoxygenation is quite independent of the quantity of dissolved oxygen present.

The evidence accumulated thus far is very favorable to a view emphasized by Adeney and other British experimenters, namely, that under aerobic condi-

tions the stabilization of organic matter proceeds in two distinct and strictly consecutive stages; the carbonaceous matter, etc., is first oxidized; then, and only then, does nitrification set in. The second point of inflection on the deoxygenation curve, therefore, marks the onset of the nitrification stage. It will be convenient to discuss these two distinct stages separately.

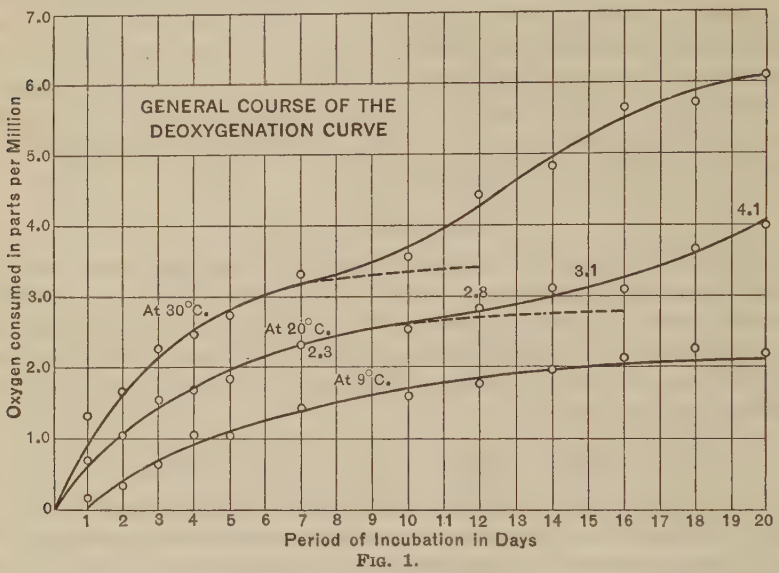

FIG. 1.

RATE OF DEOXYGENATION FORMULA

Considering only the average oxygen demand values corresponding to the first or carbon-oxidation stage, an attempt was next made to determine whether these results conformed with reasonable accuracy to a formula proposed some years ago by Phelps. The formula in question is based on the assumption that the rate of deoxygenation at any instant is directly proportional to the amount of organic matter present in a sample. In the differential notation:

$$\text{Rate of deoxygenation} = \frac{d\,(L_a - L)}{d\,t} = \frac{-d\,L}{d\,t} = K'\,L \ldots\ldots\ldots (1)$$

in which,

L_a = oxygen absorbed during the first stage.

L = oxygen requirement of the sample at the time, t.

K = a constant at a given temperature.

The integration of this expression leads directly to the equation:

$$\log \frac{L_a}{L} = \log \frac{L_a}{L_a - X} = K\,t \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which,

X = oxygen absorbed in t days (the value generally reported as the oxygen demand of the sample).

$K = 0.4343\,K'$ = the deoxygenation constant.

Solving for X in Equation (2), the following expression is obtained:

$$X = L_a (1 - 10^{-Kt}) \quad \ldots\ldots (3)$$

By the aid of tables giving the value of the term, $1 - 10^{-Kt}$, the validity of the Phelps formula may readily be tested. It is only necessary to observe whether a value of L_a exists which satisfies the condition imposed by Equation (3). The agreement between the observed and the computed values is represented graphically by the data plotted in Fig. 2, where the average values obtained in twelve separate series of observations have been recorded. In order to place all values on a comparable basis, and for the sake of avoiding a multiplicity of charts, the results have been plotted, not in parts per million, but as a percentage of the oxygen absorbed during the first stage of the deoxygenation. At each temperature, the line drawn through these average results is simply the graph of the expression:

$$X = L_a (1 - 10^{-Kt})$$

For periods of incubation of less than 8 days at 30° cent., 10 days at 20° cent., or 15 days at 9° cent., the agreement between the observed and the computed percentage values is excellent.

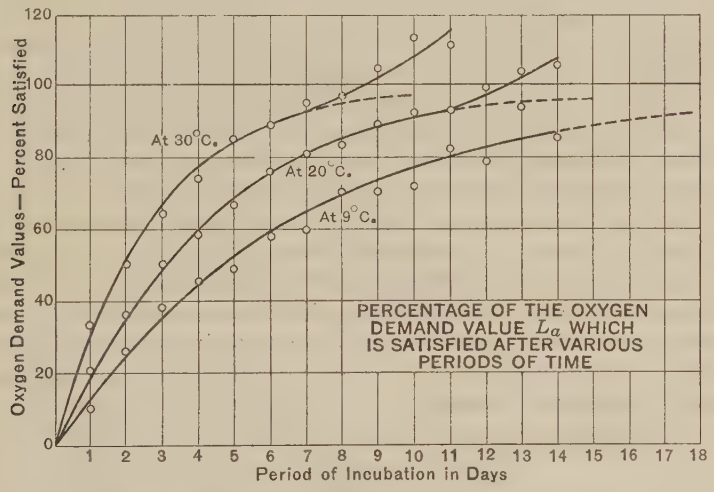

FIG. 2.

TEMPERATURE CONVERSION FORMULAS

a.—The Value of K at Different Temperatures.—It is also to be noted that in plotting the theoretical curves the value of K was computed by the equation:

$$K_T = K_{20} (1.047^{T-20}) \quad \ldots\ldots (4)$$

in which,

K_T = the deoxygenation constant at $T°$ cent.

K_{20} = the deoxygenation constant at 20° cent. = 0.100.

The indication is that, in the interval from 9° to 30° cent., the deoxygenation constant is accurately defined in terms of Equation (4).

b.—The Value of L_a at Different Temperatures.—One further point to be considered in connection with Fig. 2 is the value of L_a at different temperatures. Denoting the value of L_a at 20° cent. by 100, the value of L_a at 9° cent. becomes 78 ± 5. Similarly, the relative value of L_a at 30° cent. is 120 ± 7. These values may be represented empirically by the equation:

$$(L_a)_T = (L_a)_{20} (0.02\ T + 0.60) \quad \ldots\ldots(5)$$

in which,

$(L_a)_T$ = value of L_a at T° cent.
$(L_a)_{20}$ = value of L_a at 20° cent.

The failure to correct for this variation in the oxidizability of a sample with a change in the temperature of incubation does not lead to serious error when the temperature differences are small. In extreme cases a suitable correction can readily be applied.

Applicability of Formulas to Stream-Pollution Problems

Within certain limits, therefore, the possibility exists of converting an oxygen value obtained at any temperature over any period of incubation into terms of the oxygen demand value which would have been obtained under any other given set of conditions. It is to be borne in mind, however, that the applicability of the formulas is restricted to heavily polluted waters, such as raw river water or recently diluted sewage. By inspection of the data plotted on Fig. 1, it is obvious that an entirely different type of deoxygenation curve would be obtained if samples in a more advanced state of oxidation were to be selected. As it is seldom necessary to consider periods of flow exceeding five or ten days below a point of fresh pollution, these limitations are of little consequence in stream-pollution studies. On the whole, it appears safe, therefore, to conclude that, when the various formulas discussed in this paper are applied to the average values corresponding to reasonably large groups of observations on recently polluted water, the cumulative error should not exceed 10 per cent. For the purposes of stream-pollution studies, this degree of precision is entirely satisfactory.

Applicability of 5-Day Oxygen Demand Test to Sewage Treatment Problems

From the foregoing discussion, it may be inferred that for highly polluted waters the oxygen demand values obtained over relatively short periods of incubation possess a clear-cut significance, so that the interpretation of such results offers no difficulty. Attention will now be directed to samples which have reached a higher state of oxidation. The discussion will be conducted with particular reference to sewage treatment problems.

Considering the data plotted in Fig. 1, and assuming that the 5-day oxygen demand of the sample at 20° cent. had been determined only after a preliminary conditioning period of seven days, corresponding to the relatively flat portion of the deoxygenation curve, the observed depletion would have

been about (2.8 — 2.3) = 0.5 part per million. However, if the examination had been delayed for fifteen days, so that nitrification was about ready to start, the observed loss of oxygen would have been about (4.1 — 3.1) = 1.0 part per million. Referred to a sewage effluent which had been diluted fifty times before conducting the test, the two oxygen demand values obtained would have been 25 or 50 parts per million, depending on the amount of preliminary purification which the sample had received. It is noteworthy that under these special conditions the 5-day oxygen demand of the more highly oxidized sample was apparently twice as great as that of the same sample in a less highly purified state. In part, the discrepancy arises from the fact that one set of values has been selected from the relatively flat portion of the deoxygenation curve (8 to 14 days at 20° cent.).

The findings in this respect have a direct bearing on the calculation of the percentage removal of organic matter effected by a treatment plant, and on similar problems in connection with the operation or the comparison of various types of treatment plants. The usual procedure is to base such calculations on the 5-day oxygen demand value of the influent and effluent wastes. In the extreme case in question, it is obvious that the percentage values obtained would stand in inverse relation to the purification actually accomplished. It is not inconceivable that a good measure of the efficiency commonly attributed to Imhoff tanks and similar treatment devices may be due to an effect of this nature. For filter effluents, however, the maximum effect produced by the abrupt change in the slope of the curve may generally be discounted, because the nitrification stage should be fully established when such samples are examined. The possibility of error from this source is nevertheless to be borne in mind.

As regards the time required under laboratory conditions to effect the complete oxidation of the organic matter in a polluted water, definite conclusions can hardly be drawn. On the basis of nitrite, nitrate and free ammonia determinations, it is probably safe to conclude that, at 20° cent., the oxidation of the purely nitrogenous impurity is virtually completed after forty or fifty days. Appreciable quantities of dissolved oxygen, however, continue to be absorbed even after several months of incubation at 20° cent. (See Fig. 3.) The absorption of oxygen beyond the sixtieth day is probably due to the slow oxidation of cellulose-like materials. As it would be impractical to conduct routine tests over such extended periods, it is obviously necessary to conclude that the ultimate oxygen demand of a sample is an indeterminate quantity.

Continuing the discussion of the results derived over long periods of incubation, it appears that when a stage of oxidation has been reached corresponding to that which obtains when a sample of raw sewage is incubated for 30 days at 20° cent., the deoxygenation curve is approximately a straight line. (See Figs. 1 and 3.) The 5-day oxygen demand of a given type of waste, therefore, should be a constant when a sufficiently high degree of purification is reached. It follows that the percentage purification figures computed on the basis of the 5-day oxygen demand test should also tend to be constant when samples in an advanced state of oxidation are examined.

The findings in this respect are in satisfactory accord with the direct observation that the removal of organic matter effected by a representative group of treatment plants was always approximately 90% when partly nitrified effluents only were considered. In view of wide variations in the strength of the raw sewages, in the nature of the treatment devices, and in the methods of operation, this approximate constancy* of the percentage purification values obtained was an unlooked-for result.

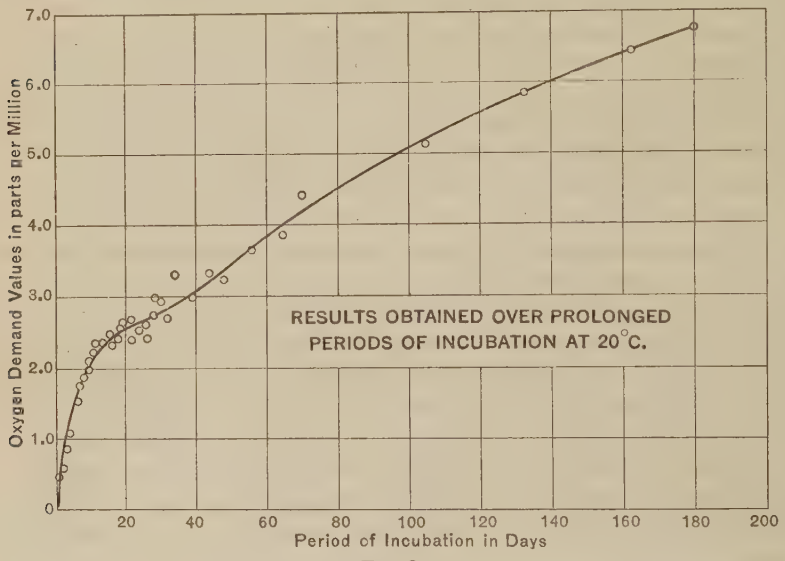

FIG. 3.

Finally, it need hardly be pointed out that a statement to the effect that the 5-day oxygen demand of a sample is, say, 20 parts per million, is of little significance unless a great deal is known concerning the nature or, more precisely, the state of oxidation of the sample. Thus, a 5-day oxygen demand value of 20 parts per million could be referred, with equal reason, to the middle or relatively flat portion of the deoxygenation curve, corresponding to a highly polluted sample, or to the last portion when the nitrification stage has been virtually completed.

CORRESPONDENCE BETWEEN ANALYTICAL DATA AND OBSERVED NATURAL CONDITIONS

The results thus far presented, although indicative of great uniformity, could hardly be referred to natural conditions without further supporting data. Evidence to the effect that the oxygen demand values obtained during the first stage of the oxidation are directly related to the quantity of organic matter present is given in Table 1. Using the 5-day oxygen demand of a raw sewage as a measure of its organic matter content, and given the contributing popula-

* "Sewage Treatment in the United States", *Public Health Bulletin No. 132*, p. 29.

tion and the total flow of sewage, the per capita contribution of organic matter has been computed for places where fairly accurate data were available. The average per capita oxygen requirement is 51.1 grammes per day, with an average deviation from this figure of 5 grammes. The high value obtained at Columbus, Ohio, is probably due to the presence of relatively large quantities of industrial wastes. Omitting the Columbus result, the average per capita oxygen demand is 48.8 ± 3.1 grammes per day. The constancy of the per capita values is remarkable and leads to the conclusion that the 5-day oxygen demand of a raw waste is directly proportional to the concentration of organic matter present. Moreover, it is apparent that the rate of deoxygenation of diluted raw sewage is not subject to extreme variations; otherwise, the per capita values derived with different sewages would not be consistent.

† Omitting the Columbus results.

As regards the general course of the oxidation of organic matter under natural conditions, it is well established that, in sewage treatment, nitrification does not begin until considerable preliminary purification has been effected. Moreover, it has been demonstrated in experiments conducted at the New Jersey Agricultural Experiment Station that, even in a filter bed, the onset of the nitrification stage is sharply defined. In the Illinois River investigation, nitrification was not observed until a point far removed from the source of initial pollution had been reached. The exhaustive studies of the Royal Commission on Sewage Disposal of Great Britain also afford instances where the deoxygenation curve represented by Fig. 1 was clearly reproduced in streams. Similar curves were also obtained using undiluted sewage. It appears reasonable to assume, therefore, that the phenomena observed in the laboratory actually correspond to natural conditions.

Conclusions

As a result of the foregoing, the following conclusions have been reached:

1.—The Phelps formula holds with reasonable accuracy when applied to samples recently polluted with organic matter.

2.—For periods of incubation of less than ten days, it is possible to refer the results obtained under standardized laboratory conditions to the actual times of flow and temperatures of a stream.

3.—Under aerobic conditions, the stabilization of organic matter apparently proceeds in two distinct stages.

4.—The rate at which a polluted water is deoxygenated depends largely on the condition of the sample with respect to its state of oxidation.

5.—It is necessary to exercise considerable caution in interpreting the results of analyses when the nitrification stage has almost been reached.

6.—Absolute values for the purification accomplished by a treatment plant cannot be obtained without resorting to protracted incubation.

7.—A complete solution of the problem probably depends on the development of methods whereby the state of oxidation of a sample may be determined more readily.

THE RATE OF ATMOSPHERIC REAERATION OF SEWAGE POLLUTED STREAMS

By H. W. Streeter,* M. Am. Soc. C. E.

Introductory

In all problems of stream sanitation involving the maintenance of an adequate reserve supply of dissolved oxygen for the preservation of fish life or the prevention of nuisance, there are two major factors to be considered as determining the limiting degree of pollution of streams which is consistent with satisfying a given reserve oxygen requirement. One of these factors is the rate of biochemical deoxygenation of the stream water, proceeding in accordance with laws which have been described by Mr. Theriault.† The other element is the rate and extent of replenishment of its oxygen supply from three natural sources:

(*a*) Dilution water entering the stream through the medium of tributaries and local inflow.
(*b*) Biological reoxygenation through the activities of certain oxygen-producing plants.
(*c*) Atmospheric reaeration, or absorption of oxygen directly from the atmosphere.

Of these three sources of oxygen, atmospheric reaeration is by far the most important in freely flowing streams, and this paper is limited to this subject.

It has been widely recognized that atmospheric reaeration is an important factor in the recovery of dissolved oxygen by flowing streams subjected to progressive deoxygenation but, as far as is known, the first effort to evaluate its effects quantitatively as observed under natural conditions, and to correlate such measured effects with the various physical elements which modify them, was made in connection with a survey of the pollution and self-purification of the Ohio River, by the U. S. Public Health Service, in 1914, 1915, and 1916. The results obtained from this phase of the survey, which have been published in the form of a separate report,‡ have served as a basis for a further study of stream reaeration by the Service in connection with a survey of the pollution of the Illinois River, in 1921 and 1922. Although a full analysis of the reaeration data obtained from the Illinois River study has not been completed, it has been carried forward sufficiently to suggest wherein the conclusions reached from the Ohio River study concerning the laws and factors underlying this phenomenon appear to be confirmed and wherein they may require modification. In this paper it is proposed to indicate what both studies have shown, of interest to engineers, as bearing on the theory of stream reaeration and its applications to problems of river sani-

tation. For the sake of brevity, the term, "reaeration", will be used hereafter in referring to this phenomenon.

The Nature of Stream Reaeration

The reaeration of flowing streams is governed primarily by the laws controlling the absorption of moderately soluble gases by unsaturated liquids kept in a continuous state of agitation. These laws have been studied by a group of chemists, the results of whose observations have been published in the form of a Symposium.* In a paper included in this Symposium, Mr. H. G. Becker† states in the following general form the law of gas absorption which underlies stream reaeration: When a liquid and a moderately soluble gas are allowed to come in contact and the liquid is thoroughly mixed, "the rate of solution of the gas varies directly as the degree of unsaturation of the liquid." In the report on studies of reaeration in the Ohio River, to which reference has been made, it was stated that the rate of solution of oxygen at the surface is directly proportional to the existing saturation deficit (which is merely another way of stating the same law), and it was shown that results obtained by Dibdin and by Adeney and Becker afford experimental confirmation of this principle.

Expressed in terms of stream reaeration, the law thus stated signifies that in each successive unit of time a constant percentage of the remaining deficit in the dissolved oxygen content of the stream below the saturation point, will be satisfied by absorption of oxygen from the atmosphere. The percentage will vary with conditions affecting the rate of absorption, but will remain constant for a given condition. This is analogous to the law of deoxygenation discussed in Mr. Theriault's paper, except that in the latter case the rate of progress of the action is a direct function of the biochemical oxygen demand, rather than the oxygen saturation deficit of the stream water.

In the Ohio River studies, the law of oxygen absorption was formulated thus:

Let,

D_a = the initial oxygen saturation deficit, in terms of concentration;
D = the oxygen deficit at any time, t, expressed in similar terms; and
K_2 = a coefficient defining the rate of reaeration.

Then,

$$\frac{d\,D}{d\,t} = -\,K_2\,D$$

whence,

$$\log \frac{D}{D_a} = -\,K_2\,t \qquad (6)$$

On referring to Mr. Theriault's paper, it will be noted that this expression is exactly similar to that which defines the rate of deoxygenation, that is,

$$\frac{d\,L}{d\,t} = -\,K_1\,L$$

* *Journal of Industrial and Engineering Chemistry*, December, 1924, pp. 1215–1230.

† "Mechanism of Absorption of Moderately Soluble Gases in Water", *Journal of Industrial and Engineering Chemistry*, December, 1924, pp. 1220–1224.

whence,

$$\log \frac{L}{L_a} = -K_1 t \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

except that, in this case, the biochemical oxygen demand, L, replaces the oxygen deficit, D, and the coefficient of deoxygenation, K_1, replaces the coefficient of reaeration, K_2.

The coefficient of reaeration, K_2, defining the rate of absorption of oxygen, when expressed in terms of oxygen concentration in the stream, has been found, in the Ohio River study, to be modified by stream depth and by various physical conditions which influence the turbulence of flow, among which are the velocity of the current and the slope and irregularity of the channel. In the Ohio River, these relations were found to be governed by a simple equation:

$$K_2 = c\, V^n \times H^{-2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which, V, represents the velocity of flow; H, the depth; and c and n, the constants for a particular river stretch, the values of which depend in part on the channel slope and irregularity. In most cases, it has been found that the value of K_2 is very nearly inversely proportional to the discharge of the stream, which term, multiplied by a proper reducing constant, may be substituted for the square of the depth in Equation (8).

The rate of reaeration is further modified by the water temperature, being accelerated at the higher and diminished at the lower temperatures. The controlling element in this temperature effect appears to lie in the fact that the rate of absorption of oxygen at the surface is limited by the process of diffusion, which, as shown by Black and Phelps,* is governed by a similar temperature relation. It was found in connection with the Ohio River study that when observed values of the reaeration coefficient, K_2, are corrected in accordance with the factors developed by Black and Phelps, the corrected values are more closely correlated with the other stream conditions which have been noted than the uncorrected ones. A few results obtained from the Illinois River study have indicated that the rate of reaeration of this stream does not appear to be influenced as much by seasonal changes in temperature as connections based on the diffusion factors developed by Black and Phelps would imply. However, the results of the recent experiments by Becker, previously mentioned, and by Haslam, Hershey, and Keen,† carefully conducted under physical conditions closely approaching those of flowing streams, have confirmed the earlier findings of Black and Phelps in respect to the direction, and, roughly, to the extent of the temperature effect. As these experimental results are based on far more carefully controlled observations than would be possible under natural conditions, they must be interpreted, for the present at least, as affording a reasonably accurate index of the influence of temperature variations on the rate of reaeration of streams. From a plot of the data compiled by Becker, converted to terms of the reaeration

* W. M. Black and E. B. Phelps, Report on Discharge of Sewage into New York Harbor, to the Board of Estimate and Apportionment, New York City, 1911.

† *Journal of Industrial Engineering Chemistry*, December, 1924, pp. 1224–1230.

coefficient, K_2, the following temperature correction equation has been derived:

$$K_{2\,(T^\circ\text{ cent.})} = K_{2\,(20^\circ\text{ cent.})} \times [1.0159^{\,(T-20)}] \ldots\ldots\ldots\ldots (9)$$

This equation is proposed tentatively as probably representing most nearly, from available data, the effect of temperature variations on the value of the reaeration coefficient, K_2, under natural stream conditions. In Fig. 4 is shown a plot of this temperature function as compared with a similar plot of temperature correction factors affecting the rate of deoxygenation, which was developed in connection with the Ohio River studies and has been discussed in Mr. Theriault's paper.

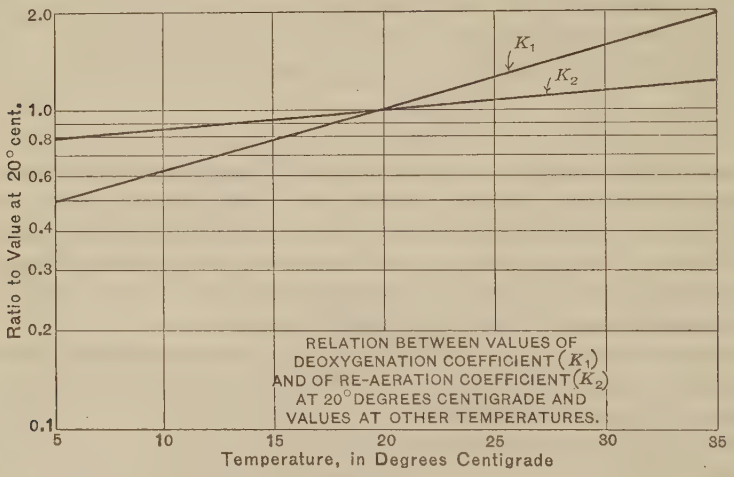

FIG. 4.

EMPIRICAL MEASUREMENT OF THE REAERATION RATE

From what has been stated concerning the extent and modes of action of atmospheric reaeration in streams acting as receivers of community wastes, it is fairly obvious that no even reasonably accurate estimate can be made of the ability of a particular stream to maintain a specified minimum of reserve oxygen supply under a given degree of pollution without a definite knowledge of its capacity for reaeration. This thought leads to a consideration of available means for measuring the reaeration capacities of streams.

Owing to the fact that the rate of reaeration is influenced by a complexity of natural conditions, such as have been noted, methods of laboratory study that have been found suitable for determining the deoxygenation rate are not applicable in this case; hence recourse must be had to measurements in the stream.

If a sufficient number of representative streams could be found in which progressive deoxygenation was not a complicating element, the solution of this problem would be comparatively simple, involving merely the observation of the rate of increase in the dissolved oxygen content of a river between two or more sampling points located at known time intervals of flow from each other. Unfortunately, such a condition never exists, for reasons which are obvious.

The true rate of reaeration, then, is always masked, as far as its observable effect on the dissolved oxygen is concerned, by having superimposed on it a rate of deoxygenation acting simultaneously in the opposite direction.

In order to take account of this condition, an equation was devised during the Ohio River studies, whereby the resultant effect of two given rates, one of deoxygenation and the other of reaeration, on progressive changes in the dissolved oxygen content of a stream can be calculated. This equation was derived by combining the differential expressions, Equations (6) and (7), into a differential equation and integrating it to a variable time, t. The equation thus derived is:

$$D = \frac{K_1 L_a}{K_2 - K_1} (10^{-K_1 t} - 10^{-K_2 t}) + D_a \times 10^{-K_2 t} \ldots\ldots (10)$$

in which,

D_a = the initial dissolved oxygen saturation deficit, in terms of concentration;
D = the dissolved oxygen deficit after time, t, in similar terms;
L_a = the initial biochemical oxygen demand;
K_1 = the coefficient of deoxygenation; and
K_2 = the coefficient of reaeration.

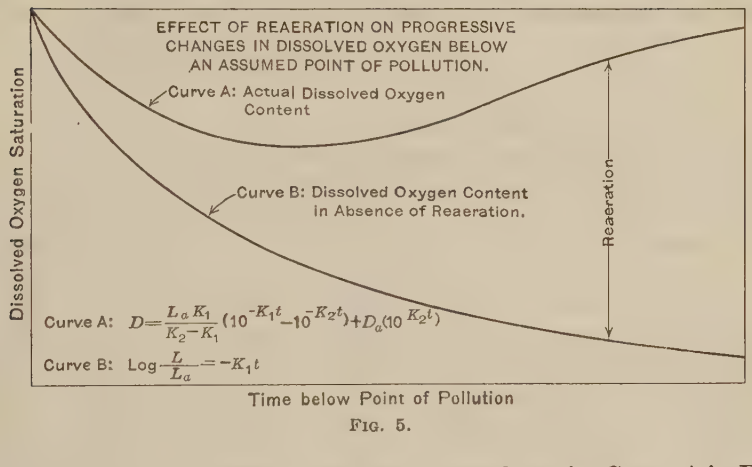

FIG. 5.

The type of curve defined by this equation is shown by Curve A in Fig. 5, which has been reproduced from the report of the Ohio River studies to which reference has been made. For comparison with Curve A, is shown Curve B, representing the progressive deoxygenation which would occur in the absence of reaeration. Curve A is characteristic of progressive changes in the dissolved oxygen content of streams which frequently have been observed in streams below points of major pollution, for example, in the Illinois River below the outlet of the Chicago Drainage Canal; also, in the White River below Indianapolis, Ind. Curve B is characteristic of conditions occasionally occurring in highly polluted streams when covered by a continuous ice sheet, temporarily cutting off reaeration.

By substituting in Equation (10) known or observed values of all terms except that of the reaeration coefficient, K_2, the latter can readily be computed for a given river stretch. A large number of calculations of this kind were made for a series of stretches of the Ohio River, based on observations of the dissolved oxygen and the oxygen demand at the terminals of each river section and on assumed values of the deoxygenation coefficient, K_1, derived from laboratory studies such as have been described by Mr. Theriault, and corrected to the stream temperature by the equation discussed in his paper. A limited number of parallel computations also have been made for a few stretches of the Illinois River. In Table 2 are shown, for comparison, values of the reaeration coefficient derived in this manner from observations in three stretches of the Ohio River and two stretches of the Illinois River presenting, approximately, similar flow and channel characteristics. The results in both cases cover the summer seasonal period, May to September, inclusive. A marked similarity is shown between values of K_2 thus derived in the two streams. It is also noteworthy that the rates of reaeration observed in these five river stretches are approximately double the corresponding rate of deoxygenation as measured by the laboratory value of the coefficient, K_1; thus, the mean value of K_2 is approximately 0.24, whereas that of K_1, at the average river temperature for the given period, is about 0.12.

TABLE 2.—MEASURED VALUES OF THE REAERATION COEFFICIENT, K_2, IN THREE STRETCHES OF THE OHIO RIVER AND TWO STRETCHES OF THE ILLINOIS RIVER.

(May to September, inclusive).

Month.	Values of Reaeration Coefficient, K_2.				
	Ohio River.			Illinois River.	
	Stations 11–19.	Stations 23–65.	Stations 104–349.	Stations 263–240.	Stations 148–122.
May	0.25	0.20	0.18	0.31	0.47
June	0.19	0.33	0.27	0.31	0.28
July	0.29	0.23	0.21	0.21	0.20
August	0.22	0.26	0.21	0.19	0.27
September	0.14	0.19	0.17	0.31	0.14
Mean	0.22	0.24	0.21	0.27	0.27

The locations of river stretches are, as follows:

Ohio River (River miles below confluence of Allegheny and Monongahela Rivers):

Stations 11- 19.....Below Pittsburgh, Pa.

" 23- 65.....From above mouth of Beaver River to above Steubenville, Ohio.

" 104-349.....From below Moundsville, W. Va., to above mouth of Scioto River.

Illinois River (River miles above mouth):

Stations 263-240.....From opposite Morris to opposite Ottawa, Ill.

" 148-122.....From Pekin to Havana, Ill.

Under some conditions, as, for example, where a stream flows rapidly over a shallow "riffle", the rate of reaeration may become greatly accelerated owing to the diminished depth and increased turbulence of flow. An instance of this kind is found in a short stretch of the Des Plaines River immediately below Joliet, Ill., where the channel is steep and rough and a series of shallow rapids is formed. Calculations of the value of K_2 for this section of the river, based on daily observations extending over a period of ten months, from August, 1921, to April, 1922, inclusive, have given indicated rates of reaeration roughly ten times those observed in deeper and less turbulent stretches of the Illinois River down stream. During the period of December to April, when conditions were most favorable for measuring the true rate of reaeration in this stretch of the river, the following values of K_2 were obtained:

December	2.42
January	2.63
February	2.70
March	2.83
April	2.25
Mean	2.57

The average value of K_2 for the full 10-month period was 2.00.

In general, optimum conditions for determining empirically the value of the reaeration coefficient exist where a stream contains a measurable quantity of dissolved oxygen and where the channel bottom is relatively free from unstable and readily oxidizable sludge deposits. When a stream is wholly or nearly depleted of dissolved oxygen and its channel contains any considerable quantities of decomposing sludge, a very sizeable proportion of the atmospheric oxygen absorbed by such a stream may be withdrawn from solution almost immediately and thereby fail to be accounted in terms either of reserve oxygen or of biochemical oxygen demand. Under such circumstances, the measured value of the reaeration coefficient may be widely in error and always will be lower than the true value. Where an excessively polluted stream contains a measurable supply of oxygen and is relatively free from sludge deposits during a part of the time, measurements of its reaeration capacity should be made when it is in this condition.

Applications

The most important applications of the theory outlined in this paper are found in the estimation of dilution or sewage treatment requirements to be met at specified points along excessively polluted streams to avoid over-taxing their capacities for maintaining a specified reserve oxygen supply, or, conversely, in the calculation of the future limiting permissible degree of pollution

of streams now in a satisfactory condition from this standpoint. Both cases are similar in that they involve the prescription of a limiting biochemical oxygen demand of a stream at certain critical points. As the rate of deoxygenation is accelerated during the summer season to a greater proportionate extent than the rate of reaeration (the latter often is actually retarded during this season owing to a greatly diminished stream flow), conditions during the summer ordinarily are the most critical to be considered in this connection.

In Fig. 6 is given an example showing the effect of temperature variations on progressive changes in the dissolved oxygen as calculated by Equation (10), assuming an initial oxygen demand, L_a, of 20 parts per million and an initial oxygen saturation deficit of zero. The values of the deoxygenation and reaeration coefficients, K_1 and K_2, have been assumed to be 0.10 and 0.20, respectively, at 20° cent. and have been corrected for temperature in accordance with the factors shown in Fig. 4. The time required to attain the maximum oxygen deficit is shown to vary from about 2 days at 30° cent. to 5 days at 5° cent.

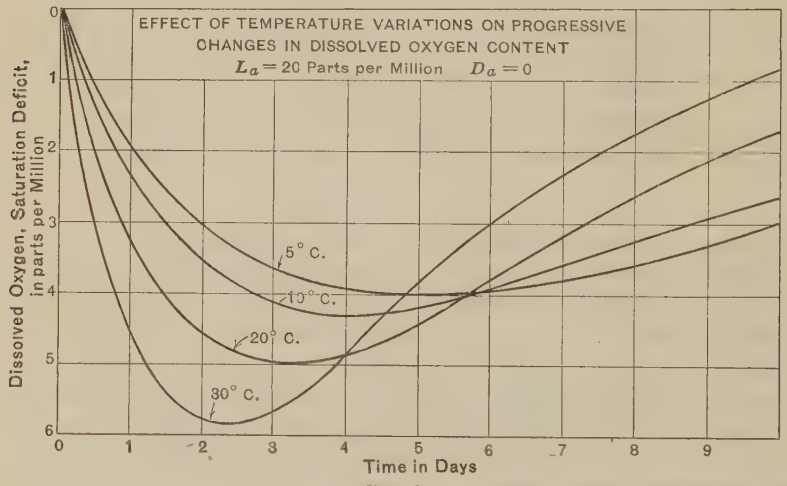

FIG. 6.

The effect of variations in the initial oxygen demand, L_a, on the dissolved oxygen content of a stream below a point of pollution is illustrated by the curves in Fig. 7, computed for a temperature of 20° cent. and with an assumed initial oxygen deficit of 1.0 part per million. In Fig. 8 is a plot of the maximum oxygen deficits and the times required to attain the maximum, as indicated by the curves in Fig. 6, the plotted quantities being calculated, however, by a formula developed by differentiating Equation (10) and placing the resulting expression equal to zero. In this case it is noted that although the maximum deficit varies almost as a straight-line function of the initial oxygen demand, the time to attain the maximum lies within a comparatively narrow range, that is, between 2 and 3 days.

FIG. 8.

It thus appears that the points of maximum dissolved oxygen depletion in polluted streams normally should lie within comparatively short distances, as measured by time, below major sources of pollution, and that their positions should be affected to a much less extent by variations in the initial oxygen demand than they are by seasonal changes in temperature. Observations on numerous streams, both in the United States and abroad, have confirmed this statement in so far as it applies to streams which are not grossly polluted. If the pollution of a stream is so great, however, as to over-tax its capacity for reaeration, zones of complete deoxygenation, indefinite in length, may be established at certain seasons of the year, notably during periods of dry-weather flow in summer. A condition of this kind is frequently aggravated by the tendency of grossly polluted streams to deposit a sludge mat in the bottom of the channel which may greatly augment the oxygen demand of the stream proper during critical seasons. Under these circumstances, the equations previously noted are not applicable and special methods of analysis must be used.

A good example of such a condition is found in the stretch of the Upper Illinois River, extending from Joliet down stream for approximately 110 miles to the head of Peoria Lake, which receives at its up-stream end the sewage of Chicago, discharged into it through the Drainage Canal and a stretch of the Des Plaines River channel. During eight months of the year, October to May, inclusive, this stretch of the river contains a measurable, although in places low, reserve supply of dissolved oxygen. During the four summer months, June to September, its dissolved oxygen content is practically exhausted throughout its entire length, owing, in part, to the lower dilution provided by the river and its tributaries, to the effect of the higher summer temperatures in causing an accelerated rate of deoxygenation as compared with that of reaeration, and to the greatly added deoxygenating effect of the dense mat of decomposing sludge with which the bottom of the river channel is covered.

Following the method previously outlined, an effort was made to calculate values of the reaeration coefficient, K_2, from observations made in the Illinois River during the summers of 1921 and 1922. Owing to the conditions at that time, previously noted, an accurate calculation was found to be impracticable, the values of the coefficient derived being obviously too low and, in some cases, negative. A similar calculation based on observations during the two months, October, 1921, and May, 1922, when the river temperatures approached those of summer and measurable quantities of dissolved oxygen were found in the river, gave results reasonably consistent both as to their agreement with each other and as to their relation to known physical conditions in the several river stretches. From these results the following values of K_2, converted to their equivalents at 20° cent., were derived for the five river stretches forming the upper section of the Illinois River between the limits stated (the station numbers referring to the locations, in stream-miles, above the mouth of the Illinois River):

River stretch.	Value of K_2
Stations 286-263.....	0.68 (mean of October and May)
" 263-240.....	0.33 (" " " " ")
" 240-227.....	0.15 (" " May)
" 227-196.....	0.23 (mean of October and May)
" 196-179.....	0.14 (" " May)

Although it is likely that the values thus derived (especially the lowest two) are affected to some extent by excessive and unaccountable deoxygenation due to sludge deposits, they are believed to be as nearly representative of the true rates of reaeration prevailing in the several river stretches as any other figures obtained from the present very incomplete series of calculations.

With the foregoing derived values of K_2 as a basis, and using the resultant oxygen Equation (10), a computation has been made of the progressive changes in the dissolved oxygen content of the Upper Illinois River occurring in the stretch extending from Station 286, below Joliet, to Station 179, located 107 miles down stream, during each one of the four months, October, 1921, and May, June, and July, 1922. In making the calculation (details of which are omitted for the sake of brevity), the value of the deoxygenation coefficient assumed was based on the laboratory figure in every instance except that of the river stretch from Station 286 to Station 263, for which the mean of the rates of deoxygenation observed in the stream during the two months, October and May, was used. The values of the reaeration coefficient assumed were the same as those just given, corrected to the river temperature. The calculated dissolved oxygen figures at each station are compared with the corresponding results of observation in Table 3 and illustrated graphically in Fig. 9.

TABLE 3.—Comparison of Calculated and Observed Dissolved Oxygen Contents of Upper Illinois River at Successive Sampling Stations.

Station.	Dissolved Oxygen Saturation Deficit, in Parts per Million.							
	October, 1921.		May, 1922.		June, 1922.		July, 1922.	
	Calculated.	Observed.	Calculated.	Observed.	Calculated.	Observed.	Calculated.	Observed.
263	8.4	9.1	8.6	8.0	8.6	8.8	6.2	8.6
240	6.4	7.1	7.0	6.3	6.4	7.6	4.8	8.0
227	6.5	7.4	7.0	6.4	6.5	8.1	4.9	8.0
196	4.3	5.3	4.4	4.3	3.6	5.9	3.0	7.5
179	4.9	6.6	3.6	4.6	2.6	6.3	2.7	8.1
	Dissolved Oxygen, Percentage of Saturation.							
263	20	14	11	19	3	1	28	2
240	39	32	28	35	28	15	44	6
227	38	29	28	34	27	9	43	8
196	59	50	55	61	60	31	65	12
179	63	37	63	52	71	26	69	9

On referring to Fig. 9, it is noted that the calculated and observed figures agree with each other closely for May and reasonably well for October, but they diverge widely for June and July. The divergence probably is due largely to the effect of sludge decomposition in the channel during the summer months, as it represents the excess of dissolved oxygen, unaccounted for in terms of reaeration or normal deoxygenation, which has disappeared from the

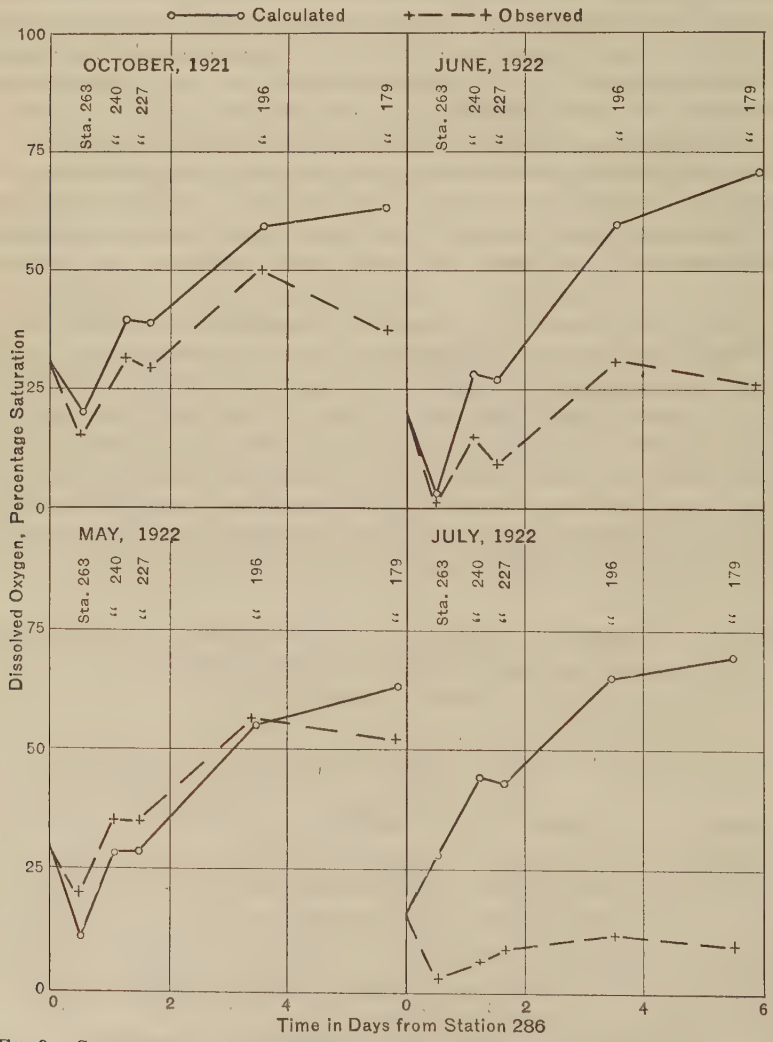

FIG. 9.—COMPARISON OF CALCULATED WITH OBSERVED DISSOLVED OXYGEN CONTENTS AT STATIONS IN UPPER ILLINOIS RIVER. (PLOT OF DATA IN TABLE 3.)

stream in passing from the uppermost to the lowest station and can be accounted for only as oxygen absorbed by the bottom sediments. The deoxygenating power of sludge deposited in the channel is thus indicated as having been sufficient, in July, 1922, to cause an absorption of a quantity of dissolved oxygen equivalent to 60% of the saturation value in a river distance of

107 miles. Although it is hazardous to indulge in speculation in a problem as complex as that presented by the Illinois River, it seems fairly evident that the mere elimination of sludge deposits from the channel of this stream would go far toward restoring the effectiveness of its powers for self-purification.

The density of pollution of the stream proper, however, is fully as important a factor as its condition in respect to sludge deposits in determining its ability to recover its reserve supply of oxygen. To illustrate this point, a series of curves is given in Fig. 10, showing calculated progressive changes in the dissolved oxygen content of the Upper Illinois River with various assumed quantities of initial oxygen demand, the calculation being based on observed conditions at Station 286, below Joliet, during May, 1922. The figures from which Fig. 10 have been plotted are given in Table 4. The comparison is not valid except for purposes of illustration, as any lowering of the initial oxygen demand at Station 286 would necessarily entail improved conditions up stream, which, in turn, would cause an increased oxygen saturation at the point of departure, or *vice versa*. The comparative trends of the curves merely serve to give a rough illustration of the improvement which would be expected if the pollution of a stream at a given point were diminished, without any change occurring in its oxygen status above that point.

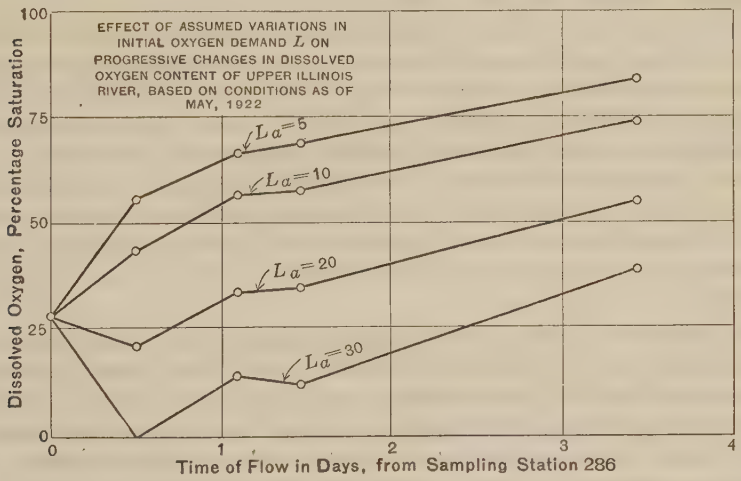

FIG. 10.

In general, it is evident that in almost any given instance where systematic measures are undertaken to relieve excessive stream pollution, a reduction in the oxygen demand of the stream proper and an improvement in its condition with respect to sludge deposits should go hand in hand. This point is an important one to be borne in mind in forecasting the extent of beneficial results to be obtained from extensive stream-cleaning activities. The illustrations given in this paper err considerably on the side of conservatism in this respect, as this fact has not been taken into account in deriving them.

TABLE 4.—Calculated Percentages of Dissolved Oxygen Saturation at Stations on the Upper Illinois River, Assuming Different Initial Oxygen Demand Values, L_a, at Uppermost Station.

(Based on conditions as of May, 1922.)

Station.	Time of flow, in days.	Calculated Percentage of Dissolved Oxygen Saturation, with Initial Oxygen Demand, L_a, Assumed as:			
		5 parts per million.	10 parts per million.	20 parts per million.	30 parts per million.
286	0.00	28	28	28	28
263	0.49	56	44	21	1
240	1.08	67	57	35	12
227	1.46	69	58	35	12
196	3.44	84	74	55	39

Conclusions

From the studies briefly described in this paper, the following tentative conclusions appear to be justified:

1.—The reaeration of flowing streams proceeds substantially in accordance with physical laws which have already been described.

2.—Its rate at any time is controlled mainly by the temperature, turbulence, and oxygen saturation deficit of the stream.

3.—The empirical method of measuring rates of reaeration which has been described, involving the use of the resultant oxygen Equation (10) and the substitution therein of quantities derived by observations in the stream made under proper circumstances, gives results which appear to be consistent with known facts concerning the physical conditions influencing such rates.

4.—By a proper combination of predetermined rates of reoxygenation and of reaeration, using Equation (10), a reasonably accurate calculation may be made of the resultant progressive changes in the dissolved oxygen content of a stream under any given or assumed condition of flow, temperature, and initial degree of pollution.

The studies of stream reaeration thus far made along lines indicated in this paper have been confined to the Ohio and Illinois Rivers, surveys of which have offered the only sufficiently extensive and properly co-ordinated data thus far available for this purpose. A much more comprehensive analysis of the Illinois River data, as yet to be completed, probably will give a more satisfactory basis for judgment as to the wider applicability of the results of these studies than it has been practicable to establish within the limited scope of this paper. Some features of the present theory of stream reaeration and its method of application doubtless will require further modification as more experience is gained in testing it against specific problems. The studies thus far completed, however, have indicated that the theory in question, applied with due consideration to its practical limitations, offers a working hypothesis for a much more rational treatment of stream sanitation problems involving the prevention of conditions contributing to nuisance and to the destruction of fish life in streams than hitherto has been available.

QUANTITATIVE STUDIES OF BACTERIAL POLLUTION AND NATURAL PURIFICATION IN THE OHIO AND THE ILLINOIS RIVERS

By J. K. Hoskins,* Esq.

The U. S. Public Health Service has been engaged for some years in studies of various phenomena concerned with the pollution and natural purification of streams. One general purpose of these studies has been to evaluate the intensity of bacterial pollution to be expected from known populations discharging sewage into streams of known discharge and velocity of flow. With this end in view detailed bacteriological data have been collected from two streams of quite different types, the Ohio and Illinois Rivers. Published observations on the Ohio River† covered a period of three years, and those of the Illinois River were continued for a complete year, so that in each instance information was obtained throughout an entire seasonal cycle.

From a consideration of the data of these studies some general tendencies in bacterial changes are indicated, which may be of assistance to sanitary engineers in forming an estimate of the effect, both immediate and prolonged, of adding sewage, from a definite population, to a watercourse of determined hydrometric characteristics.

The degree of bacterial pollution contributed by cities, about which information is most generally desired, may be separated into two principal cases. The first is concerned with the intensity of bacteria that will result in the stream in the zone of highest pollution below the point at which the sewage is discharged. The second and sometimes more important consideration, is the proportion of such contributed bacteria that will remain in the stream at a known distance, or time of flow, below the point at which they were added.

Discussion

Due to fluctuations in discharge and inflow of all streams, the bacterial concentration resulting from a constant rate of contribution may vary widely. It is essential, therefore, for a comparative study of results that not only the concentration of bacteria be considered, but that the actual quantities of organisms be taken into account as well. The quantities of bacteria present in, or added to, a watercourse can be expressed most conveniently in terms of a unit in which is combined the elements of volume, time, and bacterial concentration. Such a unit, called the "quantity unit," has been used for this purpose. The quantity unit may be defined to be the product of the discharge of 1 cu. ft. per sec. and a concentration of 1 000 bacteria

per cu. cm. Hence, the number of quantity units of bacteria in a stream equals:

$$\frac{\text{Discharge, in second-feet} \times \text{bacteria per cubic centimeter}}{1\,000}$$

Obviously, this unit is convertible into bacterial numbers per unit of time, such as the day. Thus, an average of 1 000 bacteria per cu. cm. in a flow of 1 sec-ft. for 1 day, or 86 400 sec., is equivalent to 28 317 (= number of cubic centimeters in 1 cu. ft.) $\times$ 1 000 $\times$ 86 400, or 2 446 589 000 000 bacteria per day in one quantity unit.

Immediate Pollution

In observations of the effect of pollution by sewered communities, it has been noted consistently that the zone of greatest bacterial density in the receiving stream does not occur immediately below the sewer outfalls, but at a point 10 to 30 hours down stream from the place where such pollution is added. Moreover, the location of this maximum zone seems to be influenced by seasonal temperatures, being farthest down stream during the winter months. Whether an actual multiplication of organisms in the stream takes place until this maximum is reached, or whether the observed increase in bacterial numbers is due to the physical separation of organic matter, has not been definitely determined, although the evidence seems to point to the former assumption as the most logical explanation.

Observations extending over the entire seasonal cycle have been made of the numbers of bacteria per capita added to the stream by the sewage pollution from Cincinnati, Ohio, Louisville, Ky., Chicago, and Peoria, Ill. In each instance the numbers appear to vary with seasonal temperature conditions, being considerably greater in summer than in winter. These seasonal fluctuations are shown for each of the four cities, both in terms of quantity units per capita and in billions of bacteria per capita per day, in Table 5, wherein the values for summer, for winter, and the averages for the entire year, are presented.

By combining the yearly per capita contributions of gelatin, agar, and *B. coli* counts, respectively, of all the four cities, a general average is obtained which may be considered to be roughly representative of the annual average quantity units of the respective types of bacteria contributed to these streams per capita of the sewered population.

The variation from month to month in the numbers of bacteria contributed is, in general, reasonably consistent, increasing quite rapidly to a maximum in June or July and declining again gradually until October and then more rapidly to the lower numbers found throughout the winter season. These changes in the contribution of *B. coli* from each of the four cities are shown in more detail in Table 6, in which the figures represent the ratio of the count each month to the annual average, the latter being taken as equivalent to 100. The averages of the ratios for these four cities for corresponding months represent what might be considered a general measure of the degree of change from month to month in numbers of *B. coli* contributed by urban sewered population. Similar averages have been derived for the monthly

If these average values as derived are representative of the bacterial changes in streams in general, as brought about by sewage pollution, they supply a ready means of estimating the maximum concentration of bacteria to be expected in a stream of known discharge resulting from the sewage of a known population. The bacteria per cubic centimeter thus added can be computed at once by the relationship:

$$\text{Bacteria per cubic centimeter added} = \frac{\text{Population} \times \text{quantity units per capita}}{\text{Discharge, in thousands of second-feet}}$$

As an example, the average yearly numbers per cubic centimeter of *B. coli* contributed by Cincinnati (with a sewered population of 494 300) to the Ohio River, where the mean annual flow is 97 500 sec-ft., is:

$$\frac{494\,300 \times 0.1018}{97.5} = 516$$

Similarly, the concentration for any season or month may be estimated by applying to the yearly average the proper seasonal factor given in Table 7. Thus, in July, when the discharge of the Ohio River is 19 000 sec-ft., the estimated concentration of *B. coli* per cubic centimeter contributed by Cincinnati would be:

$$\frac{494\,300 \times 0.1018 \times 2.01}{19\,000} = 5\,320$$

Applying this method of estimation to the four cities of Cincinnati, Louisville, Chicago, and Peoria, it is possible to compare directly the com-

puted concentrations of bacteria to be expected in each case with the densities actually observed to have resulted from the sewage pollution contributed. Such a comparison of computed and observed concentrations of *B. coli* is presented in Table 8, together with the average monthly rates of stream

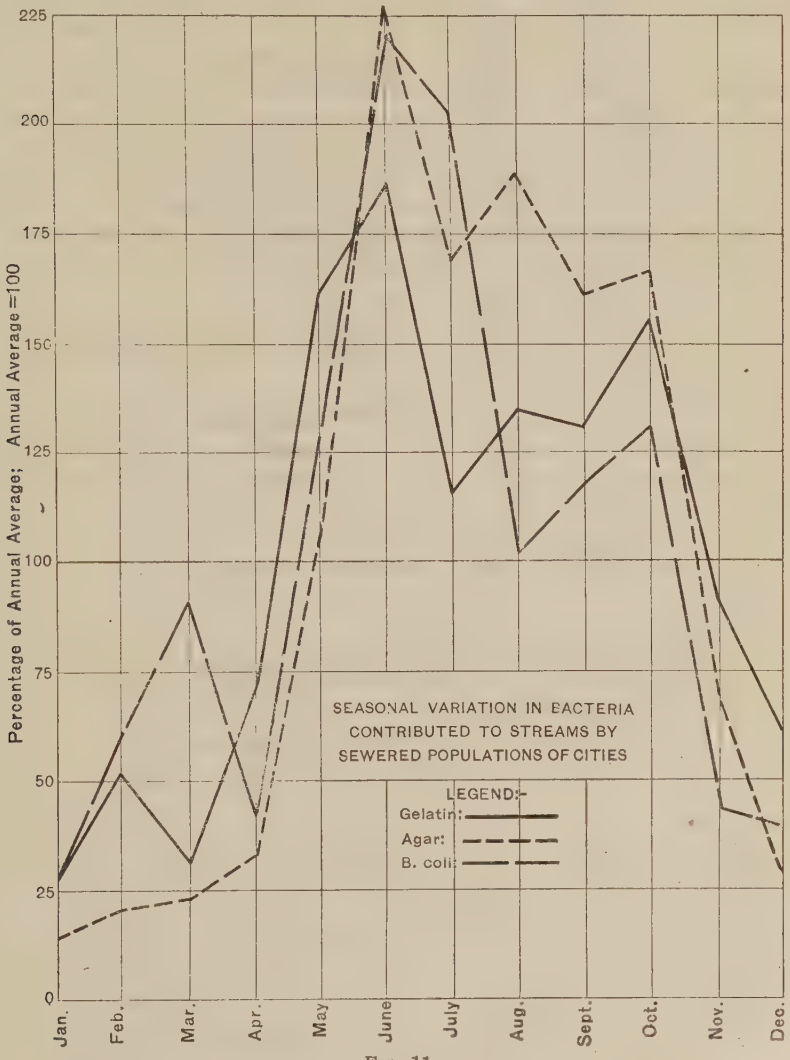

FIG. 11.

discharge and other related data. It will be noted that, although the estimated concentrations for some individual months differ quite widely from those actually observed, yet in the main the two sets of values are comparable and generally of the same degree of magnitude. Bearing in mind that the actual enumeration of *B. coli* is subject to considerable variation, it would appear that the use of the formula as a rough working model may be justified.

TABLE 8.—COMPARISON OF COMPUTED AND OBSERVED CONCENTRATIONS of *B. coli* CONTRIBUTED BY SEWERED POPULATIONS.

† Data for 1914.

Rates of Decrease in Bacterial Pollution

Quite extensive observations of the decrease of bacteria in polluted waters indicate that such changes follow a fairly regular course, modified by variations in environment, such as temperature and other factors, but yet having an orderly arrangement of reduction. Just what agency is primarily responsible for the death of such bacteria has not been definitely determined. However, there is considerable evidence suggesting that plankton activity rather than lack of food supply is the dominant influence in bacterial diminution.*

A simple and direct method for determining the rates of bacterial decrease in streams, if it were practicable, would be to observe the changes occurring in stored samples of the water under consideration. Unfortunately, the decreases in such stored samples do not correspond invariably with the natural rates occurring in the stream. Long-continued efforts—still in progress—to place the study of bacterial death rates on such an experimental basis, have thus far not been successful. Resort must then be made to the observation of natural purification occurring in streams. Under such conditions, all modifying factors are impossible of accurate control and in many cases corrections for them can be applied only in an approximate manner. Therefore, rates of decrease thus determined must necessarily be interpreted with these limitations clearly understood.

Studies of natural purification of the Ohio River† indicate that changes in the bacterial content between Cincinnati and Louisville are quite orderly and that the rates of decrease can be represented in a general way by empirical curves and formulas. Similar observations on the Illinois River have tended to confirm this conclusion and have indicated that such changes may be of general occurrence, rather than confined to these two streams. The rates of decrease in all instances are not directly comparable, however, and, as stated in the *Public Health Bulletin* referred to, these rates must be considered as approximate only, since they apparently are modified by other factors, such as density or concentration, and perhaps, also, by relative age or staleness of the sewage contributed. It is certain at least that the rates of bacterial decrease from the point of maximum concentration in the Ohio River are quite different from those observed in the Illinois. However, when the disparity in initial concentrations is taken into account and comparisons made at points of equal bacterial density, the rates coincide much more closely. This condition is perhaps best illustrated by the summer rates of decrease in bacteria growing on agar at 37° cent., as observed in the Ohio, in the Illinois River below Chicago, and, again, below Peoria, the base data of which are given in Table 9. Fig. 12 shows these rates plotted from the same origin, and Fig. 13 shows the same curves shifted so that at the points of maximum concentration they coincide with the corresponding density of the Upper Illinois River curve.

Although such an adjustment according to maximum density brings the rates into closer harmony, characteristic preliminary decreases, probably due

to other unknown factors, are still evident in each of the curves. It may finally prove to be impracticable, therefore, to develop a composite expression or curve defining accurately the general rate of bacterial decrease in all streams. A series of such expressions or curves, taking into consideration various modifying factors, may be found to best portray the actual rates of most probable change.

TABLE 9.—Decrease in Agar Counts, Summer Season.
(As read from curves.)

200	357	0.36	2 150	0.055	.....	.....

However, the decreases in bacterial numbers are in a broad way quite similar, and it is possible, from the available data collected, to indicate the general trend of such decrease. Such a general rate of purification, if applicable to a specific case, may assist in forming an estimate of the relative numbers of bacteria that may be expected to survive in the stream after any definite interval of time.

* Data from Table No. 114, *Public Health Bulletin No. 143.*

River studies, and are assembled in Tables 10, 11, and 12. The rates of decrease for the Illinois River were derived from observations on the Upper Illinois River in which the sewage of Chicago is the agency of pollution, whereas in the Lower Illinois River, the major pollution is contributed by the Metropolitan District of Peoria. Daily observations at successive down-stream sampling stations were averaged over both the summer and winter seasons, and smooth curves defining the rates of natural purification were drawn through these experimentally determined results, plotted on semi-logarithmic paper. The method of obtaining the Ohio River rates of decrease is described in *Public Health Bulletin No. 143,* referred to previously. In addition to these general curves of the Ohio, data defining rates of purification at different maximum densities of bacterial content are presented in Table No. 114 of that publication, wherein are presented observations of bacterial numbers at successive sampling stations grouped according to volume of discharge of the river. By grouping these data according to initial concentration and by times from origin, average densities for each group have been obtained at various average intervals of time in hours from the point of maximum density. The results of such grouping for different initial densities are also presented in Tables 10, 11, and 12 for summer and winter, respectively, and define average rates of decrease of *B. coli* starting from the various maximum concentrations.

* Table No. 127, *Public Health Bulletin No. 143.*

† Data from Table No. 114, *Public Health Bulletin No. 143.*

If these data are plotted on semi-logarithmic paper, in which the concentrations of *B. coli* are plotted as ordinates on the logarithmic scale and the times

from maximum concentration as abscissas on the plain scale, it will be observed that these points define, in a general way, fairly smooth curves, all of which have the same general trend. It may be noted also that the curves of winter purification are of much flatter slope than are those of summer, indicating that natural purification proceeds at much slower rates during cold weather. It is entirely possible, therefore, regardless of the generally lower numbers of bacteria contributed during the winter season, that the critical or most severe period of bacterial pollution to be expected from a given sewage discharged up stream may occur during the winter, rather than during the summer. This is, of course, the reverse of what would be expected of the critical oxygen depletion condition resulting from the same sewage pollution.

Having obtained the general rates of decrease in *B. coli* for various initial concentrations, it is possible to interpolate intermediate rates of decrease, starting from definite initial concentrations. Such interpolated rates should indicate, in a general way, the numbers of *B. coli* that may be expected to survive after definite intervals of time have elapsed beyond the point of greatest bacterial density in the stream. Such rates of decrease are for convenience placed in tabular form for ready reference in Tables 13 and 14, Table 13 representing summer conditions and defining numbers of bacteria remaining after definite intervals of time, starting from various densities at the maximum point, and Table 14 presenting the same data for winter months.

TABLE 13.—NUMBERS OF *B. coli* PER CUBIC CENTIMETER REMAINING AFTER STATED TIMES OF FLOW FROM POINT OF MAXIMUM CONCENTRATION, SUMMER SEASON.

500	260	130	70	25	8	....	....	....	....
100	40	20	12	....	....	....	....	....	....

However, before such estimates can be accepted with complete confidence, it is obviously necessary that they be checked by observations on a considerable number of streams of different physical characteristics. The empirical results herein presented outline what the observations thus far have indicated to take place, and endeavor to suggest their practical application. The explanation of the phenomena concerned in such changes must await additional research.

Summary

Quite extended observations of the pollution of the Illinois and Ohio Rivers have indicated that the numbers of bacteria contributed per capita by the sewered populations of various cities are reasonably constant; these numbers change, however, with seasonal temperature, being much greater in summer than in winter. Such bacteria tend to increase in numbers in the receiving stream for a short period and then decrease at orderly rates as the time from the point of maximum density is increased. These rates of decrease were found to be affected by water temperature and apparently by concentration, being most intensive during the warmer months and under conditions where the density of bacteria was greatest.

Having established definite quantitative relationships from these observations, and assuming that they are fairly representative of stream conditions in general, a method is suggested for estimating the maximum concentration of *B. coli* in streams of known volume of flow that may be expected to result from pollution contributed by known sewered populations. Furthermore, the concentration of such organisms remaining at any point down stream may be estimated, providing the velocity of flow is ascertained.

If the observations are representative of general biological laws, they are of practical value for estimating the increasing burden placed on streams receiving the sewage of growing communities and, consequently, the added loads that water-purification plants must be prepared to handle where such polluted watercourses are used as sources of water supply.

DISCUSSION

RICHARD H. GOULD,* M. AM. SOC. C. E. (by letter).—The methods outlined by Mr. Streeter will be of assistance to those working on stream pollution problems. The mathematical treatment is interesting and is evidence of much careful work. It must be confessed, however, that for one a little rusty in mathematics it is somewhat difficult to visualize fully all the aspects disclosed and to obtain a clear understanding of the relative importance of the factors involved. This does not detract, however, from the merit of the paper. The results secured are well worth the extra effort involved in following these new methods. The work on the Ohio and Illinois Rivers and the studies reported are of great importance, and the men who are responsible for the results deserve great credit.

A number of points as to the practical application of the methods involved will bear comment. Some of these are brought out in the paper, but it may be well to emphasize them further. One of the assumptions in this method of computation is that a load of pollution entering a stream will exert a demand on the dissolved oxygen of that stream in accordance with certain definite laws of biochemical action. The demand exerted by this polluting material proceeds in an orderly manner, depending on the time elapsed, temperature, etc. The duration of contact with the waters to any down-stream point is presumed to be that of the time of flow of the water in the stream. This assumption is essentially correct where the polluting matter is free from settleable solids so that all material producing a demand on dissolved oxygen moves down stream with the water.

A serious error would appear to be introduced if parts of the polluting matter can separate out in the form of sludge on the bed of the stream. This latter condition more often than not seems to be the one actually met. Very few natural streams receiving polluting matter maintain velocities at all places and times that will prevent deposition of sewage solids. Depositions occur most readily where the stream is sluggish or the discharge is into tidal waters with reversing currents and slack water. The problem is thus complicated in most cases by the condition that, whereas part of the polluting matter will remain in suspension or solution and, consequently, its total oxygen demand within a definite time of flow can be calculated with a satisfactory degree of accuracy, the other part will exert its demand, within a particular section, for an uncertain period of time.

Mr. Streeter has discussed the effect of sludge deposits and states that the methods proposed are not accurate where such deposits exist. As a practical consideration, it is probable that the effect of settleable solids is nearly always present to a greater or less extent when raw sewage is discharged into natural watercourses. Even where no deposition occurs, the slow rolling of solid particles along the bottom may thus lengthen their period of contact and consequent oxygen demand within a given stretch of river. The relative importance of these two classes of material producing oxygen demand will

* Prin. Asst. Engr., James H. Fuertes, New York, N. Y.

vary in any particular case. Not much is known about the demand exerted by sludge and sludge deposits, but enough is known to indicate that this demand may have a considerable effect.

Another factor which adds to the importance of separate consideration of settleable solids is that solids separating out in the stream during the winter may lie more or less dormant, in regard to exertion of an oxygen demand in the stream. With the coming of the warmer summer temperatures, the rate of decomposition will increase and the decomposition of accumulated deposits will add to the oxygen demand exerted by the current summer solids. The maximum rate will be exerted at the most critical time of the year as far as the condition of the stream is concerned. The extent of this effect will depend on conditions in the stream.

The relative importance of the separate consideration of settleable and non-settleable solids may be indicated very roughly by a hypothetical case as follows: If it is assumed, for example, that raw sewage is being discharged into a sluggish stream whose time of flow to a large volume of diluting water is two days, the oxygen demand of the sewage on a per capita basis can be calculated as follows:

If the 20-day oxygen demand of raw sewage is 0.24 lb. per capita, at a water temperature of 23° cent., about 42% of the 20-day demand, or 0.10 lb. of oxygen per capita per day, would be exerted within a 2-day period by the decomposing matter, assuming that both the settleable and non-settleable solids were affected at the same time. In the particular case under consideration, however, it is assumed that the sluggish stream will permit the deposition of sewage solids, and that these will remain on the stream bed for a long time. Based on the ordinary oxygen demand test, about one-third of the oxygen demand of raw sewage is removed by sedimentation. The demand of the liquid parts of the sewage within the section considered would be then 66% of the figure for raw sewage, or 0.066 lb. per capita per day. The 20-day demand of the current settleable solids, if all were deposited and remained on the stream bed, would be one-third of 0.24 lb., or 0.08 lb. per capita. If this were increased 50%, a purely arbitrary figure, owing to the demand of old sludge banks in the stream becoming more active under the warmer summer temperatures, the total sludge demand would then be 0.12 lb. per capita, and would all be exerted in the section under consideration. The total of both the liquid and the sludge parts would be a demand of 0.186 lb. per capita per day, which is 86% above that derived on the assumption that no separation of solids took place. Absolute values will vary with existing conditions, but it would seem essential in most cases to give separate consideration to settleable and non-settleable matter.

A few engineers have felt for some time that the difference between the demand of raw and settled sewage may not be entirely brought out by the 5-day incubation test for oxygen demand. It has seemed that settled sewage would exert a higher percentage of its total demand in a period of 5 days than raw sewage with its coarser particles. How important this distinction is if there is a difference is simply a matter of speculation. In this connection, it is interesting to note in the paper by Mr. Theriault that even after

20 days a very considerable oxygen demand may be exerted, that is, the 0.24 lb. per capita oxygen demand which has been mentioned, may not represent the total, and the solids deposited in the stream may exert more of a demand than is now estimated.

The influence of sludge deposits is indeed a disturbing factor and extends to the values derived for the aeration factor, K_2. This factor, it is understood, expresses the net aeration taking place in a stream, that is, it is the total aeration taking place through the water surface less the oxygen demand of the sludge deposits in the stream. This being so, coefficients derived from rivers of the same degree of turbulence, cross-sectional areas, depths of flow, velocities, etc., might be entirely different, depending on the relative amounts of oxygen demand exerted by the sludge deposits in the different streams. If the full significance of this coefficient is clear to the writer, it would thus appear that a coefficient derived from a sluggish stream receiving raw sewage pollution might not apply to this same stream when this sewage had been treated by sedimentation or otherwise.

Definite values for the effect of sludge deposits and of the amount of aeration are difficult to determine. There is one equation with two unknowns. If the rate of true aeration in a particular case was known, the demand of the sludge could be calculated, or *vice versa*. It would seem that it might be easier to derive values for reaeration rather than for sludge deposits of uncertain age and extent. In most problems where complete data are lacking, aeration values would be the easier to apply. The three fundamental factors would be: The area of water surface, which is easily obtained; the percentage of saturation of the water, which may be measured without difficulty; and the degree of turbulence of the water. The degree of turbulence would be the most uncertain item, but it would seem that in the course of time a sufficient number of limiting values could be obtained to be of considerable aid to judgment in selecting the proper value.

The basing of aeration figures on the area of water surface rather than on the time of flow or other considerations involving the depth of water, velocity of flow, and stream characteristics, has the advantage that it may be applied both to flowing streams and to lakes and harbors where the effect of currents is not so noticeable. In most natural waters, particularly flowing streams and tidal estuaries, there seems to be little evidence that stratification of dissolved oxygen exists to any considerable extent. Where the methods outlined by Mr. Streeter are not applicable it would simplify computations if all considerations other than the area of water surface and percentage of saturation could be omitted. The particular reference in mind is that the consideration of depth of water as affecting the rate of diffusion of oxygen to the bottom layers does not seem essential. The area of water surface is readily obtainable, whereas mean depths and velocities are more difficult to secure. A convenient unit, such as pounds of oxygen absorbed per day per 1 000 sq. ft. of water surface, might be used.

An interesting approximation is suggested by the material presented by Mr. Streeter in connection with rates of reaeration. It is brought out that the rate of solution of oxygen at the surface is directly proportional to the

existing saturation deficit. It is also shown that the saturation deficit of water at 5° cent. is about 50% greater than the saturation deficit at 25° cent. when both liquids are completely devoid of dissolved oxygen. According to this law, it would be expected, neglecting the effect of temperature on the rate of solution, that oxygen would be absorbed by the colder water at a rate about 50% greater than by the warmer water. Mr. Streeter, however, gives curves, Fig. 4, showing the effect of temperature on the rate of oxygen absorption. These corrections to a large measure counteract the effect of the greater saturation deficits that are possible in colder temperatures. The relative figures for three selected temperatures are given in Table 15.

TABLE 15.—Variation of Rates of Aeration with Temperature.

Temperature, in degrees centigrade.	Saturation deficit at 0%, in parts per million.	Ratio of aeration rate to that at 20° cent.	Column (2) times Column (3).	Figures in Column (4) expressed in percentage of value at 20° cent.
(1)	(2)	(3)	(4)	(5)
5	12.80	0.79	10.1	110
20	9.17	1.00	9.17	100
25	8.38	1.10	9.22	100.3

The figures in Table 15 indicate that the net variation in the rate of absorption of the waters from the highest ordinary summer temperatures to those closely approaching the lowest in winter is not much more than 10 per cent. The difference in the range in which engineers are mostly interested is considerably less and, in any event, within the limits within which the values of aeration and oxygen demand of the waters in a stream can be determined. With the present knowledge of the values involved, would it not be permissible to express values for reaeration in terms of percentage of saturation and neglect temperature corrections, except as they are involved in determining the percentage of saturation of the liquid?

The intent of this discussion is not to detract from the importance of the work which is described by Mr. Streeter. This work marks a distinct advance in the science of the study of problems relating to the condition of polluted waters. The application of the methods outlined, however, must be made with caution in order that the fundamental assumptions in the theory developed may be in accord with the actual conditions in the particular problem to be solved.

J. Frederick Jackson,* M. Am. Soc. C. E. (by letter).—Following Mr. Hoskins' suggestion, a comparison of the results obtained by him with some of those obtained on the Naugatuck and Hockanum Rivers in Connecticut is herein attempted.

Taking the seasonal variation, the total count for bacteria in summer below Chicago, Ill., was 24 828 billions and for *B. coli,* 428 billions per capita per day; in winter, it was 4 257 billions and 42 billions, respectively. The results

* Cons. Engr., New Haven, Conn.

for Peoria, Ill., Cincinnati, Ohio, and Louisville, Ky., are similar, that is, the number of both total bacteria and *B. coli* was much larger in summer than in winter.

Below Waterbury, Conn., on the Naugatuck River, for summer the total bacteria were 4 839 billions and the *B. coli,* 1 068 millions per capita per day; and for winter the count was total bacteria, 429 billions, and *B. coli,* 1 334 millions. The results below Torrington and Ansonia, Conn., show the same relation in numbers of bacteria for summer and winter. While the results obtained on the Naugatuck River show higher numbers of bacteria in summer than in winter, the percentage increase is much less than on the Ohio and Illinois Rivers and the *B. coli* actually were greater in number in winter than in summer.

The differences are shown more clearly in the following maximum and minimum monthly counts of bacteria per cubic centimeter:

Below Torrington:	
In June: Maximum total bacteria	162 000
B. coli	37
In December: Maximum *B. coli*	1 000
Total bacteria	25 000
Below Waterbury:	
In June: Maximum total bacteria	347 000
B. coli	28
In December: Maximum *B. coli*	622
Total bacteria	23 000
Below Ansonia:	
In October: Maximum total bacteria	985 000
B. coli	8
In March: Maximum *B. coli*	280
Total bacteria	34 000

These results show a consistently higher number of *B. coli* for the winter than for the summer months. Mr. Hoskins states:

"Such bacteria tend to increase in numbers in the receiving stream for a short period and then decrease at orderly rates as the time from the point of maximum density is increased. These rates of decrease * * * being most intensive during the warmer months and under conditions where the density of bacteria was greatest."

On the Naugatuck River, the results in bacteria per cubic centimeter were:

Above Torrington:	
Total bacteria	6 000
B. coli	103
3 miles down stream below the city:	
Total bacteria	123 000
B. coli	289
5.6 miles farther down stream:	
Total bacteria	208 000
B. coli	289

Above Waterbury:
Total bacteria 30 000
B. coli 92
4.7 miles down stream below city:
Total bacteria 302 000
B. coli 164
2 miles farther down stream:
Total bacteria 424 000
B. coli 189
Above Ansonia:
Total bacteria 504 000
B. coli 28
5 miles down stream below city:
Total bacteria 479 000
B. coli 121

These results do not confirm those obtained on the Ohio and Illinois Rivers in relation to the time factor and the decrease in number of bacteria or as to the largest rate of decrease being during the warmer months.

Applying the formula proposed by Mr. Hoskins for computing the number of *B. coli* per cubic centimeter contributed to a stream by sewered populations (page 1368), and using the mean annual flow of the Naugatuck River and the coefficients used by him, the results shown in Table 16 are obtained. The difference between the computed and the actual numbers of bacteria is so great as to cast suspicion on the general applicability of the formula.

In order to determine whether industrial conditions on the Naugatuck River were responsible for the differences in the seasonal variation and the number of bacteria as computed and as actually found, the same computations were made for Rockville, Manchester, and East Hartford, Conn., on the Hockanum River where the industrial wastes entering the river are not such as should affect materially the bacteria or plankton.

TABLE 16.—Comparison of Computed and Actual Number of Bacteria.

	Total Bacteria.		*B. coli.*	
	Computed.	Actual.	Computed.	Actual.
Torrington, Conn.	1 175 000	123 000	23 088	289
Waterbury, Conn.	1 302 179	302 000	25 590	164
Ansonia, Conn.	167 721	479 000	3 295	121

Above Rockville the maximum total bacteria was, in August, 9 800, and the maximum *B. coli* was, in March, 10; 5.4 miles down stream below the city the maximum for both was, in March, total bacteria, 4 000 000 and *B. coli,* 100 000.

Above Manchester, the maximum for both was, in June, total bacteria, 765 000 and *B. coli,* 1 000; 4.6 miles below Manchester, the maximum for both was, in March, total bacteria, 620 000 and *B. coli,* 10 000; 3.5 miles down stream

at the mouth of the river, the maximum total bacteria was, in March, 780 000 and for *B. coli,* in May, 1 000.

The figures for bacteria computed according to Mr. Hoskins' formula and those actually occurring are as given in Table 17.

TABLE 17.—Comparison of Computed and Actual Number of Bacteria.

	Total Bacteria.		*B. coli.*	
	Computed.	Actual.	Computed.	Actual.
Rockville, Conn.	938 000	877 000	19 100	17 600
Manchester, Conn.	247 000	246 000	5 040	7 400
South Manchester, Conn.	70 042	150 000	12 400	2 200
East Hartford, Conn.	469 000	102 000	9 543	396

The seasonal variation compares more favorably with results on the Ohio and Illinois Rivers, and there is a fairly close agreement between the computed and the actual numbers of bacteria below Rockville and Manchester both of which have sewage disposal plants which, however, are in very poor condition. Below South Manchester and East Hartford the results vary considerably. South Manchester has a sewage disposal plant, but it is not in operation. The dye wastes discharged from the silk mills may have an inhibiting action on the bacteria. Opportunity for sedimentation in the pond above the sampling stations may be another explanation. The samples were collected above the sewer outfall at East Hartford, where the river is affected by tidal action, but this would not explain entirely the differences obtained.

While Mr. Hoskins has evidently established a relation between sewage population and *B. coli* in streams receiving wastes, the general application of his formula is apt to give quite misleading results. It is certain that it does not apply to streams of the character of the Naugatuck River, and its application to a stream similar to the Hockanum would lead to wrong conclusions unless one were familiar with conditions likely to effect its application.

The advisability of using the numbers of bacteria as an index where results are so erratic is questionable. At the best, the count of bacteria is only an estimate and the chance for error by using the prevailing technique is very great. Further, the magnitude of the number entering into the argument is so great that the variations between different places are relative only and the actual differences are hardly comprehensible.

Harrison P. Eddy,* M. Am. Soc. C. E.—The members of the Sanitary Division are indebted to Dr. Frost and the other investigators of the U. S. Public Health Service for the fundamental scientific work which they have been doing over a period of many years. Doubtless, they enjoy some satisfaction and encouragement in knowing that their investigations have provided much of the supporting data and evidence used by the Engineering

* Cons. Engr. (Metcalf & Eddy), Boston, Mass.

Board of Review in its study and in the preparation of its report on the disposal of the sewage of the Sanitary District of Chicago.

Thus far, the sewage has been disposed by dilution, only an insignificant part having received treatment prior to the discharge into the Canal System. Among the interesting conditions is the unique fact that in the summer the Des Plaines-Illinois River into which the sewage is discharged is nearly as large at its source as at its mouth. This is due to the great volume of sewage and diluting water discharged from the Main Drainage Canal of the Sanitary District into what may be termed the head-waters of the Des Plaines-Illinois River the natural flow of which is relatively small at that season of the year. At the point of confluence this flow is usually a few hundred cubic feet or less per second, whereas the discharge from the Main Drainage Canal has been as large as 10 000 cu. ft., of which about 10% was sewage.

Another matter of great interest developed during the investigations of the Board of Review is the effect of the temperature. Mr. Theriault's paper shows how the temperature has a marked effect on the volume of diluting water required to maintain certain conditions in the river. The discharge of polluting matter or sewage into a river during the cooler season of the year may be compared with refrigeration. Meat is placed on ice to prevent its decomposition and change. If sewage is discharged into a river during the winter the rate of change will be extremely slow, with the result that the volume of diluting water required to maintain a certain percentage of saturation with oxygen will be relatively small. This condition has a very important bearing in many disposal problems and advantage may be taken of it to reduce the cost of treatment of industrial wastes and sewage in many cases in the northern part of the United States. This has been done notably by certain tanneries and paper mills in Massachusetts. It is practicable for such industries to reduce the treatment of their wastes to the removal of settleable solids during the cool season of the year, whereas during the period of high temperature it may be necessary to carry the treatment much further. This principle of more fully utilizing the conditions of Nature in the economical disposal of sewage and industrial wastes undoubtedly will occupy a more important place in the operation of treatment plants in the future than it has in the past.

Another interesting subject, mentioned by Mr. Streeter, is the effect of sludge deposits in rivers. The study of the Board of Review showed that this is an important factor in the disposal of the Chicago sewage by dilution, as it has been in many stream-pollution problems in other parts of the country.

The effect of temperature upon the oxygen demand exerted by organic matter in the water is not different from the effect upon the oxygen demand exerted by the organic matter in sludge deposits. Solids suspended in the water constitute a traveling load. In winter, those which are carried by the currents from the source to the mouth of a river may not exert a great oxygen demand and they may then finally be disposed of with similar solids which may be deposited on the bed of the river. They also will exert only a relatively small oxygen demand in winter, but as soon as the temperature reaches the point where decomposition proceeds rapidly the rate at which

they exert their oxygen demand is greatly increased. Thus, a larger proportion of the oxygen demand of the year's deposit of solids is exerted in the two or three months during which the oxygen demand of the flowing load is also highest. This illustrates the importance in many cases of always removing the suspended matter from sewage and industrial wastes even if the oxygen supply in the river water during certain seasons of the year may be high.

H. A. WHITTAKER,* Esq. (by letter).—Dr. Frost presents in his paper a clear picture of the past and present scientific investigations of the U. S. Public Health Service on stream pollution and certain allied problems. The program of investigations in progress, which include intensive studies of the natural purification of streams, the subject of sewage treatment, and water purification, covers the fundamentals of the problem, and embraces most of the agencies involved in the protection of man against water-borne diseases. The fact that these investigations are being conducted under both experimental and natural conditions increases the possibility of obtaining accurate information on the basic laws relating to these subjects and their application to practical conditions. Since the results of these investigations have a nation-wide application, this field of study is logically one for the Federal Government to sponsor although certain problems may be undertaken in co-operation with the various States that are equipped to carry on similar activities.

It is now recognized that where public water supplies are involved, there is only one attitude toward this question and that is that the pollution of streams and lakes used as water supplies must be so limited as not to impair the safety or palatability of any water supply obtained from the same stream or lake. The other condition, that the stream or lake is not used as a source of water supply, is a phase of the problem which is more difficult of solution. Here, on the one hand, is the value of streams and lakes for recreational purposes—boating, bathing, fishing, etc.—admittedly of great value to the public but very difficult to place on a monetary basis; and the use of streams and lakes for commercial fishing, the value of which can be quite definitely established. On the other hand, is the relatively great expense of constructing and operating sewage treatment works to which municipalities and industries would be subjected if all sewage and waste previously discharged into inland waters were to be treated.

It must be admitted quite candidly that except where water supplies and bathing beaches are affected, or cattle are exposed to sewage polluted streams and lakes, the health aspect of this problem is relatively slight. In most cases the cost of constructing and operating sewage treatment works greatly exceeds the value of commercial fishing in inland waters. In many instances bathing beaches can be established in waters not subject to sewage pollution, or such facilities can be provided by the construction of artificial bathing places. Cattle may be affected by contact with sewage polluted waters, but the fact remains that these same cattle are probably in greater danger of contracting disease from infected animals that are pastured up stream on the same watershed than from municipal sewage. It would seem that, in most cases, cattle

* Director, Div. of Sanitation, Minnesota State Board of Health, Minneapolis, Minn.

can be more surely protected against all forms of water-borne diseases by fencing off the streams and providing the animals with clean drinking water from other sources than by the installation of sewage treatment works.

Apparently, where public or industrial water supplies are not affected, it must either be frankly admitted that the recreational value of streams and lakes is not commensurate with the cost of sewage treatment and the lakes and streams not used as sources of water supply must be considered simply as places for the natural disposal of sewage, or the intrinsic worth of preserving these lakes and streams in their natural condition must be set so high that there can be no question as to the soundness of a policy of treating practically all sewages and industrial wastes to such a degree that the condition of the stream or lake will be practically what might be expected if no sewage or wastes were discharged into it. Just what will be the final outcome only future developments will reveal. Already powerful organizations, such as the Isaac Walton League, are endeavoring to mould public opinion and create a public demand for protective measures against stream pollution.

The Minnesota Department of Health has taken the attitude that no drastic legislation should be enacted until a comprehensive sanitary engineering survey has been undertaken on the streams and lakes throughout the State, and until rather detail information relative to actual conditions has been obtained. After this has been done, it should be possible to outline a policy which would have a remedial effect so far as the State of Minnesota is concerned.

Minnesota contains the head-waters of several important rivers which flow into or adjacent to other States or provinces. Two adjoining States have already entered formal complaint regarding the pollution of interstate rivers. The Wisconsin State Legislature, during its 1925 session, appointed a committee to take up with the Minnesota Legislature, then in session, the question of the pollution of the Mississippi River. As a result of this action the Minnesota Legislature also appointed a committee to investigate the pollution of the boundary waters between Minnesota and Wisconsin. The two Committees have held a joint meeting and have decided to co-operate in their study of the problem which is of common interest to both States. The Committees have jointly requested the U. S. Public Health Service to detail a sanitary engineer to co-operate with the sanitary engineers of the Departments of Health of Wisconsin and Minnesota in working out a plan of scientific study of the Mississippi River in relation to stream pollution. The Cities of Minneapolis and St. Paul have also offered to co-operate in this study which is of interest to them in determining a future course to follow in regard to sewage disposal. The interests of the parties involved are so varied that any co-operative work, to be acceptable to all, must necessarily be directed by some disinterested and thoroughly competent agency such as the U. S. Public Health Service.

It is hoped that the splendid work already being conducted by Dr. Frost and his associates in the Service will be continued and expanded so as to insure the just and equitable solution of the stream pollution problem in the United States in all its phases.

KENNETH ALLEN,* M. AM. SOC. C. E. (by letter).—The four papers by Messrs. Frost, Theriault, Streeter, and Hoskins present an admirable summary of the notable investigations carried on by the U. S. Public Health Service on stream pollution which constitute a distinct advance in studies of this subject.

The pollution of bodies of salt water presents similar problems and although the principles controlling oxidation and reaeration are the same, the rates at which these take place and the products of decomposition are, because of the salinity of the water, quite different. Moreover, the tides present conditions as to velocity, direction of flow, and degree of dilution, that are quite at variance with those found in inland waters.

These modifying conditions as related to the problem of New York Harbor are thoroughly discussed in the three reports—issued in 1910, 1912, and 1914—of the Metropolitan Sewerage Commission and in the excellent paper† by H. de B. Parsons, M. Am. Soc. C. E. This discussion is confined to a résumé of the studies and work looking to a better control over the pollution of the waters of New York Harbor that have been carried out since 1914.

Dissolved Oxygen.—Chemical examinations to detect pollution have been practically confined to tests for dissolved oxygen,‡ as this has been found the best criterion of pollution for which field tests can be readily made. Beginning with the results obtained by the Metropolitan Sewerage Commission in 1909 there is, with the exception of 1910, a continuous record of warm-weather saturations.§

The average and minimum percentages found at certain representative stations and the average for the main branches of the harbor in 1909 and 1924 are given in Tables 18 and 19. About one-half the samples were taken from near the surface and one-half from near the bottom so that the averages furnish a fair measure of the general condition of the waters.

The general average summer saturations in the main branches of the harbor are shown in Table 20.

The most striking loss of dissolved oxygen is seen to be in the Lower East River, where the degree of saturation in 1924 was only 40% of that of 1909.

In the summer of 1921 exceptionally low saturations were noted:

At Throgs Neck, an average of 49 and a minimum of 24 per cent.
At the Narrows, an average of 35 and a minimum of 15 per cent.
In the Hudson River, an average of 30 and a minimum of 12 per cent.
In the Lower East River, an average of 16 and a minimum of 0 per cent.‖
In the Harlem River, an average of 15 and a minimum of 0 per cent.

Remembering that a few days of complete depletion in warm weather would result in a very serious condition it is significant that from past experience minimum percentages may be expected any summer, not exceeding about 20%

Population and Sewage Flow.—The chief cause of harbor pollution is the sewage from the population of the Metropolitan District,* now estimated at 8 700 000.

The population of New York City was 5 620 048, or, excluding sailors on ships and those living on islands in the East River, about 5 586 500, in 1920, and it is estimated that by 1960 this figure will have increased to 11 900 000, as indicated in Table 21.

* Including White Plains, N. Y., on the north, the mouth of Raritan River on the south, the New York City limits on the east, and Paterson, Summit, and Perth Amboy, N. J., on the west; in all about 700 sq. miles, within a range of from 15 to 20 miles from New York City Hall, Report, Metropolitan Sewage Comm., 1910.

* By Metropolitan Sewerage Commission.

In the entire Metropolitan District, as defined by the Metropolitan Sewerage Commission,* there were 5 834 857 inhabitants in New York State and 1 863 577 in New Jersey—a total of 7 698 434—in 1920, and by 1960 it is believed these figures will be increased to 12 312 000 in New York and 3 377 000 in New Jersey, or a total of 15 689 000. The distribution of these populations is given by counties in Table 22.

The volume of sewage entering New York Harbor from New York City is estimated at 940 000 000 gal. per day for 1920 and 1 757 000 000 gal. per day for 1960, and the quantity from each Borough to each of the main divisions of the harbor is given in Tables 23 and 24. From these tables it will be seen that about four-fifths of the total quantity is received above The Narrows,

* Including White Plains, N. Y., on the north, the mouth of Raritan River on the south, the New York City limits on the east, and Paterson, Summit, and Perth Amboy, N. J., on the west; in all about 700 sq. miles, within a range of from 15 to 20 miles from New York City Hall, Report, Metropolitan Sewage Comm., 1910.

through which it flows to the Lower Bay. These estimates are based on the water supply, which averaged 131 gal. per capita of the residential population in 1920 and is estimated to average 130 gal. per capita in 1960, to which is added a small volume due to infiltration of ground-water.

Aside from the sewage of New York City there is that from the outlying population. If this is taken as averaging 80 gal. per capita daily, it amounts

to 166 000 000 gal. per day from a population of 2 078 386 in 1920 and will amount to 303 000 000 gal. per day from 3 788 996 persons in 1960. The total volume then produced in the Metropolitan District will be 2 060 000 000 gal. per day.

Causes of Pollution.—As already mentioned, the chief cause of harbor pollution is the sewage from the 8 700 000 inhabitants of the Metropolitan District. That entering each main branch of the harbor from each Borough of New York in 1920 is given in Table 23 and as forecast for 1960 in Table 24. With a uniform increase the volume in 1925 may be taken at 1 050 000 000 gal. per day, and assuming a daily volume of 80 gal. per capita from the

2 300 000 persons in the outlying sections of the Metropolitan Area the total volume now produced, in gallons per day, is,

$$1\,050\,000\,000 + (80 \times 2\,300\,000 = 184\,000\,000) = 1\,234\,000\,000$$

* Allowing for 14 000 000 gal. per day diverted from the Borough of Queens to the East River at North 12th and South 5th Streets, Brooklyn.

Of the sewage received from outside of New York City by far the most important contribution is from the Passaic Valley Sewer District. The popu-

lation of this District is estimated at 995 000 and the sewage delivered to the outlet is understood to approximate 135 000 000 gal. per day. No such volume is received at any other outlet in the Metropolitan District, the 1 050 000 000 gal. per day from the City of New York being discharged through about 465 outlets, distributed as follows:

Manhattan	190
The Bronx	30
Brooklyn	100
Queens	95

Besides the domestic sewage there is more or less industrial waste. This is an important consideration in the Passaic Valley Sewer District where there are large woolen, silk, dye, chemical, and metal works and where their waste constitute a material part of the total flow. In New York there are large gas and oil works and a limited number of other plants, such as packing houses, dye works, etc., while along the New Jersey shores of the Arthur Kill there are important chemical, copper, oil, asphalt, and fertilizer works. Within the New York area industrial wastes, aside from oil, do not materially affect general conditions. Although it is admitted that, in spite of the required

use of separators at garages, large quantities of gasoline and case oil reach the sewers and are the cause of occasional explosions, the total domestic sewage is so much larger in proportion that oil from these sources is not recognizable at most sewer outlets. The fields of sleek and oil found on the open water are mainly due to the surreptitious pumping out of oil tanks on vessels, from careless or accidental spills at refineries and gas works, and from the wastes received or washed off by the tide at ship-repair yards.

Sludge beds increasing the depletion of oxygen in the outlying waters are prevalent in the slips, in Wallabout Basin, Gowanus Canal, Newtown Creek, Newark Bay, off Hoboken, Bergen Point, and Elizabethport. The channels of the Lower East River and the Jersey Flats are relatively free from deposits.

Disregarding the depletion of dissolved oxygen due to sludge deposits or other than domestic sewage and assuming 0.22 lb. per capita, the writer roughly estimated the biological oxygen demand of the harbor waters in 1920 at 1 558 700 lb. per day.

To offset the effect of this demand on the oxygen of the harbor there is the replenishment of oxygen due to that brought in by the tides and fresh-water streams, that absorbed from the air, and a certain amount set free by aquatic vegetation. In some streams the latter may be the controlling factor, and at times this is probably true of Jamaica Bay, where samples frequently show supersaturation. In New York Harbor, however, as a whole, one would not be warranted in relying on so uncertain and temporary a supply. Disregarding the production of oxygen by algæ and other vegetation, and making certain rather crude assumptions as to average saturations, salinity, temperature, and stream flow, the oxygen supplied by incoming tidal and upland waters was estimated* at 1 000 600 lb., and that due to surface absorption at 863 100 lb. per day, leaving an excess available for purposes of purification of 305 000 lb. per day, provided diffusion were complete and no other factors were involved. Where the several basic conditions are in a state of such constant flux and where so many assumptions must be made on incomplete supporting data, estimates of this kind must be taken with reservation and considered merely as indicating possible conditions.

The importance of recognizing the effect of reaeration in any forecast of conditions is made very clear by Mr. Streeter and from his able analysis of the results secured in studying the Ohio River such forecasts may be made in the case of fresh-water streams of known characteristics with reasonable confidence. The reaeration of quiescent sea water is probably at a slower rate than that of fresh water although diffusion is as a rule more rapid. When disturbed by winds, eddies, or vessels, the rate of absorption is increased by bringing the less highly oxygenated water to the surface. Owing to the limited depth affected by these causes the increased rate is less in deep than in shallow waters.

These influences are fully discussed by W. M. Black, M. Am. Soc. C. E., and Mr. Earle B. Phelps in Chapter II of their report to the Chief Engineer of the Board of Estimate and Apportionment of New York City dated Feb-

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 718.

ruary 16, 1911. In this report the attempt is made to find an average rate of absorption for the waters of the harbor after making due allowance for salinity, depth, temperature, and the mixing action due to tides, vessels, and wind. They say:

"The action of wind and tide reverses the conditions found in quiescent water, in that the rate of absorption of oxygen per million gallons increases slightly with increasing depth down to 30 ft. With the added action of boats this effect is not so noticeable, and in the final results the combined effect results in a very even rate of absorption so that special treatment of the 12-ft. depths need no longer be considered and for all practical purposes the average rate of absorption in the Bay and Lower Hudson may be taken at 0.045, in the East River at 0.050, and in the Upper Hudson at 0.019 lb. per hour per million gallons of water in all depths less than 40 ft. The effect of aeration in depths greater than 40 ft. may safely be disregarded."

During February, March, and April, 1916, experiments were made by Warrent R. Borst, Assistant Engineer, under Theodor S. Oxholm, M. Am. Soc. C. E., then Engineer in Charge, Bureau of Engineering, Borough of Richmond, to determine the absorption of atmospheric oxygen by dilutions of sewage in fresh and salt water.* The liquid was placed in one of four tanks 25 ft. long, 6 ft. wide, and 6 ft. deep, and tested at stated intervals for dissolved oxygen (*a*) when quiescent; (*b*) when slightly agitated by two electric fans; and (*c*) (in the saline mixtures) when mechanically agitated by a strip of furring extending across the tank forming waves about 4 in. high. Temperatures were maintained at about 20° cent. by exhaust steam and simultaneous samples were taken at different depths.

As a control, tightly stoppered bottles of the mixture were kept immersed in the tank during agitation, by which the oxygen demand could be determined and allowed for. The absorption was then computed by adding the oxygen demand to the increase of dissolved oxygen in the tank.

These experiments were never carried out to such an extent that specific rates of absorption could be confidently stated, but they warranted the acceptance of certain general conclusions. With twenty dilutions of sewage with fresh water and a ½-in. ripple the absorption of oxygen after the fourth hour was 0.18 parts per million per hour, whereas with a like dilution with salt water it was 0.085 parts per million per hour. With a salt-water dilution devoid of oxygen at the start and a 4-in. wave the dissolved oxygen at the end of 4 hours at all depths was 6.56 parts per million—an increase of 1.64 parts per million per hour. After 4 hours' agitation and 20 hours' rest, the dissolved oxygen had decreased to 4.50 parts per million. In general, it was found that "reaeration is decidedly rapid and uniform throughout the body of water."

Experiments along somewhat similar lines were made by Professor Edward Ellery, of Union College, and the results given in evidence before the Supreme Court in the Passaic Valley sewer case.† These comprised studies with pol-

* Report on Sewage Experimental Investigations at West New Brighton, Staten Island, N. Y., by Warren R. Borst, 1919.

† Transcript of Record, October Term, 1916, No. 3, Original. The People of the State of New York *vs.* the State of New Jersey, and the Passaic Valley Sewerage Commissioners, Vol. 3, p. 2824, and Vol. V, p. 4603.

luted and unpolluted fresh and salt water, both quiescent and in motion. The results reached by Professor Ellery may be summarized as follows: When it is 40 to 60% saturated with dissolved oxygen, water of 60 to 70% as much salinity as sea water absorbs atmospheric oxygen at about the same rate as fresh water. This rate varies from between 0.18 cu. cm. and 0.306 cu. cm. per liter per day in quiescent water to 0.515 cu. cm. in water flowing at the rate of 1 ft. per sec. It diminishes as the humidity increases and increases with increased pollution. Under conditions of low humidity a permissible dilution of sewage in water quiescent or moving less than 1 ft. per sec. is 1 to 100, while a dilution of 1 to 60 is not permissible, resulting in an appreciable lowering of the oxygen content.

Standard of Cleanness.—Suggested standards of cleanness for New York Harbor have naturally laid stress on the dissolved oxygen content. Maximum values have varied from 70% saturation, proposed by Messrs. Black and Phelps in order to avoid detriment to major fish life, to 25% proposed by the late Rudolph Hering, M. Am. Soc. C. E., who stated: "I consider a standard of 25% with frequent sludge removal from the harbor bottom a safe protection against any nuisance arising from the water." Opinions of other authorities range between these limits. In a review of the subject* the writer gave as his opinion:

"That to ensure a supply of dissolved oxygen at all points of a stream or harbor a liberal margin is required in the main body of the water, which, in the case of New York, should not be less than from 30% to 50% saturation, depending upon the intensity of local pollution due to sewage, the septicity of the sewage, the temperature of the air and on the amount of the sludge deposits on the bottom."

The essential matter is to provide that at no point shall the water be deprived of all its dissolved oxygen. Owing to the difficulty in expressing this in definite terms that might not be misconstrued, the Metropolitan Sewerage Commission finally omitted reference to any specific degree of saturation from its recommended standard which was as follows:

"Proposed Standard of Cleanness

(1) "Garbage, offal, or solid matter recognizable as of sewage origin shall not be visible in any of the harbor waters.

(2) "Marked discoloration or turbidity, effervescence, oily sleek, odor or deposits, due to sewage or trade wastes, shall not occur except perhaps in the immediate vicinity of sewer outfalls, and then only to such an extent and in such places as may be permitted by the authority having jurisdiction over the sanitary condition of the harbor.

(3) "The discharge of sewage shall not materially contribute to the formation of deposits injurious to health or navigation.

(4) "The quality of the water at points suitable for bathing and oyster culture should conform substantially as to bacterial purity to the drinking water standard. It is not practicable to maintain so high a standard in any part of the harbor north of The Narrows, or in the Arthur Kill."

No further attempt has been made to formulate a standard.

* Annual Report, Chief Engineer, Board of Estimate and Apportionment, New York, N. Y., 1917.

Plans for Remedy.—The general principles underlying any reasonable plan of main drainage are set forth in Part II, Chapter I, of the Final Report of the Metropolitan Commission, which proceeded to describe in some detail a plan that it could recommend. Similarly, Messrs. Black and Phelps, in their report to the Chief Engineer of the Board of Estimate and Apportionment of New York, previously mentioned, presented a general plan for the collection and disposal of the sewage, while, in 1920, the writer also presented a report to the Chief Engineer of the Board reviewing the entire subject and submitted a tentative revision of the general plan.* Based on these earlier studies and taking advantage of the more recent developments in methods of treatment, the tentative plan as now proposed to meet 1960 conditions may be briefly stated, as follows:

Where a high degree of stability as well as freedom from solids is demanded, the activated sludge process promises to afford the most desirable form of treatment, and plants of considerable size are contemplated: (1) At Wards Island, to handle 187 000 000 gal. per day of sewage; and (2) south of Jamaica to handle 114 000 000 gal. per day. These, it is believed, will control the serious pollution that would otherwise occur in the neighboring parts of the East River and Jamaica Bay.

Large populations on other areas, tributary to the East River, Jamaica Bay, and the waters of Coney Island, will make it necessary to remove a much larger quantity of polluting material than can be accomplished by screening, and sedimentation plants will probably be installed in the East River at Old Ferry Point, Tallman's Island, Rikers Island, Welfare Island, near Sheepshead Bay at the precipitation plant now known as Caisson No. 4, and on Rockaway Point.

For other localities it is believed that fine screening will suffice. Of these screening plants the most important now contemplated will be at West 155th Street, Manhattan, to which about 92 000 000 gal. per day will be diverted from areas now tributary to the Harlem River and carried to a submerged outlet 1 000 ft. or more from shore. If this plan should be carried out it would be equivalent to a reduction in population on the tributary drainage areas roughly estimated at 1 180 000 in 1960, or 33% of the resident population, as follows:

Assuming a removal of 5% of the putrescible matter by fine screening, 33⅓% by sedimentation, and 85% by the activated sludge process, the results would be:

5% of 1 992 000 persons by screening	100 000
33⅓% of 342 000 persons by sedimentation	181 000
85% of 1 052 000 persons by activated sludge.....	899 000
Equivalent to a reduction in population of.....	1 180 000

Stated another way, the result would be the same as if the population were decreased from 3 586 000 to 2 406 000. The estimated cost of carrying out this

* Annual Report, Chief Engineer, Board of Estimate and Apportionment, New York, N. Y., 1920.

project, including interception, is $33 442 000, or $28 341 for the elimination of the pollution resulting from each 1 000 persons.

Most of these projects have never advanced to the point of authorization or even of general discussion and acceptance. It is probable that they will, in large measure, be adopted and the works built piecemeal as demanded, but modified as to detail to meet the situation. It is hardly open to argument (*a*) that to protect the waters of the Lower East River and Jamaica Bay, either a large volume of the sewage must be entirely removed or else some method of treatment equivalent to the activated sludge process must be used; and (*b*) that, for the further protection of the large volumes of sewage that will eventually reach the East River, other large volumes will have to undergo some more complete treatment than fine screening, but for the majority of the smaller installations this will be all that can be reasonably required. Chlorination is desirable where bathing beaches or shellfish are to be protected, but otherwise would appear to be an unwarranted expense.

Progress already made in carrying out this program includes the following items:

On the Hudson River, a fine-screening plant with two 14-ft. Riensch-Wurl screens, chlorination, and submerged outlet has been installed at Dyckman Street, Manhattan.

A fine-screening plant with three 6 by 55-ft. Rex screens and chlorination has been installed at Canal Street, Manhattan, for the Clarkson Street sewage brought to the plant by a 54-in. intercepting sewer.

On the Upper East River, a fine screening plant with two 14-ft. Riensch-Wurl screens, chlorination, and a 36-in. submerged outlet, 3 280 ft. long, has been installed at 25th Street, near North Beach, Queens.

On Staten Island, a fine-screening plant with two Dorrco screens, 6 ft. in diameter by 4-ft. face, with chlorination and a submerged outlet, was installed in 1923. This is operated in the summer for the protection of bathers at South Beach and Midland Beach.

A fine-screening plant with two Link-Belt screens, chlorination, and a submerged outlet to protect a bathing beach near Great Kills is under construction.

On the shores of Jamaica Bay at the old 26th Ward Plant, Brooklyn, two 14-ft. Riensch-Wurl screens which have been in operation for several years and two new 26-ft. screens of the same type have been installed in the building that heretofore has housed the tanks of a precipitation plant.

In Queens, a plant comprising two 26-ft. Riensch-Wurl screens is being constructed south of Jamaica to serve the Fourth Ward of that Borough (north of Jamaica Bay) and one with two 22-ft. Riensch-Wurl screens at Hammel to serve the Fifth Ward (The Rockaways). The former constitutes the first installation of an activated sludge plant to treat 120 000 000 gal. per day of sewage from the entire Fourth Ward of Queens.

These fine-screening plants (not to mention several temporary hand-operated screens in Queens) probably handle about 85 000 000 gal. per day of sewage—a small quantity, considering the outlay—but at most of the plants the increase in volume will be rapid. In the greater part of the city the main lines of development are fairly well determined. The two major remaining problems

are those relating to the sewage tributary to Wards Island and that of South Brooklyn. Wards Island, although belonging to Manhattan, is leased to the State for institutional purposes until 1963, but it is hoped to obtain a release of about 50 acres through legislative action. This will clear the way for initiating the work of interception and treatment—a measure of great sanitary importance to the city.

The entire subject of handling the sewage of Brooklyn and Queens tributary to Jamaica Bay was treated in a report submitted by the writer to the Chief Engineer* in 1917. At that time a plan originating with the Metropolitan Sewerage Commission was recommended, conveying all the sewage tributary to the Bay from the north to a treatment plant on Barren Island. Since then developments at Barren Island and Rockaway Point to the south and a greater confidence in the reliability and inoffensive character of the activated sludge process have resulted in a modification of the original plant,† whereby the sewage of the Fourth Ward, Queens, will be treated locally by this process and the sewage of Brooklyn—at least from Coney Island to Canarsie—will be brought to an old existing precipitation plant near Sheepshead Bay, known as Caisson No. 4, for some suitable method of treatment. The sewage tributary to the 26th Ward Plant may later be treated by activated sludge or, more probably, brought to Caisson No. 4 for treatment.

To provide a central authority to co-ordinate interborough problems of sewage disposal and the control of harbor pollution a Committee on Main Drainage has been appointed, consisting of the President of each of the five Boroughs of New York and the Chief Engineer of the Board of Estimate and Apportionment, Arthur S. Tuttle, M. Am. Soc. C. E. In a broad sense, these problems are of general concern, affecting the welfare of the city as a whole, and by the agency of this Committee the interests of the different Boroughs not only may be presented, but their importance to the entire subject of the city's sanitation may be correlated and unified.

William Firth Wells,‡ Esq. (by letter).—Consideration of the natural changes which pollution undergoes in water is as essential in controlling the quality of water as artificial processes of purification. Engineering practice has been principally concerned with artificial purification, but the present administrative tendency to treat water quality as a natural resource has shown the need of further study of the phenomena of self-purification. From this viewpoint the U. S. Public Health Service studies are particularly valuable. They separate the basic factors, develop methods of measure, determine the relations existing, and lead to a simple and logical system of expression.

The fundamental conditions treated are: (1) Infection, the power of water to convey living forms which may directly affect persons, studied bacteriologically; (2) pollution, the condition produced by the decomposition of dead organic matter, determined biochemically; and (3) contamination, the altera-

* "The Main Drainage and Sewage Disposal of the Area Tributary to Jamaica Bay."

† The plan as proposed in 1917 for the Fifth Ward, comprising Far Rockaway and the Rockaway Peninsula, has since been adopted and is now under construction with a temporary screening plant and outlet at B. 87th Street, Hammel.

‡ Biologist and Sanitarian, New York State Conservation Comm., Glen Cove, N. Y.

tion in quality by contact with foreign substances, tested chemically, as in the studies of trade wastes.

The oxygen studies have been discussed and the importance of the bacteriological work should also be recognized. From data representing years of work under diverse conditions, the determinations of the average daily number of *B. coli* contributed per capita, with the seasonal variation and the rate of disappearance from the streams, make a valuable addition to quantitative bacteriology. The utilization of logarithms in presenting the results is significant. Many advantages can be pointed out: First, it would be impractical to plot directly the ordinary variations in bacterial numbers, whereas the logarithm of the number per liter gives a convenient unit throughout the entire range, from drinking water to the most intense pollution; second, self-purification expressed in logarithmic terms approximates a straight-line function; third, Wolman and Streeter have shown that the ratio of the logarithm of the bacterial content for the influent to that for the effluent in purification processes is nearly constant; fourth, the distribution of these logarithms approximates the normal frequency law, and the average logarithm, therefore, approximates the median sample; fifth, the recognized scale of water quality is more directly represented by the logarithm than by the actual number of bacteria, and water-borne typhoid is more nearly proportional to the logarithm than to the actual number of *B. coli* in a water supply; and, sixth, the dilution method used in bacteriology actually gives a logarithmic scale by the simple numbering of dilutions.

The direct use of the highest positive dilution number, therefore, gives immediately the advantages of the logarithm in a rational system of quantitative bacteriology.

J. K. Hoskins,* Esq. (by letter).—Mr. Jackson has brought out a point that should be emphasized, namely, that excessive quantities of industrial wastes, especially those of a toxic nature, such as acids, metal salts, dyes, etc., materially affect the normal biological regimen of streams into which they are discharged. In such special cases obviously it is impossible to apply any general method of quantitative estimation of the bacterial content.

The Naugatuck River in Connecticut is seriously polluted with copper and brass factory and acid wastes practically throughout its length. Below Torrington, the uppermost city on the stream, where such pollution is less intense, the average concentration of bacteria for the summer months is 248 000 and for the winter 20 800. At points farther down stream, higher counts in winter than in summer might be expected to result because of the greater dilution of the toxic wastes effected by higher stream flows.

On the Hockanum River, above sources of serious industrial waste pollution at Rockville and Manchester, computed estimates, as presented by Mr. Jackson, compare quite favorably with actual observations (Table 17). However, at South Manchester, where silk mill wastes constitute 78% of the total sewage, the lack of correlation of computed and actual results is evident. Furthermore, the observations of the stream at East Hartford were

* San. Engr., U. S. Public Health Service, Cincinnati, Ohio.

made above the sewer outlet and as stated in the published report* of this work, "the results have not indicated the presence of this sewage in the samples collected." This would appear to justify the elimination of East Hartford results from consideration.

This same bactericidal effect of toxic wastes was observed during the course of the studies of Ohio River pollution, notably in the vicinity of Pittsburgh, Pa., where the Monongahela River carries large quantities of acid mine drainage. Here, the weighted average bacterial content of the Allegheny and Monongahela Rivers above Pittsburgh was found to be 4 120 per cu. cm., and of the Ohio River, 11 miles below the city, after receiving the sewage of 827 000 people, only 1 900 per cu. cm., or a reduction of 2 200 per cu. cm.

In closing, the writer desires to state again that justification for the acceptance of the empirical formulas presented in his paper must depend on the results of further observations on numbers of different streams.

Paper No. 1595

NOTES ON SHEAR IN COMPRESSION MEMBERS*

By Ralph E. Goodwin,† Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. C. A. P. Turner, E. G. Walker, Henry S. Prichard, Anders Bull, and Ralph E. Goodwin.

Synopsis

The object of this paper is to apply the principles of Mechanics to the subject of shear in compression members. A method is presented by which given conditions can be analyzed and those which produce the greatest shear can be determined, thus enabling the engineer to design for the most dangerous conditions that he considers it advisable to assume.

The relationship between shear and the slope of the column axis herein given has already been published elsewhere, but as far as the writer is aware, the interesting possibilities of this relationship have not previously been developed.

In spite of the general discussion concerning shear in compression members, which took place following the collapse of the first Quebec Bridge in 1907, the fundamental principles governing shear are not so generally understood by engineers as could be desired, in view of the importance of the subject. On account of the difficulty of applying these principles directly to practical problems, their significance appears to have been overlooked by the Engineering Profession. As the slope of the column axis is a controlling condition, but is seldom known, a theoretical analysis might seem at first glance to be of no practical value. Such a conclusion, however, would be far from the truth. Closer study shows that it is impossible to make safe assumptions without a knowledge of the fundamental principles involved. Without such knowledge the engineer can not even know what possibilities exist, and, therefore, can not

* Published in December, 1925, *Proceedings*.

† Instr., Civ. Eng., Coll. of the City of New York, New York, N. Y.

design for the worst possible condition. It will be shown that the actual shear in Member A-9-L of the first Quebec Bridge must have been approximately double that indicated by the beam analogy which is used by some of the standard engineering reference books and present-day specifications. This fact could not have been determined or explained without a knowledge of the fundamental principles involved in the problem.

It is not claimed that the analysis given in this paper reduces the computation of shear to a mathematical certainty, but it does furnish a scientific basis for the necessary assumptions, and leads to the following interesting conclusions:

1.—The minimum possible shear for a given deflection, instead of the maximum value, which is desired in designing, is given by the time-honored assumption that, in respect to shear, a column is similar to a simple beam with uniform load. If the maximum deflection occurs anywhere except at the middle of the column, the maximum shear will be greater than that indicated by the beam analogy.

2.—Purely theoretical deflection curves which show the maximum deflection occurring at the middle of the column, also give the minimum possible shear for a given deflection.

The reason the actual shear in Member A-9-L of the first Quebec Bridge was twice that indicated by the beam analogy is that it deflected in an **S**-curve (see Fig. 2), and, in general, an **S**-shaped deflection curve will produce double the shear indicated by the beam analogy or by the commonly assumed deflection curves.

Fig. 1 shows a column with hinged ends deflected under load. The shear at the end of this column is obviously ab, the component of the load which is normal to the axis of the column, or

$$\text{Shear} = ab = P \sin G$$

For a parabola, $cd = f$, so that:

$$\tan G = \frac{2f}{\frac{L}{2}} = \frac{4f}{L}$$

As the sine of small angles is approximately equal to the tangent:

$$\sin G = \tan G \text{ (approximately)} = \frac{4f}{L} \text{ (approximately).}$$

Therefore,

$$\text{Shear} = P \sin G = \frac{4Pf}{L} \text{ (very nearly).}$$

As Pf is the maximum bending moment:

$$\text{Shear} = \frac{4M}{L}$$

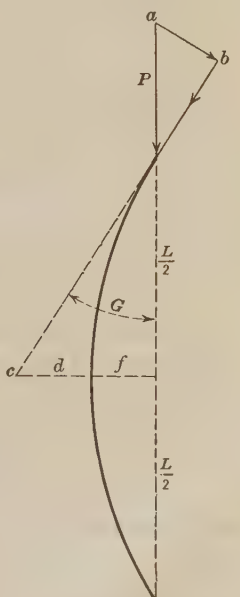

FIG. 1.—COLUMN WITH HINGED ENDS DEFLECTED UNDER LOAD.

The illustration chosen is one in which the maximum shear occurs at the end of the column. In

certain other cases the maximum shear will be elsewhere, but it will always be at a point where a tangent to the deflection curve makes the maximum angle with the direction of the applied load. This last statement may be checked from a different point of view. From the principles of Mechanics it is known that the greatest shear will occur at the point where the bending moment changes most rapidly. For a column, this will be where the tangent to the deflection curve makes the largest angle with the direction of the applied load, as stated previously.

In applying the equations given, it should be noted that the theoretical deflection curve shown in Fig. 1 produces the minimum possible shear. If the same maximum deflection occurred at the quarter-point, the inclination of the axis at the end would be greatly increased, and the shear would be increased proportionately. If an **S**-shaped deflection curve were assumed, the shear would be double that produced by the curve of Fig. 1, or $\frac{8\,M}{L}$. The expression,

shear $= P \sin G$, however, will always be true, if G is the angle between a tangent to the deflection curve at the point in question and the direction of the applied load.

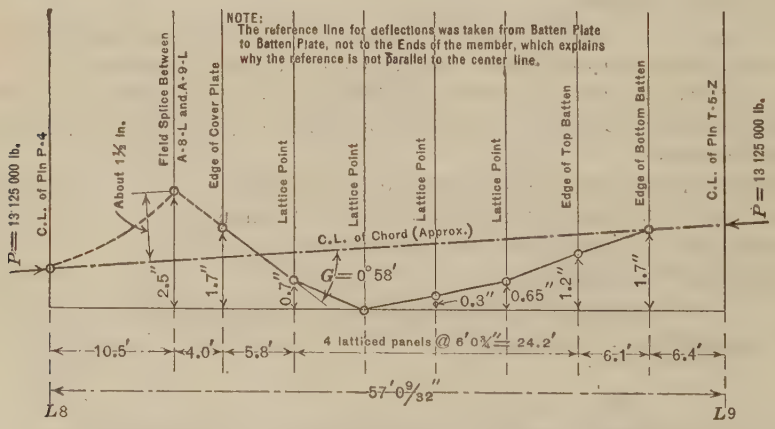

FIG. 2.—DEFLECTION OF CHORD MEMBER A-9-L, FIRST QUEBEC BRIDGE.

A frequently used allowance for shear in columns is 0.02 P. Exactly what this means can be found by applying the principles set forth. It means that the maximum value of the angle, G, must not exceed 1° 09′, if the column is to be safe. For the theoretical case shown in Fig. 1, it also means that:

$$\text{Shear} = \frac{4\,P\,f}{L} \text{ must not exceed } 0.02\,P$$

and, therefore,

$$f \text{ must not exceed } \frac{0.02\,P\,L}{4\,P} = 0.005\,L$$

The application of these principles to the much discussed chord member, A-9-L, of the first Quebec Bridge, which collapsed, is interesting. The

latticing of this member was double, at 45 degrees. There were two ⅞-in. rivets in the end of each lattice-bar. According to the report of the Royal Investigating Commission, the ultimate strength of the rivets in single shear was 50 960 lb. per sq. in., and the total compressive load, P, on the chord at the time of failure was 13 125 000 lb. The maximum total shear indicated by the expression, $P \sin G$, for conditions just prior to failure (Fig. 2), is 223 125 lb., computed as follows:

$$\sin G = 0.017 \text{ (found by scaling Fig. 2)}$$

$$P \sin G = 13\,125\,000 \times 0.017 = 223\,125 \text{ lb.}$$

The total shear indicated by the beam analogy for a maximum deflection, $f = 1\frac{1}{2}$ in. (the maximum deflection reported just before failure) and a length, $L = 57.02$ ft. $= 684.3$ in., is:

$$\text{Shear} = \frac{4\,P\,f}{L} = 115\,100 \text{ lb.}$$

The ultimate total shear necessary to cause failure of the latticing on this member, computed from the value in single shear of the end rivets in the lattice-bars, is:

$$8 \times 0.601 \times 50\,960 \times \sin 45^\circ = 173\,224 \text{ lb.}$$

The method here used for computing the shear corresponding to a given stress in the lattice-bars is the approximate one that assumes the total transverse shear to be resisted by the lattice-bars. The conclusions are not changed, however, when the shear is computed by the rigorous method; that is, the actual shear (as indicated by the deflection curve and the load) was greater than the shear theoretically necessary to cause failure, and was nearly twice as great as the shear indicated by the beam analogy.

As the results just given speak for themselves, extended comment is unnecessary. The method herein described is based on the fundamental conditions of equilibrium and eliminates all assumptions as to the similarity between columns and beams. The difference between practical and purely theoretical cases has been explained and a means furnished by which engineers can design for shear in columns intelligently and with complete understanding of the significance of their assumptions. For purely theoretical deflection curves, it is not difficult to find the maximum shear corresponding to the bending allowances of the standard column formulas. It is highly important, however, to bear in mind that in practical problems the deflection curve may assume a shape which produces much greater maximum shear than the theoretical curve, without causing any increase of bending moment. The example shown in Fig. 2 illustrates such a condition.

A fixed-ended column is acted upon by end couples in addition to the applied load. These couples do not cause any shear because they produce constant bending moment and no shear results from a constant bending moment. For the purely theoretical deflection curve usually assumed, having points of contraflexure at the quarter-points, the maximum shear is found to be $\frac{4\,P\,f}{L}$, which is the same as that derived for the example represented by Fig. 1. In this

case, however, the maximum bending moment is only $\frac{P f}{2}$, owing to the counter moment of the couples, so that the maximum shear for the purely theoretical deflection curve will be $\frac{8 M}{L}$.

In this paper, the term "applied load" signifies the total force acting at the end of a column. If there is a lateral reaction in addition to the load supported (for example, the case of a column fixed at one end and hinged at the other), the applied load will be the resultant of the two forces.

An eccentric load does not produce any greater shear than is produced by a concentric load of the same amount, provided the eccentricity is the same at both ends of the column and provided the deflection curve is the same in the two columns. In the eccentrically loaded column the bending moment will be the sum of the bending moment which exists in the concentric column plus a constant bending moment due to eccentricity; but a constant bending moment does not produce any shear. Therefore, the shear in the two columns will be the same. If, however, the deflection is increased by the added bending moment due to eccentricity, the shear will be increased also, for shear is always equal to $P \sin G$.

In practical problems the eccentricity will ordinarily not be the same at the two ends, and lateral reactions will be introduced which must be considered in the computation for shear. Fig. 3 shows a column which bears on its left-hand edge at the top and on its right-hand edge at the bottom. P_1 is the load supported; P_2 is the lateral reaction, the value of which is $\frac{P_1 e}{L}$; and P_r is the resultant of the two forces. The shear at the middle of the column is $P_r \sin G_r$, but it is not necessary to compute the direction and amount of the resultant force, P_r, because the shear will be $P_2 + P_1 \sin G_1$ (very nearly). The error involved in assuming that P_2 is normal to the direction of the column axis at its middle point is negligible. For this column:

$$\sin G_1 = \frac{8 f}{L} \text{ (approximately), and shear} = P_2 + \frac{8 P_1 f}{L}$$

As this condition is usually considered dangerous, but indeterminate, it will be interesting to examine it somewhat in detail. Let it be required to find the maximum shear in a standard latticed channel column, 25 ft. long, composed of two 10-in. by 30-lb. standard channels.* It will be assumed that the conditions are similar to Fig. 3, and that no allowance was made for eccentricity, as central loading was assumed and the eccentricity resulted from poor workmanship:

Safe total load, by the formula,† $\frac{P}{a} = 19\,000 - 100 \frac{L}{r}$, = 180 000 lb.

8 in. = value of e (Fig. 3), assumed.

* Carnegie Pocket Companion, 1923, p. 225.

† Column formula, American Bridge Company.

$$P_2 \text{ (Fig. 3)} = 180\,000 \times \frac{8}{300} = 4\,800 \text{ lb.}$$

$$\text{Shear} = P_2 + \frac{8\,P_1\,f}{L}$$

In order to avoid exaggeration, f will be assumed to be only 0.1 of 1% of the length. It was 0.22 of 1% for the member, A-9-L, of the first Quebec Bridge. Therefore:

$$\text{Shear} = 4\,800 + \frac{8 \times 180\,000 \times 0.3}{300} = 4\,800 + 1\,440 = 6\,240 \text{ lb.}$$

Therefore, for the conditions assumed, the maximum shear would be 0.035 P_1.

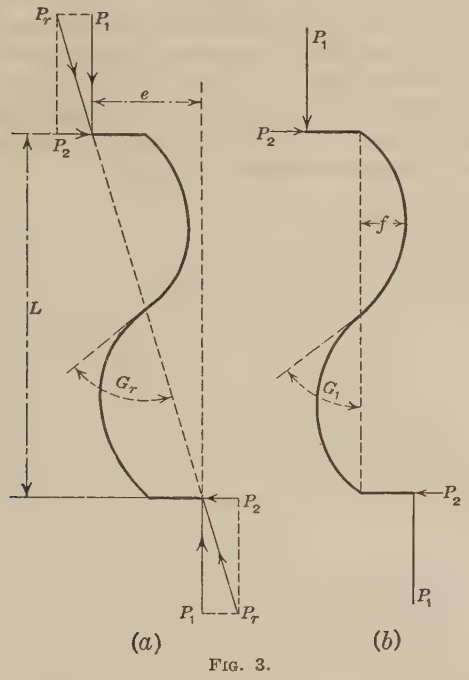

FIG. 3.

No one, least of all the writer, would claim that this result represents actual field conditions with a high degree of precision. The method, however, does furnish a rational basis of attack. It is applicable, not so much to actual design, as to the determination of standard allowances to be included in specifications and rules for standard practice.

Throughout this paper, the theoretical deflection curve has been assumed to be a parabola. Engineers who demand a more rigorous treatment will find that the difficulty of the problem is increased little, if any, by the assumption of a sine curve. A sine curve indicates a theoretical shear about 20% less than a parabola, and is, therefore, less conservative.

In closing, a word of caution is necessary against drawing unwarranted conclusions from the statements that have been made. It has been stated that, for a given deflection, an **S**-shaped deflection curve will produce twice the shear indicated by the beam analogy. It does not necessarily follow from this, however, that the shear allowance for a given column should be twice that indicated by the beam analogy. For example, a centrally loaded column, having round ends and an **S**-shaped deflection curve, is theoretically equivalent to two columns of one-half the length placed end to end. The bending effect (assuming a straight-line column formula) is only one-half what it would be if the deflection curve were a bow, and the theoretical shear to be allowed for in such a case is the same, whether the curve is a bow or **S**-shaped. The fact remains, however, that the beam analogy is a false and misleading concept. Applied to Member *A*-9-*L* of the first Quebec Bridge, it not only gives a result approximately one-half the true value, but also fails to show at what point in the member the maximum shear occurred. It gives results too small for columns designed as fixed-ended, and for all columns that develop the full contemplated bending moment at any point except the middle.

Acknowledgment is due to J. P. J. Williams, M. Am. Soc. C. E., for valuable suggestions in the preparation of this paper.

DISCUSSION

C. A. P. Turner,* M. Am. Soc. C. E. (by letter).—The difficulty in adapting beam theory to the column is that such a theory, like a playful pup, chases its tail in a circle without practical progress. Thus, the fiber stress caused by bending varies as the bending moment; the deflection varies as the fiber stress due to bending; but for the same load, the bending moment varies as the deflection. Hence, the magnitudes of the fiber stress, deflection, and bending moment are theoretically unstable under the applied beam theory and the assumption that the bending is parabolic does not help in stabilizing sin G on which the author's calculations depend.

The amount that a column under load bends or deflects has no direct proportion to the amount of the load; nor, in fact, to the apparent eccentricity of the stressed area at mid-length; nor to the ratio of the mean compressive stress, u, to the maximum, f. However, when $\frac{f}{u}$ equals unity the eccentricity, e, is zero and the deflection also is zero.

When $\frac{f}{u}$ at mid-length equals 2 the area of fiber stress distribution is triangular and entirely compressive, that is, zero on the convex side and increasing uniformly to a maximum on the concave side. Relative deflections for a given ratio of $\frac{L}{R}$ may be plotted to illustrate typical column action, rating as unity† the deflection when $\frac{f}{u}$ equals 2.

Such a curve of relative deflections shows that the solid column of uniform material obeys Hooke's law in its elastic lateral deflections, since these deflections are proportional to the product of two factors, namely, (1) the eccentricity, e, at mid-length of the total stressed area (the lever arm); and (2) the magnitude of the triangular area (the force).

The lateral deflection of the column is a continuous function. The fact that the deflection is almost negligible at the critical load (under which the stress area changes from total compression to part tension) and reduces to but a minute fraction of this almost negligible amount under working loads, has given rise to the erroneous supposition that the deflection is a discontinuous function absolutely instead of being approximately zero under ordinary working loads.

In test specimens, except those in which the slenderness ratio, $\frac{L}{R}$, is large, no tension parallel to the axis will exist in any of the fibers until the column may be said to have failed. The common conception of the bending of a column is erroneous, being founded on the impression obtained from the curve of flexure used in deriving the formula, which indicates a considerably bent member, with a tension and compression zone representing the conditions

* Cons. Engr., Minneapolis, Minn.

† "Elasticity and Strength of Materials," Turner, Section IV, p. 8.

long after the maximum load has passed and the deflection has greatly increased under reduced load in the follow-up action of the testing machine, thus giving a false impression of the true action.

Because the safe unit stress decreases as the slenderness ratio increases various unsymmetrical rolled sections, such as angles, T's, or double angles, are used in roof trusses and H-sections, Z-bar columns, plate and channel sections, etc., for larger sections in building and bridge work. If one of these hollow unsymmetrical sections be divided in longitudinal strips, each presents a slenderness ratio of a far higher order than that of the section as a whole and hence the total resistance becomes some function of the particular combination of strips presented by the configuration of the section, requiring investigation of different typical forms to determine how the formulas for the solid section should be modified for application in design.

A strip at the extremity of an angle, T, or Z-section, is relatively lacking in rigidity laterally and will tend to buckle out of line normal to the direction in which the strut tends to bend under axial compression. Such a buckling tendency gives rise to the twisting action presented by the Z-column and other sections when tested to destruction. The extent of this torsional stress should be investigated in addition to the bending action typical of the column of solid symmetrical section.

Twisting of the column about its axis under axial compression cannot occur in a solid shaft, such as a round or a square column, because the resulting deformation increases the length of the shaft, which, under a force tending to shorten it, is contrary to Hooke's law. The failure of the solid column, therefore, is one of pure crushing and bending; and the same reasoning applies to the hollow cylinder. In the unsymmetrical section or hollow section other than a cylinder the phenomenon of twist occurs, and for a given twisting (in this case the lateral buckling tendency of the strips) the angle of distortion increases as the free length of the shaft twisted. For a column with round ends the full length of the shaft may contribute to this deformation, but if the ends be pin-connected or clamped they are fixed against torsional rotation at the ends and the free length for the summation of the twist is diminished to one-fourth the length of the column.

Christie's tests* show the strength of an angle-iron strut with ball-and-socket ends having a slenderness ratio, $\frac{L}{R}$, greater than 140, to be four-sevenths as great as one with pin ends; but the pipe column has identically the same strength whether it is pin-ended or has ball-and-socket bearings.† For the same ratio, $\frac{L}{R}$, a pipe of the same area and the same material is substantially one-seventh stronger than a corresponding angle, pin-ended, and with ball-and-socket bearings the pipe is twice as strong as an angle when the equal slenderness ratios are greater than 140. Calculated according to column

† See, "Columns," by E. H. Salmon, p. 219, Fig. 70, showing Watertown Arsenal Experiments Nos. 1915 and 1947 (1909–10).

theories which have been derived from the erroneous application of beam theory the three kinds of struts have the same theoretical strength although they differ 75 to 100% in actual strength.

No wonder that German engineers, after adopting sections for their bridge structures which would readily twist, strove to find a new theory of action of the main members that would account for the failures. They accordingly developed a theory of secondary stress instead of rectifying their theory of primary stress. They have inflicted on the profession the illogical secondary stress computations which have no practical value when the primary stresses are rationally provided for and when suitable triangular elements are adopted for the frame.

Only the minimum radius of gyration of a member is considered in the ordinary column formula, yet the maximum radius of gyration has a marked effect as regards the manner in which the section fails under compression. The Z-bar column having the same radius of gyration in both directions, if it is of minimum section, twists like a corkscrew before failure. On the other hand, the same Z-section, if the Z's are spread so that one radius of gyration is much greater than the other, will fail as they did in Strobel's tests,* by pure bending and crushing.

In large columns the symmetrical section will develop far higher resistance than those commonly used in American bridge design. The column sections in the Forth Bridge present a satisfactory distribution of metal, but the work involved was excessive. To obviate this difficulty the writer has devised a stave column, octagonal in form, with covers inside and outside the apices, using cast-steel rings at intervals to maintain the symmetrical shape of the section. Such a section is more readily spliced than those in ordinary use. It lends itself readily to the connection of riveted web members and lateral struts, and can be made accessible for painting and inspection inside as well as out.

The collapse at Quebec was the last step in the practice of saving weight of pin-plates by concentrating the metal in the cross-section of the web. The chord sections differed little from those of the Blackwell Island Bridge and of other bridges except in the seemingly conservative increase in the slenderness ratios, but this increase gave greater opportunity for twisting and buckling of the built channels, which were sadly lacking in stiffness in comparison with the rolled sections usual in the laced channel compression bridge member. The laminated webs were not comparable to the solid web of the rolled channel while the flanges, the function of which is stiffening the web against buckling, were of negligible area and small width. The need of correspondingly substantial bracing and connections of the bracing was assumed to be unnecessary. Thus, a forceful object lesson in the need of applying the principles of proportion from models of known strength and resistance is brought home by this failure.

E. G. Walker,† M. Am. Soc. C. E. (by letter).—The author has done service not only in applying mechanical principles to the determination of

* *Transactions*, Am. Soc. C. E., Vol. XVIII (1888), p. 103.

† Care, Maxted & Knott, Ltd., London, England.

shear stresses in compression members, but also in emphasizing the necessity for calculating such stresses in many cases that occur in practice. This necessity is overlooked frequently; in many sound textbooks on the mechanics of structures no treatment of the problem is attempted or even mentioned.

The basis of the treatment developed in the paper is not new. The writer has found it in textbooks with the modification that the deflection curve of the compression member has been taken as a sinusoid instead of a parabola. There does not appear to be much difference in the two treatments except that the author's assumption produces some simplification in the equations and arithmetic.

The author is right in deprecating the method of determining shear by calculations based on the assumption of an equivalent uniformly distributed lateral load. There seems to be no connection between the internal forces set up in a compression member and in the presumed equivalent beam except that the two have the same maximum direct fiber stress. Surely it is making a very broad assumption indeed, to consider that because of these equalities the maximum shear is the same in both cases. It is time that such a basis of calculation should be abandoned especially as the rational method is so easy of application.

There is some analogy between the present problem and the kindred one of determining the web stresses of a plate girder. Various standard specifications give different empirical ways of calculating the shear which is to be taken as an average and which must fall below a prescribed maximum. The quantity thus calculated is not a maximum stress and there is no reason why the actual maximum shear stress in a girder should not reach an unsafe value although the calculation should fulfill the specification; it is only a question of distribution of material. It is easy to calculate the actual shear stress at various critical points of the cross-section by rational methods and by the application of principles that are explained at an early stage in the teaching of structural mechanics. There is little justification, therefore, for the use of empirical or semi-empirical methods in this case, and the same argument applies to the problem considered in the paper.

The author's illustrative calculation is possibly the most useful feature of the paper, as it draws attention in a very definite manner to the risks inherent in the use of the equivalent beam method of calculation and cuts away the support often given to that method by illustrative examples, in which the shear calculated by it is shown to be considerably greater than that from direct calculation. The author shows that the reverse may easily be the case to a dangerous extent. The writer hopes, therefore, that this paper will draw attention to the defects of the equivalent beam method of estimating shear stress in compression members and cause more exact methods to be substituted in standard specifications.

HENRY S. PRICHARD,* M. AM. SOC. C. E. (by letter).—The "frequently used allowance" mentioned by the author is one of the requirements in the

* Analytical Engr., Am. Bridge Co., Pittsburgh, Pa.

"frequently used specifications", of a particular company, as follows: "The latticing of compression members shall be proportioned to resist a shearing stress equal to 2% of the direct stress."* The writer does not know who was the first to specify the 2%, or whether any one has attempted to give the rationale of this allowance, or whether by any mathematical ingenuity it can be made to link the "beam analogy" of a uniform transverse load with any particular column formula, as was done for a certain rule for lattice and a form of the "straight line" column formula in many editions of "Modern Framed Structures";† he does know, however, that it requires 33⅓% greater allowance for shear than, but is otherwise identical (although differently worded) with, a rule specified and used by the New Jersey Steel and Iron Company prior to 1891, referred to as Prichard's rule in the report of the Royal Commission on Collapse of Quebec Bridge,‡ which reads as follows:

"The lattice shall be so spaced that each channel between lattice connections shall be stronger than the column considered as a whole, and their size shall be obtained by treating the column as a lattice girder loaded at the middle with a load equal to 3% of the total compression on the column."

In their very able report on the collapse of the Quebec Bridge, the Commissioners state:§

"The angle of inclination may vary from point to point along the column owing to the curvature of the column. This curvature may be due to original bends or to the action of the load or to both combined. If the curvature is sufficiently small the variation of inclination due to it will be negligible. There remains, however, the original inclination or obliquity which is due to the method of application of the loads at the ends of the column. If the eccentricity of application is the same at each end and in the same plane with the axis of the column, there will be no obliquity other than that arising from the curvature of the webs which may be negligible. If, however, the eccentricities at the opposite ends are different or in different directions the obliquity may be of considerable amount. If the curvature of the column be negligible the obliquity arising from the eccentricity will be the same at every point. This obliquity causes a transfer of load throughout the whole length of the column from one web to another. This transfer of load is accompanied by longitudinal shearing stresses in the lattice system. The obliquity also causes transverse shearing stresses at every cross-section of the column."

Before the writer published his rule for lattice he realized in a general way all these facts (but he did not formulate or mathematically analyze any of them until shortly after the collapse of the Quebec Bridge when he wrote a paper on "Imperfect Butt Joints in Columns and Stress in Lattice Bars"‖). From experience and observation (which included the exciting spectacle of a violent collision on a through span of a railroad pin-connected bridge which stood the shock), he knew that columns are liable to slips and falls in handling in shop and field, to impacts in transportation, to accidental side blows in service, as indicated by telltale dents and other injuries, and to usages for which no specific provision is made in their design. After considering the

* Carnegie Pocket Companion, 1923, p. 98.

§ Vol. I, 1908, p. 123.

‖ *Engineering News*, October 3, 1907.

sundry and various possibilities, liabilities, and probabilities, he concluded, regardless of theory, that columns should possess substantial resistance to shear and torsion. From all these considerations and a diligent study of specifications and designs of other engineers, Prichard's rule was devised. It was not the formulation of a fine spun theory but a simple judgment, and probably represents about the average of the best practice of the time when it was devised. Later, in the "frequently used allowance", 33⅓% was added, presumedly for good measure.

The practice with respect to lattice at the time Prichard's rule was published remained about constant up to the date of the collapse of the first Quebec Bridge, except for a growing antipathy to batten plates at intervals in place of lattice, with little or no reason to regard the sizes of the lattice bars as inadequate.

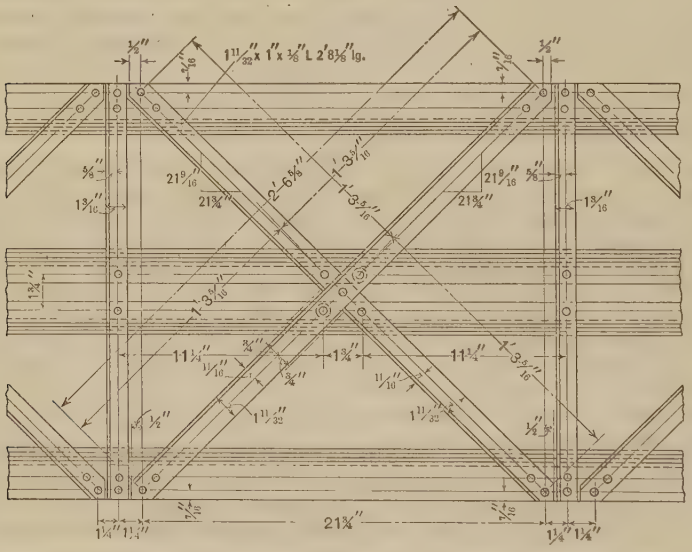

FIG. 4.

It is the consensus of opinion that the latticing of the compression chords of the first Quebec Bridge was too light. The results of an analysis of the "frequently used allowance" in connection with the "frequently used" specifications, as applied hypothetically to Member *A*-9-*L*, is strong evidence that it is conservative for a large range of ratios of length to diameter of column. Member *A*-9-*L* had a cross-sectional area of 780 sq. in.; ⅞-in. rivets; a radius of gyration at right angles to the webs of 16.1 in. and parallel to the webs of 19.7 in.; an extreme width in the plane of the lattice of 67.5 in.; and a length of 684 in.; all as given in the report of the Royal Commission.* The arrangement of cross-section and lattice bars was as indicated in Figs. 4 and 5 (which are reproductions of a portion of a drawing of a model chord, the length and

* See pp. 130 and 199.

all the linear dimension of the portion shown being one-third of those of the full-sized member):*

"The latticing between the center webs is inefficient. Intermediate latticing should have been used on these webs. One of the bars between the center webs in every panel on the upper face of the chord, *A*-9-*L*, has a net section of only 1.15 sq. in. at the center and 1.5 sq. in. for a length of about 4 in., whereas between the center web and the outside web the section is 2.48 sq. in. (gross)".†

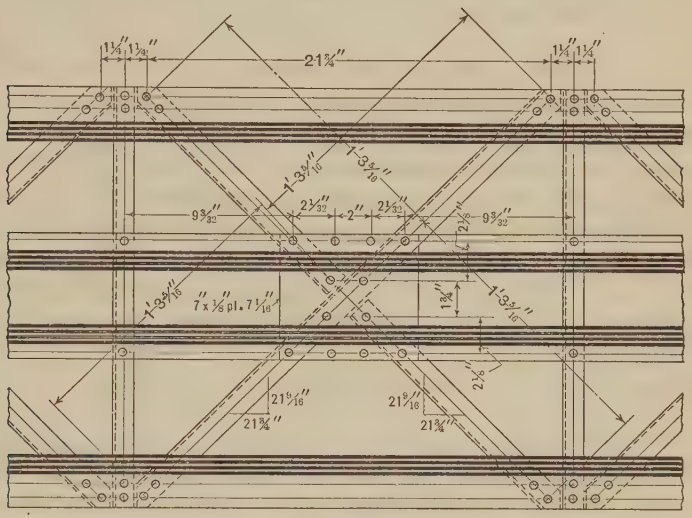

Fig. 5.

Between each panel of latticing, the chords of the member were connected by a cross-tie consisting of a 3½ by 3 by ⅜-in. angle. For this case, the "frequently used" specification with its "frequently used allowance" for shear requires each of the main lattice bars to be connected to each outside built channel by ten rivets instead of two,‡ as shown by the following computation.

The member is composed of four units (built of web-plates and angles) of equal or nearly equal cross-sectional area; and the distance of the center of gravity of each outside unit from the center of gravity of the member is 4.5 times as great as the similar distance of each inside unit; hence the bending stress in the outside units is 4.5 times as great as in the inside units, and, therefore, the shear in the lattice between the outside and inside units, is $\frac{4.5}{5}$ of that between the inside units (assuming intermediate latticing between the inside units, to meet the criticism of the Commission).

The limiting load on the member is:

$$13\,000 \text{ lb.} \times 780 = 10\,140\,000 \text{ lb.}$$

* Report of the Royal Commission on Collapse of Quebec Bridge, p. 112.

† *Loc. cit.*, p. 133.

‡ Correspondingly, the "frequently used allowance" requires larger lattice, but the number of rivets affords the simplest comparison between the "frequently used allowance" and the actual provision.

The member should be proportioned for shear of 2%, or 202 800 lb.; $\frac{4}{5}\frac{5}{5}$ of 202 800 lb. between outside and inside channel equals 166 000 lb.

The lattice bars, of which there are four per panel or four cut by a cross-section, make an angle with the channels of slightly more than 45°, with a secant of 1.42:

The direct stress in each bar from the shear in the member = (166 000 × 1.42) ÷ 4 =	58 900 lb.
The direct stress in the member transferred to each lattice-bar as explained hereinafter =	9 200 "
Total	68 100 lb.

The number of rivets required = 68 100 ÷ 7 200 (the permissible shearing value of each rivet) = 9.46 or, say, 10.

The two rivets by which each lattice bar was actually connected to each outside unit, or web, did not shear until the computed load on the member exceeded an intensity of 16 800 lb. per sq. in. The lattice intersected at points well outside the center of gravity of the outside webs, thereby producing bending stresses in the webs and lattice and tending to increase the shear on the rivets, but the amount of the increase would doubtless have been trivial in a 10-rivet connection.

The effect of the tie at the panel points of the latticing was to force the lattice to take part in the direct compression in the member. For each lattice bar (4 by 3 by $\frac{3}{8}$-in. angle), each tie ($3\frac{1}{2}$ by 3 by $\frac{3}{8}$-in. angle), and each lattice making an angle of 45° with the webs, the writer has shown, in a discussion dealing with latticing,* that the theoretical intensity of the stress in the lattice from this cause is 28.4% of the intensity of the direct compression in the member, or 28.4% of 13 000 lb., which, applied to the gross area, 2.48 sq. in., gives 9 200 lb. as already used.

The fact that a member of the first Quebec Bridge, with a 2-rivet connection at each end of each lattice, collapsed after the computed compression in the member exceeded 16 800 lb. per sq. in., is no reason for doubting the adequacy of a rule which, as applied to the lattice bars of the member, requires a 10-rivet connection.

The other important questions which the author raises are: (*a*) The position of the eccentricities which will induce the greatest lateral reactions and, therefore, shears from lateral reactions; (*b*) the amount of unintentional eccentricity to which a member is liable from "poor workmanship"; and (*c*) the increase which deflection causes in shear.

In those cases in which the ratio of shear to direct compression is greatest, the computed increase which deflection causes in shear is small in comparison with the shear from the lateral reaction, even when the deflection, instead of being correctly computed, is arbitrarily chosen much too great, and "the theoretical deflection curve has been assumed to be a parabola", as illustrated by the author's computation of 4 800 lb. of shear from the lateral reaction and

* *Engineering News*, October 3, 1907, p. 368.

1 400 lb. increase from deflection "in a standard latticed channel column, 25 ft. long, composed of two 10-in. by 30-lb. channels."* The author has high authority for assuming a parabola† but for the purpose of determining the increase in shear, it does not give a close approximation. By correct theory the increase is much smaller than that computed by the author and may be neglected without serious error, as will be shown.

For a definite longitudinal load and definite eccentricities in application at opposite ends of the column, the lateral reactions and shears therefrom are greatest when the eccentricities are on opposite sides of the axis and are as indicated by a simple formula given by the author, which may be expressed as follows:

$$\text{Lateral reaction} = \frac{\text{Load} \times \text{sum of eccentricities}}{\text{Length of column}}$$

This simple formula strikingly shows that, other things remaining constant, the lateral reaction, and, therefore, the shear from the lateral reaction, increases inversely as the length of the column.

The unknown quantities in the formula are the eccentricities. There may be eccentricities caused by unsymmetrical variations in cross-sectional area, slight unsymmetrical variations in the modulus of elasticity, and slight curves or bends in the axis, all of which are unintentional and may be important; they will be referred to again after a discussion of eccentricities caused by "poor workmanship". The discussion of eccentricities from poor workmanship is restricted to cases in which the longitudinal load, or the major portion of it, is received, through contact of surfaces intended to be plane and intended to make a known angle, usually 90°, with the axis. The poor workmanship, where it occurs, consists in the surfaces not being plane, or in the angles not being true, or in unspecified lateral forces being applied so as to open or to tend to open the joints between the ends of the columns.

Contracts for fabrication and erection of framed structures should be awarded only to concerns which are properly equipped to face the ends of columns so that they will be smooth and square or true to angle and to properly erect the structures of which the columns are a part, and which employ engineers and superintendents who understand the importance of these matters, including the proper position and setting of the shoes and base-plates on the foundations, and the proper design, fabrication, and placing of the pieces which connect the columns. Structural engineers probably understand and are alive to these matters to a greater extent than the author realizes. For instance, certain large compression members of a comparatively recent structure were designed and faced so that they were in contact for about the middle-third and only about the middle-third of their depth. This was accomplished by a slight flare from the middle-third toward the edges.

* Carnegie Pocket Companion, 1923, p. 225.

† The late C. C. Schneider, Past-President, Am. Soc. C. E., in his report, "Quebec Bridge Inquiry," 1908, p. 195.

It is not disputed that it would be well to exercise more discretion in the award of contracts, more intelligence in their execution, and greater care in inspection, but the writer does not see the need for modifying specifications to provide for any such unintentional eccentricities as the author assumes in the suppositious case of "a standard latticed channel column" (previously referred to) to examine the matter "somewhat in detail." He assumes an eccentricity of 4 in. at each end of the column and to opposite sides of the axis at opposite ends. For this, say, the first case (with $P\ A = 180\,000$ lb., $L = 25$ ft.; $A = 17.6$ sq. in.; $I = 323.25$ in.^{4}; $R = 4.29$ in.; and $V = 6.75$ in.),* using the method of computation and significance of symbols to be indicated subsequently in this discussion, the computed maximum shear (which occurs at the middle of the column) is 5 180 lb., or 2.88% of the load, as compared with the "frequently used allowance" of 2%, and a computed maximum stress in the extreme fiber (which occurs at the ends) of 25 260 lb. per sq. in., as against 16 000 lb. permitted by the "frequently used" specifications. If the 4-in. eccentricities were on the same side of the axis for, say, the second case, the computed maximum shear (which, for this case, occurs at the ends) is 2 349 lb. and the computed maximum stress (at the center) is 29 070 lb. per sq. in. It is almost needless to say that none of the well-known specifications provides for such eccentricities, and structures are not designed for them, yet failures have been exceedingly rare notwithstanding that loads on bridges have steadily increased.

Structures and the methods of erecting them vary so greatly that no extended discussion of erection will be attempted and attention will be called to only a few points.

A compression member in the course of its erection, held in the approximate position while connections with enough temporary bolts are made to hold it, stands more or less chance, as there is clearance in the holes, of being placed with, and temporarily held by, the friction of bolt-heads and tightly screwed nuts, with a slight V-shaped opening where it joins the adjacent member, a condition which may seem alarming to a novice; but such bolts will not hold much load without some slippage.

Even the best workmanship is not made with the precision required in astronomical and other scientific instruments. It is not surprising, therefore, that after the successive columns in buildings and chord members in bridges have come to a bearing they are likely, collectively considered, to form a slightly inclined, or bent, or wavy or curved line. The extent to which this occurs may perhaps be judged by the provision in the "Code of Standard Practice", October 1, 1924, of the American Institute of Steel Construction:†

"In the setting or erecting of structural steel work, the individual pieces shall be considered plumb or level where the error does not exceed 1 to 500.

"For exterior columns and columns adjacent to elevator shafts or multiple-story buildings, the error from plumb shall not exceed 1 to 1 000 for the total height of the column."

* Carnegie Pocket Companion, 1923, pp. 109, 113, 156.

† See p. 11.

Unsymmetrical yielding of foundations under eccentric pressure, elastic deformation of columns, and, on occasion, plastic deformation of small portions of their outer and nearly outer fibers and crushing of their bearing edges, may be useful in effecting adjustments which bring adjacent surfaces to a bearing. In a short properly proportioned column with unintentional eccentricities to opposite sides at opposite ends, buckling of the column as a whole will not occur, shortening from deformation will be trivial, and plastic deformation will relieve the column of the excessive stress which caused it. Elastic deformation of the lattice-bars will also help and plastic deformation may help; but, on the other hand, excessive stress in the lattice may shear the rivets, or break or severely cripple the bars.

For short columns particular attention should be given to the problem of shear. Columns subject to heavy loads in buildings are usually built with cover-plates instead of lattice; hence the problem of the sufficiency of the latticing in very short columns in buildings does not often arise. In columns and compression members in outdoor construction exposed to the elements it is desirable that the interiors shall not be inaccessible for painting. It is also highly important that accessibility for purposes of fabrication, erection, and painting shall be achieved in such a way that an employee engaged in such service, if overcome by exhaustion, accident, heat, cold, fumes, or otherwise, will not be in an almost closed interior from which he can not be readily rescued. To make adequate provision for the greatest possible shear in short members requires a high degree of practical as well as engineering knowledge. Concerns that understand the subject in all its phases take particular pains in such cases to reduce the possible shear from poor workmanship to a minimum.

The engineer may ask how does he know that the designedly abutting surfaces of compression members actually come to a good bearing. The fact is that, except for the cases he has personally examined and the testimony of others regarding the cases they have personally examined, he does not really know; but failures of such members are exceedingly rare, and he can infer from this fact that sufficient bearing is achieved to keep the stresses from the actual loads within safe limits; and he knows, if he is experienced, that in many cases the actual loads sustained by structures in service have been greater than those for which they were designed. The writer knows of only one failure, the first Quebec Bridge, where either the latticing or the butt joints are under suspicion. In this bridge, the bottom chord, *A*-8-*L*, extended beyond the panel point 10.5 ft. (almost one-fifth of the panel length) to a butt joint with the member, *A*-9-*L*. This long distance to the joint was occasioned by a strut which ran from the panel point making an acute angle with *A*-8-*L*. The details of *A*-8-*L* between the panel point and the butt joint are not shown in the report of the Commission previously mentioned, but it seems to the writer from the data in the report, that the out-of-line distance of 1.5 in. observed at the joint before the collapse should be regarded as the individual outward bending of insufficiently connected webs loaded at their ends rather than the deflection of a compression member between panel points.

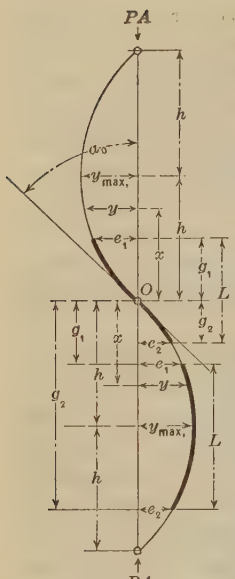

FIG. 6.

For short columns, the possible unintentional eccentricities, from unintentional variations in cross-section, slight variation in modulus of elasticity, and slight bends or curves in the axis, are all small as compared with the eccentricity assumed by the author for the "standard latticed column 25 ft. long", and do not require further discussion.

For short columns, the theoretical maximum shear, from eccentricities to opposite sides at opposite ends, is only slightly greater, than the theoretical lateral reactions (the computation of which is much simpler). To justify the formulas on which this statement is based, and from which the writer's computations were made, and to clarify ideas regarding the theory of eccentrically loaded columns, the following general analysis is given.

Fig. 6 shows the axis of a centrally loaded, continuous, symmetrical column of constant cross-section (made of perfectly elastic steel) with three points, of no flexure, one at each end and one at the middle, where it is held against lateral movement by frictionless pins which offer no resistance to the rotary movements developed in the column in deflecting. Owing to the continuity of the two halves the deflections in each half have to be equal and to opposite sides of the axis; otherwise, each half behaves precisely like an independent column and will support the same loads and have the same elastic line.

Let A = the cross-sectional area;
$2h$ = the length of each half; and
E = the modulus of elasticity.

For steel, considering the pound as the unit of stress and the inch as the unit of length, $E = 30\,000\,000$.

Let p = the load per unit of area; and
R = the radius of gyration.

As shown by Euler and numerous mathematicians since Euler, and as demonstrated in nearly all textbooks on Mechanics, the curve of incipient deflection of such a column is a sinusoid and the load which will cause incipient deflection is given by Euler's "formula":

$$p = \frac{\pi^2 E}{\frac{4h^2}{R^2}} \qquad (1)$$

$$h = R\sqrt{\frac{\pi^2 E}{4p}} \qquad (2)$$

In Fig. 6, which shows the column deflected, the deflection is shown greatly exaggerated for convenience in drawing and clearness in illustrating, but,

for cases which have either a direct or indirect application in engineering, the curvature, even of what is considered a large deflection, is very slight. The errors involved, in considering that the arc is the same length as the chord, that the curve is a precise sinusoid, and that the load which causes incipient flexure will hold the column in equilibrium in any deflected position, are so small that they do not seriously impair the accuracy of the computations. This was shown to be the case by William Cain, M. Am. Soc. C. E.*

For any originally straight, perfectly elastic, eccentrically loaded, symmetrical column under a given load, a certain continuous, centrally loaded, column, as shown in Fig. 6, can be conceived as held in such a deflected position by the given load that a particular part of it, the centrally loaded column, will be precisely similar to the eccentrically loaded column, as regards length, elastic line, relative position of axis and line of thrust, stresses, and shears. These characteristics under a given load of such an eccentrically loaded column, therefore, can be determined by first finding from Equation (2) the quarter length, h, of the centrally loaded continuous column of the same cross-section which can be held in any deflected position under the given load, and then, with the continuous column held in the particular position corresponding to the elastic line of the eccentrically loaded column, finding the characteristics of the part corresponding to the eccentrically loaded column.

Let y equal the ordinate from the line of thrust to the sinusoid formed by the axis of the centrally loaded column, and x the corresponding arc measured from the point of contrary flexure, O, at the middle, considered as the origin.

Let y_m = the maximum ordinate;
L = the length of the eccentrically loaded column;
g_1 = the distance from the origin point, O, to its upper end;
g_2 = the distance from the origin point, O, to its lower end;
e_1 = the eccentricity at its upper end;
e_2 = the eccentricity at its lower end;
a = the angle which a tangent to the column axis at any point makes with the line of thrust;
a_1 = the angle which a tangent to the column axis at the upper end of the eccentrically loaded column makes with the line of thrust;
a_2 = the angle which a tangent to the column axis at the lower end of the eccentrically loaded column makes with the line of thrust;
a_0 = the angle which a tangent to the column axis, at origin point, O, makes with the line of thrust;
S = the transverse shear at any cross-section;
S_1 = the transverse shear at a given point the ordinate of which is e_1 and the abscissa, g_1;
S_2 = the transverse shear at a given point the ordinate of which is e_2 and the abscissa, g_2;
S_0 = the transverse shear at origin point of contrary flexure, O;

* *Transactions*, Am. Soc. C. E., Vol. XXXIX (1898), p. 96.

f = the stress intensity in the outer fiber at any cross-section;
f_1 = the stress intensity in the outer fiber at the upper end of the eccentrically loaded column;
f_m = the maximum stress intensity;
A = the cross-sectional area of the column; and
v = the distance from the axis to the extreme fiber.

Then,

$$y_m = \frac{e_1}{\sin\left(\frac{\pi g_1}{2h}\right)} = e_1 \operatorname{cosec}\left(\frac{\pi g_1}{2h}\right) \quad \ldots\ldots(3)$$

$$\tan a = \frac{dy}{dx} = \frac{\pi y_m}{2h} \cos\left(\frac{\pi x}{2h}\right) \quad \ldots\ldots(4)$$

$$\tan a_1 = \frac{\pi y_m}{2h} \cos\left(\frac{\pi g_1}{2h}\right) \quad \ldots\ldots(5)$$

$$\tan a_0 = \frac{\pi y_m}{2h} \quad \ldots\ldots(6)$$

$$S_1 = p A \tan a_1 \quad \ldots\ldots(7)$$

$$S_0 = p A \tan a_0 \quad \ldots\ldots(8)$$

$$f_1 = p + \frac{p e_1 v}{R^2} \quad \ldots\ldots(9)$$

$$f_m = p + \frac{p y_m v}{R^2} \quad \ldots\ldots(10)$$

Calling eccentricities to opposite sides of axis at opposite ends of column, Case I; and eccentricities to the same side of the axis at opposite ends of column, Case II; then,

For Case I, for $e_2 = e_1$,

$$g_2 = g_1 = \frac{L}{2} \quad \ldots\ldots(11a)$$

and for $e_2 = 0$,

$$g_1 = L \quad \ldots\ldots(12)$$

For Case II, for $e_2 = e_1$,

$$g_1 = h - \frac{L}{2} \quad \ldots\ldots(11b)$$

For any other relative value of e_1 and e_2, the values of g_1 and g_2 have to be obtained by trial, which can be readily accomplished by using Equations (13) and (14a) or (14b), with the aid of a table of sines:

$$\frac{e_1}{e_2} = \frac{\sin\left(\frac{\pi g_1}{2h}\right)}{\sin\left(\frac{\pi g_2}{2h}\right)} \quad \ldots\ldots(13)$$

For Case I:

$$\text{Angle}\left(\frac{\pi g_2}{2h}\right) + \text{angle}\left(\frac{\pi g_1}{2h}\right) = \text{angle}\left(\frac{\pi L}{2h}\right) \quad \ldots\ldots(14a)$$

For Case II:

$$\text{Angle}\left(\frac{\pi g_2}{2h}\right) - \text{angle}\left(\frac{\pi g_1}{2h}\right) = \text{angle}\left(\frac{\pi L}{2h}\right) \quad \ldots\ldots(14b)$$

Euler, and other mathematicians, who have developed Equations (1) and (2), neglected the influence of shear distortion.

Let t = the deflection due to a shear of unity in a length of unity.

The writer has previously shown* that when t is considered, Equations (1) and (2) become Equations (15) and (16):

$$p = \frac{\pi^2 E}{\frac{4 h^2}{R^2} + \pi^2 E A t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

$$h = R\sqrt{\frac{\pi^2 E}{4 p} - \frac{\pi^2 E A t}{4}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

Equations (15) and (16) clarify theory by bringing it into line with the common sense idea that even under ideal conditions potential resistance to shear is essential to capacity to support load and is really an element in determining the maximum load; but, for all cases which arise in practice, the effect of substituting Equation (16) for Equation (2) is so small it may be neglected.

The special case in which the eccentricities to the same side of the axis are equal at opposite ends, has been developed by a number of engineering authors, including Anson Marston, M. Am. Soc. C. E.,† who agree in their results. The general analysis here given leads to Marston's equation as a special case.*

For the 10-in. channel column, 25 ft. long, previously cited, the results recorded were obtained, by applying Equations (2), (3), (5), (6), (8), (9), and (10), as follows:

For both the cases previously cited:

From Equation (2), $h = 364$ in.

For Case I:

From Equations (11a) and (3), $y_m = 6.633$ in.

From Equation (5), $\tan a_1 = 0.02283$

From Equation (6), $\tan a_0 = 0.02862$

From Equation (8), maximum shear = 5 160 lb. (which is 360 lb. greater than the 4 800 lb. lateral reaction obtained by both the author and the writer).

From Equation (9) the stress in the outer fiber at the ends (which for this case is the maximum) = 25 260 lb.

For Case II:

From Equations (11b) and (3), $y_m = 5.0144$ in.

From Equation (5), $\tan a_1 = 0.1305$

From Equation (7), the shear at the end (which for this case is the maximum) = 2 349 lb.

From Equation (10), the maximum stress in the outer fiber, f_m = 29 070 lb., which is the same as would have been obtained by applying Marston's formula.

---

* *Engineering News*, February 25, 1909, p. 206.

† *Transactions*, Am. Soc. C. E., Vol. XXXIX (1898), p. 108.

For Case I with the eccentricities on opposite sides of the axis, which the author chose to "examine somewhat in detail", he assumed, and illustrated in his Fig. 3, the vertices to the elastic line as occurring about half way between the ends of the column and the point, *O*, of contrary flexure, whereas the writer's analysis shows them to occur at 364 in., or 30 ft. 4 in., from the point, *O*, in prolongations of the elastic line 17 ft. 10 in. beyond the ends. If the length of the column were, say, 63 ft. instead of 25 ft., and all other conditions, including load, were the same, the vertices would lie between the point, *O*, and the ends of the column; 30 ft. 4 in. from Point *O* and 1 ft. 2 in. from the ends.

Anders Bull,* Esq. (by letter).—To apply the method outlined by Mr. Goodwin to column-lattice design, a value must first be assumed for the deflection, or, what amounts to the same thing, for the eccentricity due to imperfect workmanship or other causes, the former being a function of the latter.

The beam analogy furnishes a simple empirical rule by which this unknown factor is taken into account, whereas Mr. Goodwin would entrust its evaluation to the judgment of the designer. This would seem to be dangerous practice because it would leave too much room for guesswork. The deflection is too complex a function of loading conditions, length, and section characteristics to be divined, even by the most experienced of designers; it is far more involved than the allowable unit stress, which is always determined by a column formula.

Neither do the examples given by Mr. Goodwin support his claims. For the column shown in Fig. 3, the deflection, f, is a function of the distance, x, from the end, or, approximately,

$$f = \frac{P_1 e}{4 E I}\left(\frac{L x}{3} - x^2 + \frac{2 x^3}{3 L}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

in which, E is the modulus of elasticity and I the moment of inertia of the column section, the other notations being those used by Mr. Goodwin.

The graph of Equation (17) is a line the curvature of which increases evenly from the middle section toward the ends. By equating to zero the first differential, the maximum deflection is found to occur at a distance of 0.211 L from either end. Substituting this value for x in Equation (17), the maximum is found to be:

$$f_{\max.} = 0.008 \frac{P_1 e L^2}{E I} \quad \ldots\ldots\ldots\ldots\ldots\ldots (18)$$

The angle of inclination of the column axis to the vertical is greatest at the ends, where:

$$\tan G = \frac{P_1 e L}{12 E I} \quad \ldots\ldots\ldots\ldots\ldots\ldots (19)$$

the inclination at the middle section being just one-half as great.

* Asst. Engr., Board of Transportation of the City of New York, New York, N. Y.

Substituting in Equation (18) the values for the column selected,

$$f_{\max.} = 0.008 \frac{180\,000 \times 8 \times 90\,000}{30\,000\,000 \times 323} = 0.106 \text{ in.}$$

This is only 0.035% of the length, as compared with the 0.1% which Mr. Goodwin takes as his starting point.

The shear, S_1, due to flexure, at the middle of the column, is:

$$S_1 = P_1 \tan G_1 = 180\,000 \frac{180\,000 \times 8 \times 300}{24 \times 30\,000\,000 \times 323} = 335 \text{ lb.}$$

as against the 1 440 lb. obtained by Mr. Goodwin.

The flexure shear at the ends is twice as large, but acts in the opposite direction and, therefore, counteracts the shear, S_2, due to eccentricity. The latter shear being 4 800 lb., there results accordingly:

$$\text{Total shear} = S_2 + S_1 = 4\,800 + 335 = 5\,135 \text{ lb.}$$

Before comparing this result with that obtained by the beam analogy it should be noted that an eccentricity of 4 in., as assumed by Mr. Goodwin, is too large for the column section selected, giving a combined stress of:

$$\frac{180\,000}{17.64} + \frac{180\,000 \times 4 \times 7}{323} = 10\,200 + 15\,600 = 25\,800 \text{ lb. per sq. in.}$$

If a maximum stress of only 19 000 lb. per sq. in. is permitted, as indicated by the column formula,

$$\frac{P}{a} = 19\,000 - c \frac{L}{r}$$

the eccentricity must be reduced in the proportion, 8 800 : 15 600, which gives:

$$\text{Total shear} = 5\,135 \times \frac{88}{156} = 2\,895 \text{ lb.}$$

This is equal to only 0.016 P_1, as compared with Mr. Goodwin's figure, 0.035 P_1.

The beam analogy applied to the same column formula, gives for a column depth, d, of 14 in.:

$$\text{Shear} = \frac{8\,c\,a\,r}{d} = \frac{8 \times 100 \times 17.64 \times 4.28}{14} = 4\,315 \text{ lb., or } 0.024\,P_1$$

Being thus 50% in excess of the actual amount as found previously, the result is well on the safe side.

The Quebec Bridge failure cannot be ascribed to any shortcoming of the beam analogy, as Mr. Goodwin seems to imply, but to a number of concurrent causes, among which the most fatal were: (1) The excessive unit stresses specified; (2) failure to make allowance for added weight; and (3) the inadequate provision made for eccentricity in designing the compression members.

In regard to the stresses in the chord member, A-9-L, it must be considered that the member was in the act of collapsing when the measurements given in Fig. 2 were made. Care should be exercised in drawing any con-

clusions from these observations, since there is no way of determining how much of the computed stress was transferred at that time to the opposite chord member, *A*-9-*R*.

Ralph E. Goodwin,* Assoc. M. Am. Soc. C. E. (by letter).—In closing, the author desires to summarize the purpose of his paper as it relates to the discussions which have been submitted. It has been his experience that many engineers have only a specialized understanding of shear and fail to comprehend it when it assumes a disguised form. This is especially true in the case of columns for which the axis may be curved and the direction of the shear not constant. The purpose of the paper was, therefore, first, to show that the applied shear is the normal component of the applied load; and, second, to call attention to the satisfactory mathematical foundation which exists as a basis for the determination of empirical shear allowances. That such allowances must be empirical is due to the fact that the initial curvature and accidental eccentricity of a column are unknown quantities, for which values corresponding to the most dangerous shear condition likely to occur in practice must be assumed. For determining what conditions of curvature and eccentricity will produce the most dangerous shear condition, the principles reviewed in the paper will be found useful.

Since Mr. Walker states that the basis of treatment is not new, the writer would call attention to his acknowledgment of this fact in the Synopsis.

Mr. Prichard objects to the shape of the deflection curve and to the value of the deflection assumed for the case illustrated by the writer's Fig. 3. Since the objection is based on theoretical grounds the writer wishes to state with emphasis that the application of the method should not be limited to theoretical deflections and theoretical deflection curves. The shear arising from initial curvature may be greater than that due to deflection caused by bending, and no method of analysis can be considered satisfactory which fails to make allowance for this factor. The general method (shear $= P \sin G$) is applicable to any curvature, regardless of the cause which produced it. The deflection assumed in the illustrative problem may be considered as arising from a combination of initial curvature with bending deflection, and as such does not appear to be unreasonable. Any deflection and any curvature that may occur in a practical column are legitimate cases for investigation.

Using the method presented in Mr. Prichard's discussion, the writer finds the maximum bending deflection (measured from the dotted line axis of Fig. 3(*b*)) to be about 0.11 in., leaving 0.19 in. to be accounted for by initial curvature. This is 0.0006 L, or 0.0013 $\frac{L}{2}$. As Mr. Prichard shows, the shear due to deflection is small in comparison with that due to eccentricity. Nevertheless, it is the amount of deflection assumed by the writer which forms the basis of his criticism. The eccentricity and direct stress are admittedly high in the illustration cited, however, and, as Mr. Prichard states, the case falls outside the limits set by specifications.

* Instr., Civ. Eng., Coll. of the City of New York, New York, N. Y.

Mr. Prichard's criticism in regard to the position of the vertex of the elastic line, in the same illustration, is somewhat misleading. When he states that the vertex lies 364 in. from the point of contrary flexure, he is speaking of the vertex determined by the axis of his equivalent centrally loaded column, which axis is inclined at an angle of about $1\frac{1}{2}°$ to the dotted-line axis of the writer's Fig. 3(*b*). If the writer's axis is applied to Mr. Prichard's elastic line, the point of maximum column deflection is found to be 85 in. from the point of contrary flexure, or 10 in. beyond the middle point of the half length, and Fig. 3(*b*), which alone formed the basis for computations, is, therefore, essentially correct in this respect, even when the possible effect of initial curvature is omitted from consideration. Fig. 3(*a*) was obtained by applying the inclined thrust line to Fig. 3(*b*), and its distortion with respect to that line results unavoidably from the exaggerated curvature adopted for the sake of clearness in illustrating.

The matter of changing present specifications, if this should be found necessary, may well be left in the hands of the Society's Special Committee on Steel Column Research. It is to be hoped that this Committee will include a study of the initial curvature of practical columns and of the curvature of loaded columns in its program.

Mr. Bull's discussion is essentially similar to that of Mr. Prichard in using a theoretical deflection curve without making any allowance for original lack of straightness, and in criticizing the writer's illustrative problem. The need of making an allowance for initial curvature has already been mentioned. It can be seen more readily if a centrally loaded column is considered. The ideal centrally loaded column has no deflection until subjected to the Euler load. Since practical columns carry less than the Euler load, no basis for shear computation exists, in this case, until allowances have been made for initial curvature and accidental eccentricity. Mr. Bull states that the deflection is a function of the eccentricity due to imperfect workmanship or other causes. This statement is based on the assumption of a column originally straight, whereas Turneaure states that a column may have an original deflection of 0.001 L, and Godfrey, one of 0.0025 L. Even in the extreme case used by the writer as an illustration an initial deflection of $0.001 \frac{L}{2}$ proves to be greater than the deflection due to bending. The total deflection from all sources should be used for the computation of shear.

It is difficult to reconcile the objections raised by Mr. Prichard and Mr. Bull to the writer's illustrative problem on practical grounds with their purely theoretical treatment of deflection, from which the practical consideration of initial curvature is omitted. Possibly the oversight is traceable to the practice of treating the deflection of a crooked column as equivalent to an equal amount of eccentricity in a straight column. The maximum bending moment will be the same in both cases, but not the shear, owing to the fact that shear depends on the inclination of the axis. Shear due to initial deflection can not be treated on the basis of equivalent eccentricity.

Mr. Bull undertakes to bring the writer's illustrative problem within the limits of good practice by reducing the eccentricity until the extreme fiber stress is reduced to a reasonable figure. For this purpose he assumes that the sum of the average stress and the bending stress may be made 19 000 lb. per sq. in., apparently overlooking the fact that the column formula of the American Bridge Company is limited to a maximum of 13 000 lb. per sq. in.

Again, in computing the beam analogy, he assumes that the bending allowance of the column formula is $100\,\frac{L}{r}$. The writer is not familiar with any specification which defines the use of the beam analogy in connection with this particular column formula, but he is quite certain that the term, $100\,\frac{L}{r}$, is not all bending allowance. The formula is limited to a maximum of 13 000 lb. per sq. in., due to the fact that the elastic limit is the practical ultimate value in compression. This particular formula, then, assumes that the elastic limit controls the design up to $\frac{L}{r} = 60$, and that bending controls from that point on. It is more nearly correct, therefore, to consider the bending allowance to be $100\left(\frac{L}{r} - 60\right)$.

These, however, are minor details. The main point of interest lies in the idea of a treatment that is fundamentally sound and applicable alike to practical and theoretical curvatures. Owing to the empirical factors inherent in the problem, rules and specifications will always be necessary in the designing room, but in order that the designer may design intelligently and with understanding of the assumptions involved, he should be familiar with the correct theory of shear.

Paper No. 1596

CO-ORDINATION OF IRRIGATION AND POWER*

By William Kelly,† M. Am. Soc. C. E.

With Discussion by Messrs. J. D. Galloway, Fred. H. Tibbetts, Barry Dibble, Markham Cheever, M. C. Hinderlider, C. S. Jarvis, and William Kelly.

Synopsis

Irrigation and power are both of great importance in the development of the Western States. Both interests require regulation of stream flow, but to different degrees, which may bring them into conflict. This paper gives a general presentation of the factors entering into the problem, illustrates the difficulties, and points out certain solutions by describing some of the specific cases that have come before the Federal Power Commission.

General

The co-ordination of irrigation and power is a problem found on nearly every stream in the arid West. The arid West is a region in which the mountains exercise a marked influence on climatic as well as on physical conditions. The annual precipitation in this region, except in the extreme Northwest, varies from 2 in. to about 15 in., whereas in the non-arid parts of the country the annual precipitation exceeds 25 in. The larger part of the precipitation in the West occurs on the mountain ranges often in the form of snow. Most of the streams get their principal supply from high up on the ranges, and the water in running down to the lower levels where farming is

* Presented at the Summer Meeting, Salt Lake City, Utah, July 8, 1925.

† Col., Corps of Engrs., U. S. A.; Director of Eng., National Electric Light Assoc., New York, N. Y.

practicable offers opportunity for power development. The area west of the Mississippi River contains about 72% of the potential water power of the United States.

There is a well-established principle in the Western States that the use of water for irrigation is superior to any other except domestic use, and the laws of those States reflect that principle. It is not the purpose of this paper to discuss the merits of that principle. States have a right to establish such principles and the Federal Government always has and always will recognize that right so long as it does not infringe on the rights of others under the Federal Constitution.

The principle must be borne in mind, however, in considering co-ordination of irrigation and power because to a considerable extent it sets aside the laws of economics and often causes co-ordination to take the form of adjusting power development so that it will not curtail irrigation development. It should also be borne in mind that, as a rule, power development has proved more profitable to investors than irrigation, and is, therefore, more easily financed. While irrigation is often seeking State or Federal aid, power does not need such aid; on the contrary, it frequently gives aid to irrigation without recompense.

Development of storage to regulate flow is more likely to be financially practicable for a power project than for an irrigation project, and most of the successful irrigation projects that have developed storage have produced power as a by-product to help carry the cost of the storage. The irrigation use of water is distinctly a seasonal use. With a few exceptions, such as the Imperial Valley, the season lasts from four to nine months and in most cases the peak demand occurs in June and July. Fortunately for farming, the maximum flow of most Western rivers being due to melting snows, occurs at the time of the maximum irrigation demand, thus reducing materially the storage capacity needed.

The power use of the water, on the other hand, is fairly uniform throughout the year, and, therefore, requires sufficient storage for more or less complete seasonal regulation. Secondary or seasonal power has a limited value. To the extent that power can be used for irrigation pumping, the power demand for water can be made to conform to the irrigation demand. Generally, the shortage of water for irrigation occurs in the latter part of the irrigation season; storage for power increases the discharge during this season, and to that extent is beneficial to irrigation. Figs. 1 to 6, inclusive, show graphically the relation between the irrigation demand and the monthly discharge for a high, average, and low-water year on the following rivers: Colorado, Columbia, Snake, San Joaquin and principal tributaries, Sacramento and principal tributaries, and Kings.

Examination of Fig. 1, Colorado River, shows that there is not much need for storage for irrigation for the Lower Basin provided it is practicable to keep the demand down to 5 acre-ft. per acre per year at the point of diversion. For the Upper Basin, however, storage is essential to provide for the irrigation demand from July to October, inclusive. The irrigation demand and its dis-

tribution through the year is taken from an unpublished report by the United States Bureau of Reclamation.

Examination of Fig. 2, Columbia River, indicates that the stream flow is more than ample to take care of irrigation at any and all times. As explained later, however, the irrigable lands lie so high above the main river that gravity diversion is possible only on the tributaries at points where the discharge is not adequate without storage.

TOTAL DEMAND

Irrigable Area - Lower Basin 1 000 000 Acres at 5.0 Acre Ft. = 5 000 000 Acre Ft.

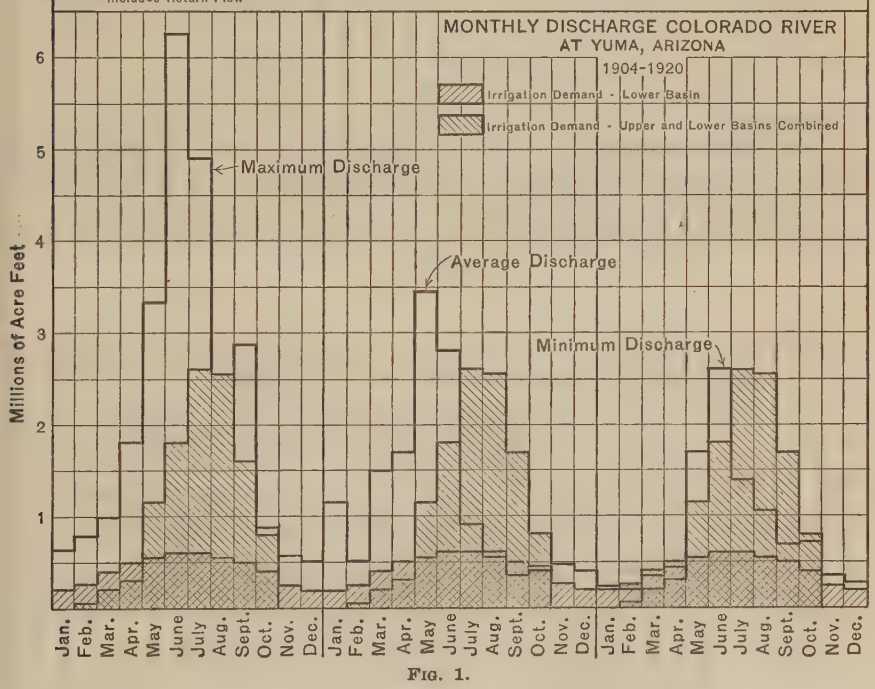

FIG. 1.

Fig. 3 shows that storage for irrigation on Snake River is needed from June to September, inclusive. The Snake River in Idaho presents an interesting example of co-ordinated irrigation and power. (See Fig. 7.) At several places on the Snake all the low-water flow is diverted for irrigation, and yet a short distance below such diversion the river flow is revived by underground contributions. In Southern Idaho the river flows through a lava formation and between the more or less horizontal layers of lava are water-

bearing strata. Diversion for irrigation greatly exceeds consumptive use and much of the water diverted finds its way back to the river.

Storage has been developed at Jackson Lake, Wyoming, and Lake Walcott, Idaho, and is being developed at American Falls, Idaho. The irrigation developments have been made both by districts organized under the State law and by the U. S. Bureau of Reclamation. Power has been developed by the U. S. Bureau of Reclamation and by the Idaho Power and Light Company. Practically all the power is used for irrigation pumping and for domestic purposes by the communities supported by the irrigation projects. In this part of Idaho, farming and stock-raising are practically the only industries. In such a situation there can be no serious conflict over the relative use of water for irrigation and power, because the market for power depends on the success and extent of the irrigation developments, and power is economically and practically secondary to irrigation.

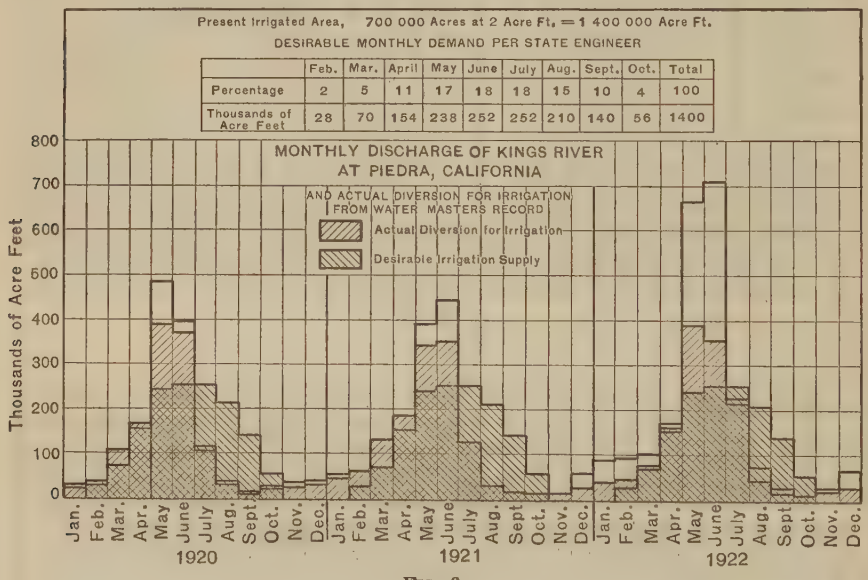

FIG. 6.

Fig. 4 shows that the water supply in the San Joaquin Valley, California, is deficient generally from July to October, inclusive, for the area now irrigated, which is only about one-half the area that would be irrigable if the water could be found. The deficiency is more or less overcome by pumping from the underground supply. Storage in connection with power developments has aided by building up the flow during the period of deficiency. Storage by irrigation interests has been undertaken recently on the Tuolumne River and is under construction on the Merced. Such projects are under consideration also on the Mokelumne, Stanislaus, and Kings Rivers. A more detailed description of the Kings River situation follows.

Fig. 5 shows that there is more than enough water in the Sacramento River to irrigate all the land suitable for irrigation, but that the natural flow

is deficient for the irrigation demand in the months of July to September, inclusive. The Sacramento River presents an interesting and complicated problem of conflicting interests of up-river and down-river irrigationists in the use of the water, and the effect of such use on navigation and on the infiltration of salt from the ocean. There is also a problem of flood protection which has been fairly well solved. Power development requiring head-water storage, building up the late summer and fall flow, and using the streams only in the mountain sections, is generally beneficial to all other interests, and not particularly difficult to bring into co-ordination. The Sacramento and San Joaquin Rivers have dependent on them the greatest irrigation development in the world. The problems of these rivers are being studied by the substantial, practical irrigators to whose efforts the present developments are due, by the various power producers, and by various Federal, State, municipal, and private experts, and continued progress and success are certain.

Perhaps the best way to bring out in detail the difficulties encountered in co-ordinating irrigation and power will be to describe some of the problems of this kind that have come before the Federal Power Commission. Nearly every stream presents a special problem of its own.

In connection with certain applications for power development the Federal Power Commission found a need of comprehensive studies to determine the relations between irrigation and power on the following streams: The Deschutes River, in Oregon; the Columbia River, in Washington, Idaho, and Montana; and the Trinity, American, and Stanislaus Rivers, in California.

Deschutes River, Oregon

A Board consisting of J. B. Cavanaugh, Colonel, Corps of Engineers, U. S. A., D. C. Henny, M. Am. Soc. C. E., Consulting Engineer, U. S. Bureau of Reclamation, and F. F. Henshaw, M. Am. Soc. C. E., District Engineer, U. S. Geological Survey, was appointed to report on the Deschutes River. (See Fig. 8.) The report of the Board was published by the Federal Power Commission in 1922, and has shaped the policy of the Commission with respect to the Deschutes River since that time.

The Deschutes Basin lies immediately east of the Cascade Range in Oregon, and a considerable part of the water supply comes from that range. The river flows generally north paralleling the Cascade Range and enters the Columbia a few miles east of The Dalles. From its mouth to Crooked River, a distance of 112 miles, the Deschutes flows in a canyon from 1 000 to 2 000 ft. deep, with a river slope of about 12.8 ft. per mile. From Crooked River to Benham Falls, about 70 miles, the slope increases to an average of about 38 ft. per mile, and the depth of the canyon gradually diminishes. Above Benham Falls the gradient suddenly flattens to about 1.5 ft. per mile for the next 36 miles. Storage is practicable above Benham Falls either in the main valley or in numerous small mountain valleys and lakes higher up. The rapid fall below Benham Falls and the relative shallowness of the canyon for about 20 miles down stream render irrigation diversion comparatively easy, and all present gravity diversions take place in this stretch of the river. Diversions

more than 25 miles below Benham Falls are impracticable on account of the depth of the canyon.

The flow of the Deschutes River is remarkably uniform. At the mouth, it generally fluctuates between 5 000 and 8 000 sec-ft. The lowest flow during the last 14 years was about 3 700 sec-ft., and short-time flood peaks usually do not exceed 16 000 sec-ft. This is due to the very large inflow of underground water from the porous volcanic formation above Crooked River as well as to the well-sustained low-water surface flow from the high Cascades. The minimum monthly mean flow of the Deschutes at Metolius, Ore., is 3 250 sec-ft. This minimum will not be materially affected if all the surface water reaching Benham Falls is diverted for irrigation. If all the Upper Deschutes water is dedicated to irrigation, the present irrigated area of about 81 000 acres can be expanded to 191 000 acres, and 555 000 h.p. can be developed on the Lower Deschutes.

There are at present six small hydro-electric developments on the Deschutes, all above the mouth of Crooked River. Their aggregate installed capacity is 3 230 h.p. The water rights of these developments conflict with irrigation expansion and will have to be extinguished for full irrigation development. The expansion of irrigation is likely to be delayed by the fact that all the irrigable areas are more than 4 000 ft. above sea level, so that only the hardier crops can be grown, and also by the fact that much of the area is now used more or less successfully for dry farming. This river presents an unusual condition in that all the irrigable areas lie above the main fall in the stream, and the peculiar physical and geological formation makes it possible to develop practically all the power in the lower river without curtailing irrigation development. Much of the power in the lower river can be developed at a very low cost and it undoubtedly will be developed whenever a market can be found.

On June 25, 1924, the Federal Power Commission issued a license to the Columbia Valley Power Company for developments at the Pelton and Metolius, Ore., sites on Deschutes River, with an ultimate installed capacity of 185 000 h.p. The Company proposed to sell power to the utility companies in Portland, Ore.

On November 28, 1922, the Federal Power Commission issued a preliminary permit to the Pacific Power and Light Company for a development at the Reclamation site on Deschutes River, with a proposed installed capacity of 54 000 h.p.

On November 13, 1924, the Federal Power Commission issued a preliminary permit to the Pringle Falls Electric Power and Water Company for a project near Bend, Ore., with a proposed installed capacity of 5 400 h.p.

No other applications are now before the Commission for developments on the Deschutes.

Columbia River

A Board consisting of J. B. Cavanaugh, Colonel, Corps of Engineers, U. S. A., D. C. Henny, M. Am. Soc. C. E., Consulting Engineer, U. S. Bureau of Reclamation, F. F. Henshaw, M. Am. Soc. C. E., District Engineer, U. S.

Geological Survey, C. S. Heidel, M. Am. Soc. C. E., State Engineer of Montana, W. G. Swendsen, Assoc. M. Am. Soc. C. E., Commissioner of Reclamation, Idaho, and Marvin Chase, M. Am. Soc. C. E., Supervisor of Hydraulics, State of Washington, was appointed to make a study of the Columbia River (see map, Fig. 9), from Flathead Lake, Montana, to the mouth of Snake River; to report on the character and extent of present and prospective uses of the river for navigation, irrigation, and power, with a discussion of the relative merits of each and of their relation to each other; and to outline a program of development that would harmonize the conflicting uses in such manner as to secure, in the long run, the greatest combined benefit from all.

After nine months' investigation, the Board submitted a report which was published by the Federal Power Commission in 1923. The report was concurred in by all members of the Board except the representative of Washington, who concurred in all conclusions and recommendations except those with respect to the Columbia Basin project.

The Columbia drains an area of about 259 000 sq. miles segregated by stream basins, as follows:

	Square miles.	Percentage.
Columbia River above Clark Fork in Canada..	34 000	13.1
Clark Fork	26 000	10.0
International Boundary to Snake River.....	43 000	16.7
Snake River	109 000	42.1
Columbia River below Snake River.....	47 000	18.1
Total.....	259 000	100.0

The mean annual precipitation of the Columbia Basin varies according to location, from 6 to more than 100 in. Where the precipitation exceeds 20 in. the country is generally forested and mostly mountainous, and where it is less than 15 in. the country is arid. The areas with low rainfall lie in two broad belts, one comprising East-Central Washington and extending northward up the Okanogan Valley into British Columbia, the other lying in the inter-mountain valley of Montana and British Columbia. Most of the land sufficiently smooth for agricultural development lies in the arid area.

The mean annual discharge at various points from Flathead Lake to the mouth of the Snake River is shown in Table 1.

TABLE 1.

Station.	Mean annual discharge, in acre-feet.	Drainage area, in square miles.
Flathead River, Polson, Mont.....	8 108 800	7 200
Clark Fork, Plains, Mont.....	14 914 400	19 900
Clark Fork, Metaline Falls, Wash.....	19 982 400	25 100
Columbia River, International Boundary.....	72 841 200	60 000
Columbia River, Pasco, Wash.....	94 699 200	103 000

The Upper Basin of the Columbia abounds in lakes, nearly all of which present possibilities of water storage. The three principal lakes are:

Flathead Lake, in Western Montana, at an elevation of nearly 2 900 ft., which has a surface area of 120 000 acres. The lake has a fairly steep shore

except at its upper end where the Upper Flathead River has built up a large delta. A considerable part of this delta is flooded at ordinary high water, but the remainder is used for agriculture which constitutes the principal support of the country around Kalispell. The outlet of the lake is through a rocky gorge below Polson offering satisfactory foundation for a dam. Storage to the amount of 1 600 000 acre-ft. can be obtained without serious damage from flooding.

Lake Pend Oreille, in Northern Idaho, has a surface area of 86 000 acres at low water and 98 000 acres at high water. The shores are generally steep, but much of the western portion is bordered by gravel beaches. The meadow lands at the head of the lake have the characteristics of a delta which the river overflows in flood. The outlet of the lake is between rocky banks and at Albany Falls the river crosses a dike of hard rock affording satisfactory foundation for a controlling dam. A storage capacity of 1 750 000 acre-ft. can be obtained without serious damage from flooding.

Priest Lake forms an enlargement of Priest River which discharges into Clark Fork about five miles above Albany Falls. It has an area of about 24 000 acres. The average run-off is about 862 000 acre-ft. The shores are fairly steep and the area subject to flooding by a raise of water surface is not large. The outlet is over a bed of boulders between banks of sand and gravel. The fall is about 30 ft. in the first 2 miles to a point where the river passes through a narrow defile with rock exposed on both sides to a considerable height. A dam can be built either at the gorge or at the outlet. Storage capacity of 600 000 acre-ft. can be obtained without serious damage from flooding.

Fig. 2 shows the monthly discharge of the Columbia River at Vernita, Wash., for high, average, and low years. It also shows the maximum irrigation demand above Vernita based on the irrigation of 4 000 000 acres, which figure was determined by using the largest estimates that could be found. It will be seen from this that the natural flow is more than ample in the main river. The irrigable lands, however, lie at such a height above the main river that, if high-lift pumping projects are to be avoided, diversion must be made on tributaries where the natural flow is inadequate without storage. The figures in Table 2 were furnished by the State representatives as to present and possible future irrigable areas in the Columbia Drainage Basin above Pasco, Wash.

The only project included in Table 2 which will have any material effect on the stream flow of the main river is the Columbia Basin project proposed by the State of Washington. This project contains about 1 750 000 acres in what is known as the Big Bend Country along the east side of the Columbia, north of Pasco and west of Spokane, Wash. The gross diversion required by this project as estimated by the State of Washington is shown in Table 3.

Two methods of diverting the water for this project have been studied: First, by gravity, diverting just above Albany Falls at the outlet of Lake Pend Oreille; and, second, by pumping from the river near the head of Grand Coulee. If the first method, which is favored by State authorities, is adopted, storage will be necessary.

Table 4 shows the storage that would have been required during the period, 1903-21, under the three different methods of regulating the flow.

Method I is based on a storage of 2 350 000 acre-ft. in Pend Oreille and Priest Lakes controlled for irrigation, with natural flow from Flathead Lake.

TABLE 2.

State.	Acres Irrigable.		
	Present.	Future.	Total.
Montana	274 000	425 000	699 000
Idaho	0	150 000	150 000
Washington	95 000	1 870 622	1 965 622
Total	369 000	2 445 622	2 814 622

TABLE 3.

Month.	Acre-feet.
April	561 000
May	1 152 000
June	1 152 000
July	1 152 000
August	1 092 000
September	685 000
October	436 000
Total	6 228 000

Method II is based on a storage of 2 350 000 acre-ft. in Pend Oreille and Priest Lakes controlled for irrigation, with 1 600 000 acre-ft. in Flathead Lake controlled for power.

Method III is based on a storage of 3 350 000 acre-ft. in Flathead and Pend Oreille Lakes controlled for irrigation.

It will be seen that 1919 was the only year when there would have been a shortage under any of the methods of regulation described. This shortage under Method II amounts to about 10% of the seasonal needs after July 1, and, being the only shortage in a cycle of 19 years, is not serious.

The Board concluded, therefore, that storage in Flathead Lake is not essential for the Columbia Basin project. If the second method is adopted, no storage for irrigation is necessary. The total lift from the river to Coulee is 630 ft. and a dam 200 ft. high would leave a remaining height of 430 ft. as pump lift. There is a good dam site at Grand Coulee with bed-rock at 60 ft. below low water. A pumping lift of 430 ft. is considerably greater than that of any successful pumping project now in existence, and its economic feasibility has been challenged. Whether or not economically feasible, a study of the pumping project made for the State by Mr. W. T. Batcheller, Electrical

and Mechanical Engineer, Seattle, Wash., shows that the cost per acre of a pumping project would be less than that of a gravity project, and this fact was confirmed by estimates made by the Columbia River Board.

TABLE 4.

Year.	Method I.	Method II.	Method III.
1903	649 000	1 005 000	1 118 000

1919	2 787 000	2 706 000	3 360 000
1920	1 080 000	1 165 000	1 848 000
1921	1 593 000	1 515 000	2 051 000

A new study of the Columbia Basin project is being made by the U. S. Department of the Interior, the results of which are not yet available. All authorities appear to agree that the soil and climatic conditions are excellent, but there is a wide difference of opinion as to the probable costs. The costs have been variously estimated at from $145 to $240 per acre for the water system, including storage, diversion, main canals, main laterals, and distribution system.

The fall in the river from Flathead Lake to Pasco is 2 567 ft. Data with respect to dam sites are not complete, but based on the dam sites that look feasible, 1 398 ft. of the fall can be developed for power. Table 5 shows the all-year power possibilities under various assumed conditions.

From Table 5 it is evident that a decision between the methods of irrigating the Columbia Basin affects not only the project itself, but also future power possibilities. The selection of the gravity method will destroy nearly 650 000 all-year effective horse-power.

There is a tendency to under-estimate the value of power in a region such as the Northwest where the potential power is great and present demand relatively small. The demands of a rapidly increasing power market are being felt all over the United States. Twenty years ago California had a great excess of water power, but it is now evident that before many years additional sources of power will have to be sought, and the Northwest seems certain to follow the same trend.

The conclusions of the Columbia River Board were that:

(*a*) Freedom should be given to fullest irrigation expansion in Montana, Idaho, and Washington, and no rights should be allowed to accrue to the lower

interests, which would legalize limitation of or interference with irrigation above.

(*b*) The Columbia Basin project is the most important single item to be considered in the uses to be made of Columbia River water above the mouth of Snake River.

(*c*) The Columbia Basin project can be irrigated by gravity from the Clark Fork at Albany Falls, or by pumping from the Columbia River at Grand Coulee.

(*d*) The Columbia Basin gravity project can be supplied adequately by the aid of storage in Pend Oreille and Priest Lakes in Idaho, conditioned on the maintenance of natural flow from Flathead Lake when needed.

Total.....		....	1 725 000	1 796 000	2 443 000

(*e*) The Columbia Basin project can be supplied with practically no shortage without the aid of storage, with a dam at Grand Coulee about 156 ft. above low water.

(*f*) Information on which to base a final decision between a gravity and a pumped supply for a Columbia Basin irrigation project is not complete and should be completed. Any decision should take into account the effect on potential power.

(*g*) Pending such decision no permanent rights of storage should be granted in Pend Oreille and Priest Lakes.

(*h*) If ultimately the decision is in favor of a Columbia Basin gravity project, storage rights in Pend Oreille and Priest Lakes should be granted

to such project, but should be limited to storage of inflow in excess of 7 000 sec-ft.

(*i*) If ultimately the decision is in favor of a Columbia Basin pumping project, storage rights in Pend Oreille and Priest Lakes should be granted to the joint interests of power on the Lower Clark Fork and the Columbia River subject to limitations contained in Section (*a*).

(*j*) Storage rights in Flathead Lake should be granted to Flathead power interests, subject to the fullest development found to be practicable after complete investigation. Prior to such development, rights may be advantageously granted to power interests on the Clark Fork subject to conditions protecting ultimate control for Flathead power and natural flow release when needed for the protection of the Columbia Basin project if built on the gravity plan.

(*k*) Storage control at Flathead, Pend Oreille, and Priest Lakes should be under impartial supervision.

(*l*) A permit to develop power at the Grand Coulee site, or at any point on the Columbia River as far down stream as the Foster Creek site, should not be granted to power interests until it is known that such site will not be needed by the Columbia Basin project. In case the Columbia Basin project shall require a power site for irrigation and power on this stretch of the Columbia River, a permit should be granted to it after the best location and height of dam shall have been determined from the standpoint of the project and the public interest.

These conclusions appear to be sound and equitable and are, therefore, likely to be followed by the Federal Power Commission.

The following is the status of applications to the Federal Power Commission for power projects on the Upper Columbia:

Application for preliminary permit by the Rocky Mountain Power Company, of Butte, Mont.: A project on Flathead River below Flathead Lake with five dams and a proposed installed capacity of 272 000 h.p. Action indefinitely suspended awaiting completion of investigation of Columbia Basin irrigation project.

Application for license by the Washington Irrigation and Development Company, of New York, N. Y.: A project on the Columbia River at Priest Rapids with a proposed installed capacity of 300 000 h.p. License authorized March 2, 1925.

Application for preliminary permit by Hugh L. Cooper, M. Am. Soc. C. E., of New York, N. Y.: A project at Z Canyon, Clark Fork, with a proposed installed capacity of 350 000 h.p. Action indefinitely suspended awaiting completion of investigation of Columbia Basin irrigation project.

Application for preliminary permit by the Washington Water Power Company, of Spokane, Wash.: A project on the Columbia River at Kettle Falls with a proposed installed capacity of 153 400 h.p. Permit issued August 26, 1922.

Application for preliminary permit by Mr. Hugh L. Cooper, New York, N. Y.: A project on the Columbia River at Grand Coulee with a proposed

installed capacity of 800 000 h.p. Action indefinitely suspended awaiting completion of investigation of Columbia Basin irrigation project.

Trinity River

A Board consisting of W. F. McClure, M. Am. Soc. C. E.,* State Engineer of California, D. C. Henny, M. Am. Soc. C. E., Consulting Engineer, U. S. Bureau of Reclamation, U. S. Grant, 3d, Major, Corps of Engineers, U. S. A., Assoc. M. Am. Soc. C. E., and E. W. Kramer, M. Am. Soc. C. E., Hydraulic Engineer, U. S. Forest Service, was appointed by the Federal Power Commission to study the Trinity River (see map, Fig. 10), in California, in order to indicate the most beneficial uses that can be made of its waters and especially to determine whether diversion to the Sacramento River will be to the general benefit. The Board submitted its report in February, 1924. The report will probably not be printed.

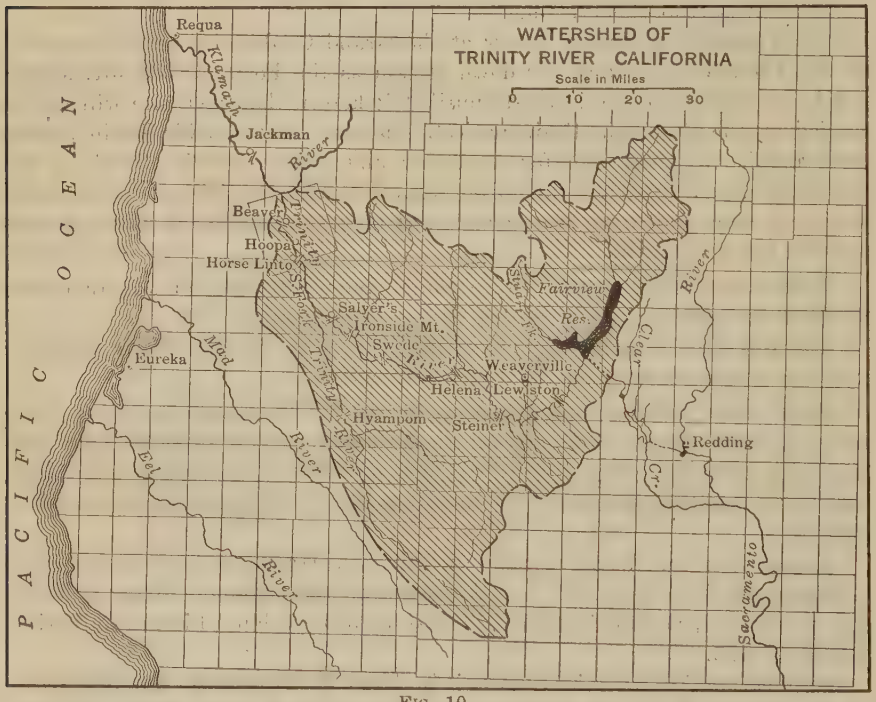

Fig. 10.

The following are the main facts, conclusions, and recommendations set forth in the report:

Trinity River is the main tributary of Klamath River and drains 2 925 sq. miles of mountainous and wooded area on the west slope of the Coast Range in Northern California. The annual precipitation, dependent on altitude and nearness to the ocean, ranges from 35 to 80 in. Its average for the water-shed is about 50 in. The only town of consequence on the water-

* Mr. McClure died June 22, 1926.

shed is Weaverville, an old mining town which derived some importance from hydraulic mining operations that have practically ceased. Agricultural development is small and is confined mostly to the Hoopa Valley Indian Reservation at the lower end of the stream. There are not more than 6 000 acres of irrigable land in the Trinity Basin. There is a great seasonal variation in the flow of the river. At Lewiston, Calif., the mean flow is about 1 600 sec-ft., the maximum is 25 000 sec-ft., and the minimum 52 sec-ft. The areas available for irrigation are so small that the minimum flow is more than enough to irrigate them. It is evident, however, that for successful power development large storage is essential.

There are reservoir sites on Stuart Creek, which enters the Trinity six miles above Lewiston, that have sufficient capacity to regulate the flow of that creek. On the main stream there are only two opportunities for large storage above Lewiston, one at Trinity Center and one at Fairview. The latter is probably the more favorable, because it takes in the flow of Stuart Creek. It can be developed by a dam 270 ft. high to a capacity of 600 000 acre-ft., is at an elevation of more than 2 000 ft., and receives the flow from the best yielding part of the drainage area.

Fig. 11 shows the run-off of Trinity River past Fairview Dam site and the contents of Fairview Reservoir on the basis of maintaining a regulated flow of 1 053 sec-ft. The suitability of foundations and abutments for a dam 270 ft. in height above the stream bed at this site has not been established by borings.

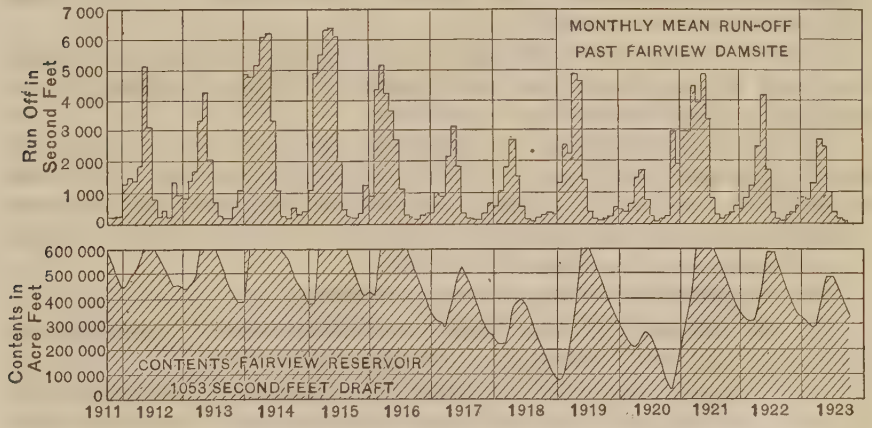

FIG. 11.

The average elevation of the surface of Fairview Reservoir would be 2 138 ft. above sea level. From this point to tail-water at the Jackman site, on Klamath River, the fall is 2 091 ft. A reconnaissance of the Trinity, made by Mr. E. W. Kramer, of the U. S. Forest Service, indicates that dam sites can be found, that will permit development for power of about 1 738 ft., or 83% of this fall. On this basis and with 560 000 acre-ft. of Fairview storage, the all-year power that can be developed on the Trinity is about 250 000 h.p.

It is possible to divert the Trinity at a point just below Fairview into Clear Creek, a tributary entering the Sacramento River 7 miles below Redding, by a tunnel 6.3 miles long. The tunnel would discharge at a height of 487 ft. above Clear Creek, giving an opportunity for power development. The tail-water from the power-house would flow into a reservoir on Clear Creek with a dam, at Whiskeytown, 210 ft. high and a storage capacity of 135 000 acre-ft. From this reservoir a conduit and pressure tunnel could conduct the water to a power-house with a head of about 660 ft. on the Sacramento River 3 miles above Redding. The usable head in case of diversion is about 1 268 ft. as against 1 738 ft. on the Trinity, and the all-year power in case of diversion would be about 115 000 h.p. as against 250 000 h.p. on the Trinity. After diversion, it would still be possible to develop about 105 000 all-year horse-power on the Trinity. The net loss of power by diversion is, therefore, about 30 000 h.p. This loss would be reduced by about 7 000 h.p. if the Iron Canyon project on the Sacramento River were built.

Irrigation on the Trinity will not be injured by diversion of Trinity water at Fairview, whereas about 160 000 acres can be irrigated in the Sacramento Valley by such diversion. It is well recognized that the water supply in the Central Valley of California is sufficient to supply only a part of the irrigable land in the Valley. The shortage is in the San Joaquin or southern half of the Valley, but any water supplied to the west side of Sacramento Valley can be made to release water from the Sacramento to supply the northern part of the San Joaquin. In other words, water diverted from the Trinity will increase the irrigated area in the Central Valley by about 160 000 acres, but with the loss of about 30 000 h.p.

Before a decision can be definitely reached the cost of the diversion project must also be considered, and, unfortunately, the data available are not sufficient to permit of satisfactory estimates.

The Federal Power Commission has recently granted a preliminary permit for the diversion project to Mr. W. H. Sampson, of Corning, Calif., with conditions that require him to make investigations and procure the data necessary to determine whether the project is economically feasible. If it is found to be feasible, it will undoubtedly be built.

The conclusions of the Board were, as follows:

(*a*) The full use of Trinity River water makes essential large storage at its head-waters where required storage facilities exist.

(*b*) Potential power of Trinity River water regulated by available storage is slightly greater if flowing down its natural course than if partly diverted.

(*c*) Irrigation possibilities in the Trinity Basin are relatively small and will not be adversely affected by diversion.

(*d*) The Sacramento River water supply and the potential means of regulating it are sufficient for the irrigation of the entire Sacramento Valley.

(*e*) The joint water supply of the Sacramento and San Joaquin Rivers and means of regulating it are insufficient for the irrigation of both valleys.

(*f*) Diversion of Trinity River water will permit more complete irrigation development in the joint valleys than is otherwise possible, involving a potential addition of at least 160 000 acres of irrigated land.

(*g*) Trinity River water, if diverted, is likely to be used on the west side of the Sacramento Valley, thereby permitting later Sacramento storage development to supply part of the Lower San Joaquin Valley.

(*h*) The only important industrial use made of Trinity River water is in connection with gold dredging. Diversion will not interfere with this industry. Storage above diversion may flood prospective dredging lands in the reservoir site, which fact does not justify delay in reservoir construction.

(*i*) Navigation is confined to Klamath River below the mouth of the Trinity. It may be interfered with to a small extent by diversion which, on the other hand, may benefit Sacramento navigation.

(*j*) The advantages of diversion greatly outweigh its disadvantages.

In harmony with the conclusions, the Board made recommendations as follows:

(*a*) That no power rights be granted to prospective Trinity River water users, that will interfere with ultimate diversion of Trinity water to the Sacramento Valley.

(*b*) That any permission to divert water from the Trinity River to the Sacramento Valley provide for the maintenance of a flow of at least 20 sec-ft. in the Trinity River below the point of diversion.

American River

A Board consisting of D. C. Henny, M. Am. Soc. C. E., Consulting Engineer, U. S. Bureau of Reclamation, W. F. McClure, M. Am. Soc. C. E., State Engineer of California (represented by Paul Bailey, M. Am. Soc. C. E.), U. S. Grant, 3d, Major, Corps of Engineers, U. S. A., Assoc. M. Am. Soc. C. E., and E. W. Kramer, M. Am. Soc. C. E., Hydraulic Engineer, U. S. Forest Service, was appointed by the Federal Power Commission to study the American River, in California (see map, Fig. 12), in order to indicate the most beneficial uses that can be made of its waters and especially to determine whether diversion from one to another tributary will be to the general public benefit. The Board submitted its report in April, 1924. The following is abstracted from the report and the records of the Federal Power Commission:

The American River System with its three main Forks—South, Middle, and North—drains the mountainous area lying to the east and northeast of the City of Sacramento. The steep river gradients descending about 6 000 ft. in the upper 50 miles of the stream courses favor economical power development. This is offset to some extent, however, by the wide fluctuations of stream flow throughout the year, by the occurrence at intervals of unusually dry years, and by the paucity of storage facilities at high elevations.

Some agricultural land is found on the ridges between the branches of the rivers at elevations less than 3 500 ft., but the only tract that is feasible of irrigation is on Georgetown Ridge between South and Middle Forks. This tract contains 25 000 acres of irrigable land. The only practicable source of supply for this land is Rubicon Creek, and 50 000 acre-ft. will be required, about 30 000 acre-ft. of which must be supplied from storage. It will be

FIG. 12.

possible to irrigate about 400 000 acres adjacent to the American River and below Folsom on the floor of Sacramento Valley with water from the American River, provided storage can be developed to the amount that appears practicable.

The flood period in the American River generally extends from February to June and during this period about 80% of the annual run-off is discharged. The dry seasonal flow becomes very small in August, September, and October. At times, the September outflow from the entire basin averages as low as 250 sec-ft. The average annual run-off of the American River since 1905 has been more than 3 000 000 acre-ft., but in dry years it has been as low as 1 250 000 acre-ft.

The Coloma Reservoir site at a river elevation of about 600 ft. on the main stream of the South Fork, has a possible storage capacity of at least 300 000 acre-ft. The flat gradients and narrow gorges at corresponding elevations on the Middle and North Forks make it probable that ample storage may be found at low elevations on these Forks to regulate the flow so as to meet the seasonal demands of irrigation on the floor of the Sacramento Valley. Such storage is all up stream from Folsom Dam on the main American River which would serve as a logical diversion point for distribution on the Valley floor. The storing of water for irrigation on the lower reaches of the stream will permit the use of the limited up-stream storage for power, except for 30 000 acre-ft. on the Rubicon, needed for Georgetown Ridge. Storage in the upper drainage area is believed to exist to the following extent:

North Fork	0 acre-ft.
Middle Fork:	
Main stream: French Meadows	64 000 " "
Rubicon: Rock Bound and Buck Island Lakes	24 000 " "
Hell Hole	32 000 " "
Parsley Bar	13 000 " "
Loon Lake on Gerle Creek	47 000 " "
Middle Gerle Creek	8 500 " "
Upper Pilot Creek	5 600 " "
South Fork:	
*Silver Creek: Ice House	45 000 " "
Union Valley	165 000 " "
Main stream: Medley and Echo Lakes	11 000 " "
*Silver Fork: Twin and Silver Lakes	50 000 " "
Alder Creek and Plum Creek	31 000 " "
Total	496 100 acre-ft.

The following are the existing power developments on American River:

Folsom Project, Pacific Gas and Electric Company: Main stream, head, 55 ft.	4 000 h.p.
Western States Gas and Electric Company: South Fork, head, 572 ft.	6 500 "
El Dorado Plant, Western States Gas and Electric Company: South Fork, head, 1 905 ft.	21 500 "
Total	32 000 h.p.

* Silver Creek must not be confused with Silver Fork.

The Federal Power Commission has before it the following applications for power development on American River:

American River Water and Power Company:

Diversion of Rubicon River to French Meadows and development of power on Middle Fork.

City of Sacramento:

Development of storage on Rubicon River and diversion to Silver Creek.

Development of storage and power on Silver Creek.

Development of power on South Fork below Silver Creek and diversion of water from Coloma to Sacramento for domestic and irrigation supply.

Rubicon River diversion was disapproved and preliminary permit for Silver Creek and South Fork, American River, development was issued October 25, 1924.

Western States Gas and Electric Company:

Additional development of storage and power on Silver Fork and South Fork. License issued February 23, 1922.

There have also been applications, now canceled, to divert Middle Fork into North Fork and North Fork into Middle Fork. Middle Fork and Silver Creek have more than enough storage capacity on their head-waters to equalize their stream flow. Rubicon River and South Fork have sufficient head-water storage to regulate their flow in part. North Fork, so far as is known, has practically no head-water storage. It is on account of this condition that projects have been proposed for diverting North Fork and the Rubicon to Middle Fork and for diverting the Rubicon to Silver Creek. On South Fork the head-water storage is controlled by water rights held by the Western States Gas and Electric Company, and that Company proposes to proceed with complete development above Silver Creek as fast as its power demand permits.

The conflicting applications on the other tributaries caused the Federal Power Commission to appoint the Board to determine the best plan of development.

Mr. E. W. Kramer, of the U. S. Forest Service, made a study of various plans of development, the results of which are given in Table 6. Credits from irrigation have been arbitrarily based on an estimate of $20 per acre.

The Federal Power Commission has adopted a general rule, that diversions from one stream to another shall be permitted only when positive advantages outweighing all disadvantages can be shown. The studies of the Board show that such advantages exist in the diversion of the North Fork of American River to the Middle Fork, and that they do not exist in the case of any of the other proposed diversions.

The Board also investigated the use of American River water for navigation in the Sacramento, and for improving salt-water conditions below

Sacramento, and the use of American River storage for flood control. On the basis of its studies, the Board concluded:

(*a*) That navigation and salt-water conditions in the Sacramento River below Sacramento will not be injuriously affected by any now anticipated uses of the American River water, including domestic water supply, irrigation, and power.

(*b*) That storage facilities in the American River Basin should be dedicated to irrigation and power primarily, since their economic value for these purposes is too great to justify their developments solely for flood control.

TABLE 6.

Plan of development.	All-year horse-power.	Total cost, exclusive of transmission.	Credit for Irrigation.		Net cost of power.	Cost per all-year horse-power.
			Acres.	Amount.

Silver Creek	136 000	32 099 000	87 000	1 740 000	30 359 000	223
Total	253 000	$60 179 000	149 000	$2 980 000	$57 199 000	$226
2.—Diversion, North Fork to Middle Fork:						
North and Middle Forks	87 000	$21 250 000	36 000	$ 720 000	$20 530 000	$236
Rubicon	99 000	20 509 000	77 000	1 540 000	18 969 000	192
Silver Creek	79 000	19 250 000	45 000	900 000	18 350 000	232
Total	265 000	$61 009 000	158 000	$3 160 000	$57 849 000	$218
3.—No Diversion:						
North Fork	0					
Middle Fork	45 000					
Rubicon	99 000			Not computed		
Silver Creek	79 000					
Total	223 000	.....	.....	.....	.....	....
4.—Diversion, North Fork to Middle Fork: Diversion, Upper Rubicon to Middle Fork:						
Middle Fork	118 000					
Rubicon	0			Not computed		
Silver Creek	79 000					
Total	197 000	.....	.....	.....	.....	....

(*c*) That the fullest practicable irrigation of the cultivable lands of the American River Basin is in the interest of the public and requires that any power or irrigation projects developing upper storage reservoirs in the Rubicon drainage area under Federal Power license, shall be obligated to supply at reservoirs, shortage in irrigation water for approximately 25 000

acres on the Georgetown Ridge, at a price based on investment and cost of service, and not on value of power lost by supplying this irrigation need.

(*d*) That until investigations show that large storage for Valley irrigation cannot be feasibly developed on the lower reaches of the North and Middle Forks below River Elevation 1 150, it is inadvisable to permit power development which would interfere with irrigation storage below this elevation.

(*e*) That the Coloma Reservoir has sufficient capacity and is located so that it can regulate for the benefit of irrigation, almost the entire flow of the South Fork of the American River below power developments. Its primary value is for irrigation storage.

(*f*) That the Folsom Dam site admits raising the dam to a considerable additional height and that this site is located at the logical point for diverting American River water for all lower gravity irrigation.

(*g*) That the potential power of the North and Middle Forks of the American River can be best developed by the diversion of the Upper North Fork drainage to French Meadows Reservoir on the Middle Fork.

(*h*) That the diversion of Rubicon water to the Middle Fork would be wasteful of power.

(*i*) That the diversion of Rubicon water to Silver Creek would prevent maximum power utilization and would tend to increase the total power cost.

(*j*) That the municipal power, domestic water supply, and irrigation requirements of the City of Sacramento and the Sacramento Municipal Utility District, for a reasonably extended future, can be satisfactorily supplied from Silver Creek without Rubicon diversion.

Stanislaus River

The Federal Power Commission also requested the Board which reported on the Trinity and American Rivers in California to report on a proposed enlargement of the present development on the North Fork of Stanislaus River, California, with a view to determining the best method of development. The report was submitted December 1, 1924, and will probably not be printed. The questions involved are probably not of sufficient general interest to merit discussion herein.

Kings River

The San Joaquin Light and Power Corporation has been planning to undertake the complete development for power of North Fork, Kings River (see plan, Fig. 13), since 1913. After many delays, on July 28, 1922, the Corporation was issued a Federal Power Commission license for the entire project. Section 9 (*b*) of the Federal Water Power Act, reads, as follows:

"Satisfactory evidence that the applicant has complied with the requirements of the laws of the State or States within which the proposed project is to be located with respect to bed and banks and to the appropriation, diversion, and use of water for power purposes and with respect to the right to engage in the business of developing, transmitting, and distributing power, and in any other business necessary to effect the purposes of a license under this act."

On account of this section, however, the license was made subject to the following proviso:

FIG. 13.

"Provided, that this license shall not become effective with respect to the following separable parts of the above described project works until the Licensee has complied with the requirements of the laws of the State of California with respect to appropriation, diversion, and storage of water contemplated in the development of said separable parts:

(*a*) Wishon Dam, Reservoirs and Power Plant
(*b*) Meyer Dam and Reservoir
(*c*) Peart Dam, Reservoir and Power Plant
(*d*) Rancheria Creek Diversion Dam and Tunnel
(*e*) Bear Creek Diversion Dam and Canal."

The Corporation was issued water permits by the State for the use of the natural flow of North Fork, Kings River, but its applications to store water were held up on account of protests from the irrigation interests that use Kings River water. The Division of Water Rights, State Department of Public Works of California, notified the Commission, however, that it was expected that water rights for the entire project of the San Joaquin Light and Power Corporation would be granted as soon as action could be taken on the Pine Flats Reservoir project, application for which was made to the State on January 1, 1916.

The Pine Flats project proposes the construction of a reservoir with a capacity of 600 000 acre-ft., located at the outlet of Kings River Canyon, just above Piedra, Calif. The primary object of the project is to regulate the flow of Kings River for irrigation. The area irrigated varies from 500 000 to 700 000 acres, and it is estimated that about 1 000 000 acres can be irrigated when the Pine Flats project is completed. With the possible exception of Kern River, Kings River presents more complications for the organization of a comprehensive irrigation development than any other stream in California. The are twenty-three different groups of interests, with ten or twelve additional subsidiary interests using Kings River water. The water rights are very complicated and, as might be expected, are more or less in conflict. The interest having the last water right can take no water except when the flow in the river exceeds 9 500 cu. ft. per sec. The Kings River territory is one of the largest and most successful irrigation developments in the United States. The present use of water is not as economical as it should be, and the advantages of expanding the development by construction of the Pine Flats project are so great that undoubtedly the difficulties will eventually be overcome.

The low-water flow of North Fork, Kings River, is so meager and the cost of power development is so great that the power project of the San Joaquin Light and Power Corporation is not economically feasible without storage. The complete development will include four reservoirs, as shown in Table 7.

The power capacity of the project under the Federal Power Commission's definition will be about 215 000 h.p., and the proposed installed capacity about 400 000 h.p.

There are also considerable power possibilities on the South and Middle Forks of Kings River, but the region is very rugged and difficult of access,

and the projects will be relatively expensive so that some years may elapse before they are built. After the construction of the Pine Flats project, the development of power on South and Middle Forks will benefit irrigation development, but the data available are so meager that the ultimate relation between power on these Forks and irrigation cannot now be determined.

Since 1917 the diversion of water from Kings River for irrigation has been supervised by a Watermaster appointed by the State Division of Water Rights. Table 8 has been compiled from the records of the Watermaster. Table 9 has been compiled from the discharge records of the Watermaster and the irrigation demands set forth in a report on "Irrigation Requirements of California Lands."* Table 9 shows that the unregulated discharge is deficient in July, August, September, and October properly to supply the irrigation need, the deficiency running from 318 000 acre-ft. to 660 000 acre-ft. Table 8 indicates that this deficiency is made up as far as practicable by over-irrigation in May and June. It is also partly made up by pumping underground water, and with this in view water is diverted, when available, to build up the underground supply. Table 8 shows also that during the period of record there was each year water unused for irrigation which might have been stored for power, the quantity varying from 111 000 acre-ft. to 842 000 acre-ft., which would be sufficient to make the power project feasible. Use of this excess water for power has been prevented thus far by the irrigation interests near Tulare Lake, who claim this undiverted water is necessary to underground storage from which they pump. Fig. 6 shows graphically the relation between discharge, present diversions, and desirable irrigation supply.

TABLE 7.

	Height of dam, in feet.	Elevation of crest, in feet.	Capacity, in acre-feet.
Wishon Lake	250	6 545	128 000
Meyer Reservoir	190	6 845	21 000
Peart Reservoir	315	5 645	54 600
Helms Reservoir	297	8 177	102 000
Total capacity	....	.....	305 600

The effect of the power storage on the irrigation supply will depend on the rate of release of stored water for power. Under any practicable method of operation, however, the power storage will reduce the capacity needed in Pine Flats Reservoir for seasonal regulation, and to that extent will increase its capacity for hold-over storage and will thus benefit irrigation.

The Pine Flats Reservoir will make possible the full use of the waters of Kings River for both power and irrigation.

Green River Above Flaming Gorge

On January 24, 1921, the Utah Power and Light Company made application to the Federal Power Commission for a preliminary permit for power

development at the Flaming Gorge power site on Green River, Utah (see Fig. 14). A preliminary permit was granted for a period of three years on August 15, 1923. The permit contains the following special conditions:

"If license is issued for said proposed project it * * * may contain the following special conditions or provisions:

"*A*. The rights of the Licensee to appropriate, store, divert, and use the waters of said Green River in connection with said project shall be subject to and be limited by the provisions of the 'Colorado River Compact' signed at Santa Fé, New Mexico, on November 24, 1922, if, when, and as said Compact is ratified.

"*B*. Said rights to appropriate, store, divert, and use waters of Green River shall be subordinate to all present and future rights to the use of the waters of said river above said dam for purposes of irrigation or of domestic water supply."

The second of these special conditions was inserted by the Federal Power Commission to meet objections by the State of Wyoming which, with the other arid States, is following a policy of giving the use of water for irrigation unqualified precedence over its use for power.

The Utah Power and Light Company has completed its investigation of the power site and prepared plans for the project structures, but has not yet applied for a license. It is understood that the Company feels that it can not finance the project if Special Condition *B* is included without qualification in the license, and therefore it has modified its construction program and will extend its development on Bear River to meet immediate market demands in the hope that sentiment in Wyoming will change so that the reservation of water for irrigation use on Green River may be definitely limited to what will be needed to meet the probable growth of irrigation. A brief review of the physical features of the situation will show the principal factors involved.

The power project proposed consists of a dam about 220 ft. high in Horse Shoe Canyon, about 40 miles by air line below Green River, Wyo.; a tunnel, 3½ miles long, leading from the reservoir above the dam through Bear Mountain; and a power-house on the river, 15 miles by river below the dam. The latter part of the project may be modified on further study, but the power capacity will not materially change. The reservoir capacity is 3 476 000 acre-ft., but probably only the top 50 ft., with a capacity of 1 710 000 acre-ft., will be drawn upon as that amount of storage is sufficient to equalize the flow of the stream. The average power capacity of the project continuously available will be about 75 000 h.p. and the installed capacity will be more than 100 000 h.p. There appear to be no serious construction difficulties, and although the site is about fifty miles from the nearest railroad and the project is not a cheap one, it probably can be built at a cost that will not raise present power rates. The Company now furnishes power to most of the State of Utah, and this project would be connected to and supplement its power system.

There is considerable difference of opinion as to the amount of irrigation development that is feasible in Green River Valley, Wyoming. Some believe that there will be little increase over that of the present while others believe that the entire stream flow above Green River, Wyo., will be needed for irrigation. The following information is taken mostly from unpublished reports by

FIG. 14.

Mr. R. R. Woolley, of the U. S. Geological Survey, dated February, 1923, and by the U. S. Bureau of Reclamation, dated February, 1924.

The Green River Basin in Wyoming covers an area of about 15 000 sq. miles. All the irrigable land lies at an elevation of 6 000 ft. or more above sea level. The average precipitation in the valley ranges from 6 in. in the south to 11 in. in the north with much higher precipitation on the mountains. The average annual temperature varies from about 42° Fahr. at Green River, Wyo., to 34° Fahr. in the northern part of the valley. The growing season varies from 105 days to 30 days. Frosts may be expected any month (Table 10).

TABLE 10.—Frost Data.

Station.	Number years of record.	Average date of first killing frost, fall.	Average date of last killing frost, spring.	Earliest date of killing frost, fall.	Latest date of killing frost, spring.
Green River.....	10	September 4	June 10	August 11	June 23
Daniel.....	13	August 13	June 22	July 7	July 9
Pinedale.....	7	August 17	June 29	July 31	July 16
Manila.....	8	September 8	June 22	August 25	July 10

Coal mining and stock-raising are the principal occupations. The population is about 20 000, more than 65% of which live in towns along the Union Pacific Railway. The irrigable land lies from 10 to 100 miles from the railroad. The present irrigated area is largely made up of bottom-lands developed by individual effort to supplement the stock industry. The principal crop is wild hay.

Diversion from the tributaries is not difficult, but for the large projects, with lands away from the river, long main canals are required because of light river grades. Under the Carey Act, many projects have been outlined by surveys and much development proposed and several projects have been partly built. A total of about 500 000 acres is covered by permits for appropriation of water. Diversion demands range from 2.5 acre-ft. to 3.0 acre-ft. per year, with a net consumption of water averaging 1.5 acre-ft. Lack of reservoir sites at strategical points will prevent the use of the entire run-off of the basin.

Table 11 gives the U. S. Reclamation Bureau's classification of irrigable lands.

Class A.—

1.—Undeveloped areas of constructed or partly constructed projects not requiring undue expenditures.

2.—New projects concerning which no serious construction difficulties are known and for which water supply seems ample.

3.—Increase in area under small ditches already built or anticipated to be built shortly.

Class B.—

Developments similar to those of Class A but by reason of relatively higher cost not likely to be carried through in the immediate future.

Class C.—

Developments possibly feasible from the standpoints of construction and water supply, but out of the question in the near future by reason of excessive cost.

The average annual discharge of Green River at Flaming Gorge, deducting present irrigation use and probable evaporation losses in the reservoir, is about 1 810 000 acre-ft., giving about 2 500 cu. ft. per sec. available for power.

According to the estimate of the U. S. Bureau of Reclamation the depletion of flow caused by future development per Table 11 is:

Class *A* projects,	279 000 acre-ft. per year	equivalent to	385 cu. ft. per. sec.
Class *B* " ,	255 000 " " "	" "	352 " " " "
Class *C* " ,	236 000 " " "	" "	326 " " " "
Total.....	770 000 acre-ft. per year	equivalent to	1 063 cu. ft. per. sec.

Henrys Fork:					
Small ditches	20 000	8 000	7 000	5 000	.....
Grand total	728 000	220 000	202 000	171 000	135 000

At the Flaming Gorge project 1 cu. ft. of water will produce about 30 h.p., and the average continuous horse-power will be:

With present water supply.....	75 000	h.p.,	or	492 750 000	kw-hr.	per	year
After Class *A* developments.....	63 450	"	"	416 866 000	"	"	"	"
" Class *B* "	52 890	"	"	347 487 000	"	"	"	"
" Class *C* "	43 110	"	"	283 233 000	"	"	"	"

The estimated cost of the Flaming Gorge project is $24 300 000. The power at the switchboard will cost about:

With present water supply.....	$0.00589	per	kw-hr.
After Class *A* developments.....	0.00697	"	"
" Class *B* "	0.00836	"	"
" Class *C* "	0.01026	"	"

Present power rates in Utah will hardly justify a cost of $0.006 per kw-hr. for power at this plant. It is possible that as the load grows and more head can be developed below Flaming Gorge the regulated flow through the greater head will reduce the costs so that the project will be feasible with a reduced flow, but, at present, any considerable reduction in flow will make the project impossible.

Any prediction as to rate of growth of irrigated area is perhaps hazardous, but a study of the rate of growth of Green River Valley, Wyoming, is interesting.

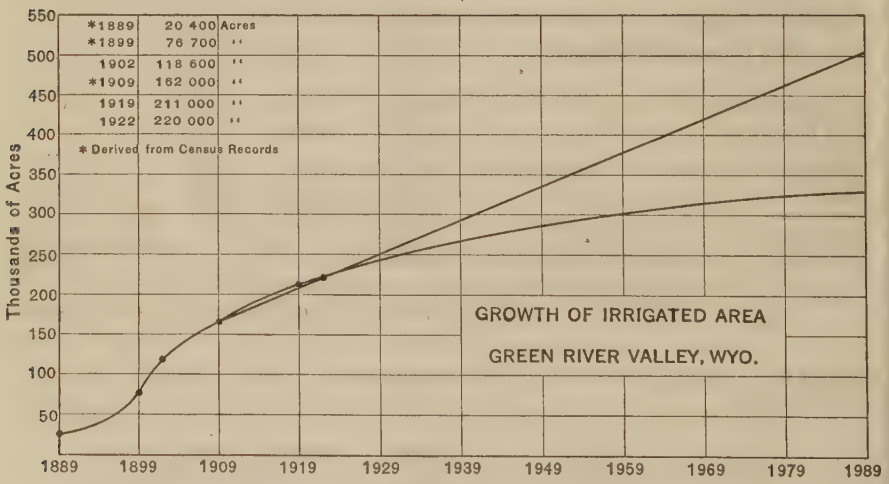

Fig. 15.

Fig. 15 shows the growth of the irrigated area from 1889 to 1922. It also shows what the future growth may be: First, by projection of the curve; and, second, by projection of a straight line through the points for 1909 and 1922. Considering the very short growing season, the inaccessibility of the region, and the expense of developing the larger projects, there is reason to believe that the irrigated area will not increase faster than is indicated by projection of the curve, and it certainly is unlikely that it will increase faster than the

straight-line projection. In other words, 50 years hence, the irrigated area may have increased to 320 000 acres, and it is unlikely that it will have increased to 445 000 acres. Successful agriculture in this region of high altitude is likely to be limited in the future, as in the past, to the raising of winter feed for stock that can be grazed on the many miles of adjoining range. Such irrigation is usually confined to individual effort on small ditches. Referring again to the classification of the U. S. Reclamation Bureau, it will be seen that, under Class *A*, there are 52 000 acres that can be irrigated with small ditches.

Irrigation is much better known than it was twenty years ago. Private capital will be difficult to obtain for any large project in Green River Valley, Wyoming. Strong efforts are still made from time to time to get the Federal or the State Governments to undertake projects that are considered infeasible for private interests, but fairly strong opposition generally is met, and of late such undertakings have been very rare.

The probabilities are that irrigation in Green River Valley, Wyoming, will not seriously interfere with the Flaming Gorge power project but, in order to finance that project, it may be necessary to set a schedule specifying the rate at which the water supply may be depleted for irrigation.

Salt River Valley

Since 1912, Frank G. Baum, M. Am. Soc. C. E., of San Francisco, Calif., has had under consideration and, since 1914, has been trying to obtain Federal authority for a power project on Black River, a tributary of Salt River, in Arizona. (See Fig. 16.) In December, 1920, he made application to the Federal Power Commission for a preliminary permit. The project included three reservoirs with a combined capacity of 35 000 acre-ft. at an elevation about 8 000 ft. above sea level. The power-house would have a head of about 870 ft., and an installed capacity of about 10 000 h.p. It was proposed to find a market for the power in Globe, Clifton, Miami, Jerome, or other mining centers.

The Salt River Valley Water Users' Association made a strong protest against the project on the ground that storage of water on Black River in low-flow years would deplete the water supply for about 200 000 acres of irrigated land in the Salt River project by at least 10 000 acre-ft., and would also cause a power loss of about 700 000 kw-hr. per year which, if available, would pump about 10 000 acre-ft. of ground-water. The total loss of water, it was claimed, would amount to from 20 000 to 30 000 acre-ft. It was stated that the seepage losses in the main canals of the Salt River project amounted to about 200 000 acre-ft. per year, and that the loss due to the Baum project could be compensated for by lining some of the canals or by paying for pumping the seeped water from the ground-water supply. Mr. Baum claimed that his project would cause no loss to the Salt River Valley Water Users' Association, but on the contrary would be beneficial. The data available are too meager to determine accurately what increased evaporation loss might be due to the maintenance of a fairly uniform flow throughout the year in the 125 miles of river channel between the Baum project and Roosevelt Reservoir,

instead of sending most of the water down on the flood flows, as at present. From such data as are available studies were made by engineers of the Federal Power Commission. These studies indicate that for about 5 years in the past 35, the Baum project would have diminished the available water supply by perhaps as much as 2 000 acre-ft., out of a total of about 900 000 acre-ft., and would have reduced the mean head at the power plant at Roosevelt Dam by perhaps 2 ft. out of 80 ft. For 17 years it would have increased the water supply and head for power, and, during the other 13 years, its effect would have been negligible. As the detrimental effect during the 5 years of low flow can be remedied by lining canals or by supplying power for pumping ground-water, the problem is one of determining the cost of such operations and balancing that cost against the value of extra power in the 17 years during which the Salt River project would have benefited. It is doubtful whether the balance would be in favor of, or against, the Baum project, but it is fairly certain that the amount involved would be small.

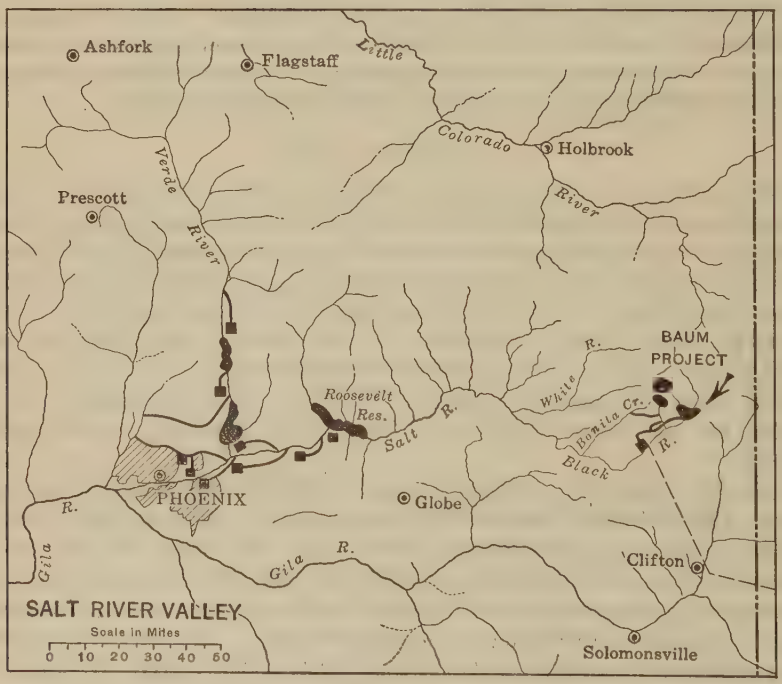

FIG. 16.

The drainage area above Roosevelt Dam contains about 6 000 sq. miles and is capable of economically developing about 75 000 continuous h.p. whenever a market offers, provided head-water storage can be obtained. The State of Arizona has adequate laws to protect the existing water rights of the Salt River Valley Water Users' Association, but practically the entire State supported the Association's protest and the Federal Power Commission, wishing to avoid putting the Association to the expense of a lawsuit, decided to

attempt to adjudicate the question itself, and, therefore, inserted in the Baum permit the following conditions:

"For the purpose of safeguarding the interests of the United States and the Salt River Valley Water Users' Association, the permittee shall, prior to the issue of a license, amend the notices of appropriation of the waters of the tributaries of Salt River so as to eliminate therefrom all reference to appropriations for irrigation purposes, and the license, if issued, shall contain a condition that the licensee shall not use said waters for the purposes of irrigating lands, and that the licensee shall:

"1. Permit the total normal flow of Black River to pass continuously through the power plant or through by-passes at the power plant, except when the flow of Salt River at the diversion dam at the head of the Roosevelt Power Canal of the Salt River project is greater than 250 cu. ft. per sec.

"2. Return all waters diverted or stored for any purpose to the natural channel of Black River immediately below the power plant.

"3. Replace to the satisfaction of the Commission any net loss of water to the Salt River Valley Water Users' Association caused by evaporation from the storage reservoirs and other project works of the licensee by an equal amount of water for the use of said Association or by compensation for such loss in an amount approved by the Commission. Provided that, if satisfactory settlement be made between the permittee and said Association during the period of the permit, this provision will be omitted from the license or modified as required by such settlement."

Mr. Baum was unwilling to accept the conditions in Section 3, and asked reconsideration. Before anything was done, Mr. Dell M. Potter, of Clifton, Ariz., who had protested Mr. Baum's water rights, won a suit establishing his own water rights. Mr. Baum did not contest Mr. Potter's claim and the Federal Power Commission thereupon decided to rescind its authorization of Mr. Baum's permit and to reject his application.

The present demand for power in the head-water region of the Salt River probably does not justify development, but some day it will. The claims of the Salt River Valley Water Users' Association appear to be exaggerated, but the Association has indicated quite clearly that it will not willingly permit anybody to go in on the drainage area above it.

The Salt River project is one of the most successful of the Reclamation projects, and it should be and is fully protected. On the other hand, it should not be permitted to prevent any development in the 6 000 sq. miles of country above it which can be made without infringing upon its rights.

Although this case presents an example of conflict between power development and irrigation, the Salt River Valley Water Users' Association is demonstrating on the same stream the benefits that can be derived by co-ordinating irrigation and power. The Association is developing power itself wherever such development is practicable in its district, and the returns from the sale of power are contributing materially toward paying the cost of irrigation.

These cases illustrate fairly well the problems of the Federal Power Commission on the subject of co-ordinating irrigation and power. The function

of the Commission in this respect is prescribed by Section 10 (*a*) of the Federal Water Power Act, which reads as follows:

"That the project adopted, including the maps, plans, and specifications, shall be such as in the judgment of the Commission will be best adapted to a comprehensive scheme of improvement and utilization for the purposes of navigation, of water-power development, and of other beneficial public uses; and if necessary in order to secure such scheme the commission shall have authority to require the modification of any project and of the plans and specifications of the project works before approval."

This function has been regarded by the Commission as one of the most important with which it is charged.

DISCUSSION

J. D. GALLOWAY,* M. AM. SOC. C. E. (by letter).—This paper is a comprehensive and general review of the irrigation and power problems that exist on most rivers of the Western States. The diversity of the problems is illustrated by the contrast between physical conditions that exist on different rivers. In one case, as in the streams of the Sierra Nevadas, all power development is on the mountain section of the river and practically all irrigation on the broad plains below. In another case, such as the Deschutes River, or in the Green River Valley, all irrigation is above and the power development below. However, some general principles are applicable to all situations and it is of interest to discuss, in some detail, a few of the points mentioned in the paper.

The writer believes that too much emphasis has been placed on the apparent conflict between power and irrigation. This idea has been fostered by demagogues and politicians. The underlying cause has not been so much an inherent difference between the two uses of water as it has been that irrigation development, at least in recent years, has become a public function, while power development has been made by private corporations. Ever since the beginning of the hydro-electric industry, it has been the target for all forms of State and National regulation and restriction, beyond that of any other industry with the possible exception of the railroads. No real difference exists between the two agencies. Both are made up of groups of individuals organized under the laws of the State to perform certain necessary functions. It will be admitted that, as a matter of necessity, the production of food is more important than the generation of energy, but in any ordinary community, or in the United States as a whole, there is ample food, and all communities require power.

Under this conception, it is as important to develop power as it is to provide irrigation as a factor in the cycle of food production. Both are required in any community and it is a false principle to favor one as against the other, merely because of a difference in type of organization. The situation in Green River Basin, Wyoming, illustrates this point. When the Utah Power and Light Company applied for a license to develop power at the Flaming Gorge site, it is to be presumed that additional power was required in the territory served by the Company. Yet Restriction *B* of the preliminary permit, as given by the author (page 1460), was practically a prohibition against building the power plant. No capital, private or public, should ever be put into power development for which the water supply may be progressively reduced by irrigation until the stream is nearly dried up. It would seem that under such conditions a balance should be established between the power requirements and those for irrigation, as both are necessary to a community. This point becomes self-evident when, as in many cases, much power is used for irrigation pumping or for drainage. To prohibit power development, as in the case cited, is to injure irrigation. It is to be hoped that some day the American people will become sane on this subject and repeal laws that definitely place any

* Cons. Engr., San Francisco, Calif.

irrigation project, no matter how dubious its merits, above a very necessary power development.

In most cases there is no conflict between irrigation and power; both are mutually beneficial. The writer has already set forth this view at length.* Herewith, is reproduced Fig. 17,† a hydrograph of a stream on which is superimposed an irrigation demand curve and a power demand curve. This form is applicable to most rivers where power is developed in the mountains and irrigation on the plains below. To the extent that reservoirs for power are installed, there is assistance to irrigation during the irrigation season of any one year. In addition, if there is an irrigation reservoir on the lower reaches of the stream, water discharged from power system reservoirs in the period after the irrigation season is caught by the irrigation reservoir and retained for the next year's irrigation. The regulation of the stream over more than one year is thus accomplished. Where, as in California, the annual variation in total discharge may range from minimum to maximum in the ratio of 1 : 4 or 1 : 5, the regulation of the stream over more than one year is of especial benefit to irrigation in years of deficient discharge.

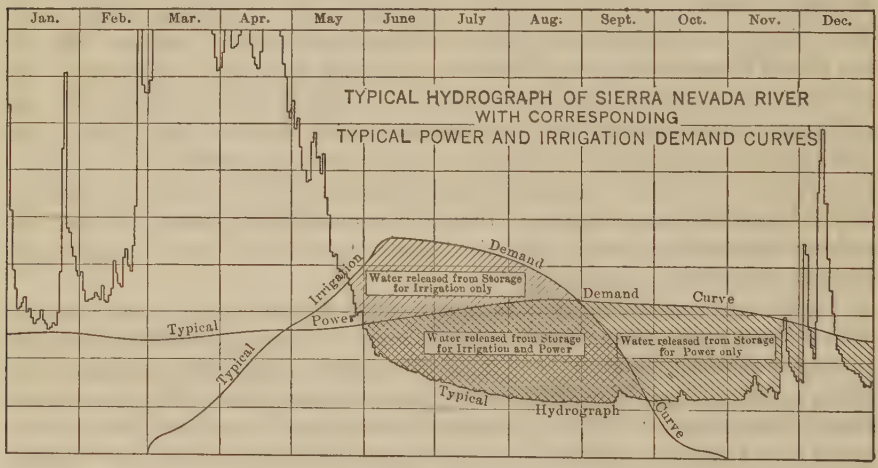

FIG. 17.

This solution is not so simple in cases such as in the Green River Valley or on the Deschutes River, where the irrigated lands lie above the power development. Here, a compromise such as that just suggested is necessary. It is aided by the fact that proper irrigation would have some reservoirs above the irrigated region and, to the extent that water was returned to the stream either by seepage or drainage, the power project would benefit. Such examples are rather unusual, and in the case of the Deschutes the natural regulation of the stream by the lava formation counteracts to a great extent the effects of irrigation diversions on the flow. All power developments on that stream will be by low-head plants. The power demand curve in the Portland, Ore., region

* "Hydro-Electric Developments on the Pacific Coast," *Transaction*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 803, and *Journal of Electricity*, May 15, 1924.

† *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 814, Fig. 25.

is fairly uniform throughout the year, and as a result of these two factors the power plants will generally be limited in size by the stream flow during the low-water season. The winter excess flow can be stored in the numerous irrigation reservoirs, and this, in time, will act to increase the low-water discharge.

It is true, as mentioned by the author, that in some cases, as on Kings River, California, there is so much irrigation that, in many years, all the flood flow is taken by irrigation ditches with varying priority to the water. Even in such an extreme case, the construction of the Pine Flat Reservoir would make more certain the water supply for all irrigation ditches and would also make possible the development of power on the upper reaches of the river.

The statement by the author that the power demand throughout the year is fairly constant, is only partly correct. On the Pacific Coast there is a wide variation in the type of annual load curve. In rainy regions, such as at Portland, Ore., or at Vancouver, B. C., Canada, the annual peak and mass of maximum demand is in the winter. In California, the reverse is true. In the northern part of the State the power demand is fairly uniform throughout the year, with the peak in the summer. In Central and Southern California the mass of energy is used in summer, the peak load occurs in June or July, and cases exist where the July demand is twice that of February. This is caused by the large irrigation and drainage load and the industries that are of the seasonal agricultural character.

A further correlation between power and irrigation lies in the need of power for drainage pumping. The writer believes that in many, if not most, cases, the drainage of low-lying lands in an irrigation region must be done by pumping, as open ditches are, in most cases, a failure for obvious reasons. They cannot be dug deep enough to produce the hydraulic gradient required to cause the water to run into them.

Many of the projects for irrigation in the West cannot be justified on account of cost and physical conditions. Irrigation has reached its most extensive development in California. On account of the climate, many of the products are of the character that could be termed luxuries—oranges, figs, raisins, and other fruits. These crops bring high prices, but, as a rule, general irrigation in California that costs more than $75 per acre, capital cost, will not pay. It is difficult to see how irrigation can pay in such regions as on the Upper Deschutes, or in the Green River Valley, where killing frosts occur in eight or ten months of the year. Crops are automatically limited to forage, grains, and hardy fruits. It would not seem that the proposed irrigation on the Columbia River at costs mentioned by the author could ever be justified on a financial basis. It must be remembered that such lands, producing wheat and similar crops, must compete with other lands, not only in America but in other countries, where there is no irrigation cost. The failure of the Reclamation projects to pay or to be settled is primarily due to the fact that with the burden of the costs of the irrigation systems the farmers could not compete with more favored regions.

Mention is made of this phase of the subject because it has a bearing on the rulings of the Federal Power Commission. The power exercised by the

Commission arises from the ownership of public lands by the Federal Government. It is conceded that water is in the control of the States. It is believed that there is too great a tendency on the part of the Commission to extend its rule into realms not justified by the divided ownership of the land and the water. The writer is not familiar with the Green River Valley in Wyoming mentioned by the author, but on the statements as made it would seem to be a wide extension of the Commission's powers to prohibit practically a present power development because at some future time there might be an irrigation development of an uncertain extent, either by the State or by individuals. The Commission might have given a license to use public lands and have allowed the State of Wyoming to adjust the use of water as between power and irrigation, that being the function of the State which owns or controls the water, the vital element in both cases.

The problems arising from the dual use of water are complex and grow more so. If treated without prejudice as to either, it can generally be found that power and irrigation are mutually interdependent and in most cases can be made to work together. Colonel Kelly is to be congratulated in having presented a paper in which the most important problems of a wide region are set forth in a clear and comprehensive manner.

Fred. H. Tibbetts,* M. Am. Soc. C. E. (by letter).—This paper is of great and timely interest in developing the viewpoint of the engineers of the Federal Power Commission regarding the principles of co-ordination of irrigation and power. However, the author's statements regarding the superiority of the use of water for irrigation and particularly his statement that this well-established principle in the Western States "sets aside the laws of economics" is but a reluctant and half-hearted admission of the limitations under which the engineers of the Federal Power Commission must of necessity work when irrigation and power interests are in conflict.

Of the total estimated installed horse-power covered by licenses of the Federal Power Commission outstanding as of June 30, 1924, 47% was included in projects lying within the State of California. The somewhat different viewpoint of the State of California has already been reported to the Society† by Everett N. Bryan, Assoc. M. Am. Soc. C. E., whose position as Office Engineer of the Division of Water Rights of the Department of Public Works of the State of California, closely corresponds to that formerly held by Colonel Kelly with the Federal Power Commission. The very title of Mr. Bryan's paper, "Hydro-Electric Power as a By-Product of Agricultural Storage", epitomizes the great difference in the two viewpoints. Power has no rights in California when in conflict with irrigation or with the domestic use of water. The author refers to the well-established principle in Western States that the use of water for irrigation is superior to any other except domestic use, and states that to a considerable extent it sets aside the laws of economics. In the writer's opinion this is a superficial viewpoint.

Empire building in an arid section is dependent wholly on the use of water for irrigation. Four thousand years ago the greatest civilizations of antiquity

* Civ. Engr., San Francisco, Calif.

† *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 910.

were built in arid regions and as soon as they ceased to use water for irrigation, the countryside became a desert and the cities uninhabited heaps of ruins.

The ultimate development of the arid West and the extent of the development of its population, its cities, and its industries, depend wholly on the number of acre-feet of water that it devotes to agricultural production. If the State of California allowed 100 acre-ft. of water to run into the ocean each year unused for agricultural production, there would ultimately be one less family tilling the soil and two less families in the cities.

In California, this principle is a fundamental feature of the organic law, having been embodied in a forceful declaration of policy by enactment of the Legislature, confirmed by popular vote. The Water Commission Act approved by a referendum vote of the people on November 3, 1914, and as amended since then, contains the following statement:

"It is hereby declared to be the established policy of this State that the use of water for domestic purposes is the highest use of water and that the next highest use is for irrigation. In acting upon applications to appropriate water the Commission shall be guided by the above declaration of policy."

The policy so emphatically stated has been continuously observed by the State authority having jurisdiction over the distribution of the State's water resources and has been supported on all occasions for ten years by the State Department of Engineering and Irrigation.

The trend of development of the State's water resources in accordance with this policy is indicated in Mr. Bryan's paper, in which he described several new agricultural developments in California where power is to be produced in connection with storage works created primarily for irrigation supply. Reservoir releases are to be regulated entirely in accordance with irrigation requirements. Such power as is produced, although of great importance and value, will be merely incidental to the main purpose.

It is the writer's belief that the intent as well as the letter of the Act by which Congress organized the Federal Power Commission, makes it mandatory upon the Commission to incorporate in its permits the same policy. Section 9 (*b*) of the Water Power Act reads as follows:

"That each applicant for a license hereunder shall submit to the Commission * * * satisfactory evidence that the applicant has complied with the requirements of the laws of the State or States within which the proposed project is to be located with respect to bed and banks and to the appropriation, diversion, and use of water for power purposes and with respect to the right to engage in the business of developing, transmitting, and distributing power, and in any other business necessary to effect the purposes of a license under this Act."

Practically all the important new irrigation developments in California are by irrigation districts which are municipally organized as State agencies and hence it is also important to note that Section 7 of the Federal Power Commission Act states:

"That in issuing preliminary permits hereunder or licenses where no preliminary permit has been issued and in issuing licenses to new licensees under Section 15 hereof the Commission shall give preference to applications therefor by States and municipalities * * *."

Finally, Section 27 of the Federal Power Commission Act states:

"That nothing herein contained shall be construed as affecting or intending to affect or in any way to interfere with the laws of the respective States relating to the control, appropriation, use or distribution of water used in irrigation or for municipal or other uses, or any vested right acquired therein."

Under these provisions of the Federal Power Act and of the Water Commission Act of the State of California, the writer can see no possible interpretation of the laws other than a mandatory direction to the Federal Power Commission to adopt the State's policy of irrigation superiority and, when irrigation and power applications are in conflict, especially irrigation applications by the State or political subdivision thereof, to cease attempts to determine relative values of kilowatt-hours and acres of irrigated or arid land. The apparent intention of the Federal Power Commission to act only in cooperation with the State authorities has been further assured by the Commission* as follows:

"The development of water power on the lands of the United States requires the approval of both the State and Federal Governments, the former granting the right to use the water, the latter the right to use the land. Under the Federal Water Power Act a license may not be issued until an applicant has secured its water rights from the appropriate State authority. Under such circumstances it is apparent that development can proceed only when the State and the Federal Governments take corresponding action."

The second and principal part of the author's paper is a series of examples of action taken by the Commission on various streams, three of which are California streams. It is of chief interest to the writer because of the conspicuous absence of the Yuba River on which is the most important example of conflicting irrigation and power interests and with regard to which the Executive Secretary of the Federal Power Commission on June 6, 1925, stated his purpose to recommend the rejection of the irrigation applications in favor of the power applications. This recommendation, in the writer's opinion, is in complete violation of all the principles stated in the first part of the paper and this, quoting the words† of Arthur P. Davis, Past-President, Am. Soc. C. E., regarding the Colorado River, "in the face of the mandatory provision of the law that the Commission shall give preference to applications from municipalities" and in "defiance of law" (Federal Power Commission Act).

In the three examples of California streams discussed by the author the Trinity and American Rivers were thoroughly investigated by a Special Board which included a representative of the State Department of Engineering and Irrigation and which, therefore, embodied in its findings the State's irrigation policy. In the third case, the Kings River, action was postponed until such time as the applicant had complied with the requirements of the laws of the State of California with respect to appropriation, diversion, and storage of water. In all three cases, the action of the Commission was in thorough accord with the adopted policy of the State.

The strategic position of the Yuba River makes it one of the most important streams in California. It is in a region of the heaviest precipitation in

* Fourth Annual Rept., Federal Power Comm., 1924, p. 10.

† *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 393.

the Sierra Nevada Mountains (in the central part of the State), is near the main centers of urban and manufacturing development, and lies opposite large bodies of the best, and as yet undeveloped, agricultural land in the State. It has excellent reservoir sites so high up in the mountains as to be particularly valuable for power development. It was the scene of the spectacular fight fifty years ago by which the agricultural interests of California in the Supreme Court of the United States checked hydraulic mining, the then leading industry in the State; and for the past four years it has been the battle ground of an exceedingly bitter fight between power and agricultural interests. The power and mining interests were represented by the Excelsior Water and Mining Company and by the Yuba River Power Company, the latter in particular a strongly organized and well conceived project for developing in a comprehensive way a water-shed of about 1 200 sq. miles, with applications before the Federal Power Commission for the development of 227 000 h.p. The agricultural interests were represented by the Nevada Irrigation District municipally organized under the laws of the State of California and proposing to irrigate about 150 000 acres of foothill lands lying, in the main, between elevations of 1 000 and 3 000 ft.

The Irrigation District by co-operation with the Pacific Gas and Electric Company, the largest going concern in Central California, proposes to develop as much of the power resources of the river as it is able and still deliver the water at the relatively high elevation at which its lands are situated. Obviously, it will get less kilowatt-hours per acre-foot of water stored at the head of the Yuba River watershed than the Power Company, whose point of delivery is below the District's lands. This latter project is mentioned in Mr. Bryan's paper,* where the irrigation features, if any, of the Yuba River Power Company are referred to as a by-product of power, as follows:

"They [referring to by-product power plants] are even distinctly different from such composite developments as the project of the Yuba River Power Company on the Yuba River, where irrigation, mining, and power are to benefit jointly, and in which case if the benefit to either enterprise may be considered a by-product, it is the benefit from stored water delivered for irrigation."

The conflict centers particularly around the Jackson Meadows Reservoir site on the Middle Yuba River at an elevation of 5 800 ft., tributary to which there is an average run-off of 146 300 acre-ft. To the Yuba River Power Company this storage site is of even greater advantage than its water yield would indicate because of its high elevation and its efficiency in regulating the run-off from the lower part of the water-shed. The Irrigation District claims that without this water-shed, from which it derives more than one-half its mountain water supply, it can never obtain sufficient water to irrigate its lands.

The Irrigation District has already contracted with the Pacific Gas and Electric Company for the sale of its power potentialities in a contract (approved by the State Railroad Commission of California and by the Irrigation District Bond Certification Commission) by means of which it will

* *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 911.

derive a revenue of about $400 000 per year. This contract and this revenue are dependent chiefly on the Jackson Meadows waters in conflict and the District is economically unfeasible and cannot even begin development without these waters. The Power Company on the other hand, while demonstrating that the waters in conflict would be of disproportionately great value to its project, has repeatedly admitted that they were not absolutely essential.

All these facts are matters of record during four years of hearings, largely joint hearings between the State Division of Water Rights and the Federal Power Commission. As the result of these hearings and after the most thorough investigation, the State Division of Water Rights on May 19, 1925, granted the waters in contest to the Irrigation District, confidently assuming that the Federal Power Commission, as by law required, would immediately follow suit.

The District has voted bonds to the extent of $7 250 000 for the construction of its works; its financial soundness is insured by its contract for the disposal of its power resources; its economic feasibility and necessity have been testified by formal resolution of the State Bond Certification Commission; and it was actually ready to proceed when it received on June 6, 1925, the most astonishing news that the Executive Secretary of the Federal Power Commission proposed to recommend the rejection of its application for storage reservoir sites or diversion from the Middle Yuba of waters which had already been granted it by the State of California.

The writer believes that the principles involved in this conflict of Federal and State authority are of vastly more far-reaching importance than either of the two other projects to members of the Society, to the State of California, and to the Nation. Governmental developments within the last twenty years have taken the form of steadily multiplying officials and commissions with overlapping authority. A National Cabinet officer, Herbert Hoover, Hon. M. Am. Soc. C. E., has probably foreseen more clearly than any one else the fateful results of this tendency if it is allowed to proceed unchecked. He is also one of the few men in politics big enough to recommend decreasing the authority of his own Department. In recent speeches on the Pacific Coast he has come out as strongly opposed to further Federal regulatory authority and has stated that the greatest need at Washington is to decentralize the National Government and to pass back into the hands of the people the responsibilities which have been gradually taken from them. The impassé which has been so long foreseen and dreaded by students of this tendency may have at last arrived in California. The Nevada Irrigation District, a political subdivision and an executive agency of the sovereign State of California, the rights of which to its water resources have never been questioned, has been awarded a portion of those public resources by State authority and the Federal Power Commission is denying that State agency the use of Government lands. Unless this conflict can be quickly resolved, the Federal Power Commission will have lost its usefulness and the development of important resources, at least in California, will be threatened with the same stagnation that existed prior to the formation of the Power Commission.

BARRY DIBBLE,* M. AM. SOC. C. E.—No argument is required to establish that agriculture is the basic industry of civilization. Before the beginnings of history, the density of population in some areas had become so great that men could not depend on wild supplies of food. The earliest civilizations that have left any record were founded on cultivation of food crops. In Mesopotamia, the staples were wheat, oats, and barley; in China, rice; in Mexico, Indian corn and maize; in Peru, the potato. It is noteworthy that much of this primitive agriculture was under irrigation.

It is in no sense a disparagement of present-day accomplishments in engineering and industry to class most modern devices as luxuries. If all electrical devices were destroyed to-morrow, mankind would continue to live and function and soon adapt itself to the changed conditions as it did before it had electricity at its service. Strange as it may be, people are willing to and do pay greater rewards to the producer of luxuries than to the producer of necessities. The more nearly a product or a service becomes a necessity, the more critical they are of its price and the profits.

So it is that the farmer thinks he has been overlooked in the distribution of prosperity; so it is that should food prices rise, tariffs will be removed or the farmer's profits in some way brought down; so it is that hydro-electric power development has proved more profitable than irrigation farming.

Nor should it be overlooked that food production in the back country has much to do with the growth of manufacturing industries and centers of population. The electric business feeds on the centers and the centers feed on agriculture. Perhaps it is a law of compensation that justifies Western agriculture in collecting some toll when irrigation water is used for power production.

Many irrigation projects in their development and growth present favorable opportunities for power production—often as a by-product. Usually, the water users are alive to the possibilities and if a market is available the question presents itself whether the power house should be constructed by the project or whether the power rights should be sold to a power company. In some cases, most or all of the power can be efficiently used for irrigation pumping on the project land. Generally, however, the power must be sold and the price at which it can be sold governs the feasibility of the power development. The primary objective of the water users is then to obtain the greatest net revenue without interfering with the application of water to irrigation.

If the irrigation district sells its power rights, its investment is reduced and the financial risk correspondingly lessened; the district is kept out of the power business, with its more or less technical requirements. On the other hand, the purchaser of power rights expects to make a profit and will discount the risks and uncertainties of the future as far as he can see them. Such an arrangement must be based on the contract in which the rights of both parties are set forth. The district will try to protect the water rights of the irrigationists; the power company will try to obtain a free hand to use water when most needed, for power purposes.

* Cons. Engr., Redlands, Calif.

Cycles of wet and dry years, changing conditions in irrigation and power demands, may give important and unanticipated economic advantage to one or the other of the parties. The power production may either be far greater than expected or the power company may find itself paying for something it does not get.

Bitterness and jealousies between the contracting organizations are likely to be aroused, and the contract will probably find its way into the Courts. If the power house is built and operated by the water users and the energy sold on a production basis, they immediately become interested in securing the largest and most saleable output from the water available. When the pinch comes, in years of drought, they will be far more ready to co-operate to get the best results than if they receive no benefit. It is much easier to draft a contract that will prove satisfactory, when the interests of the parties run along parallel lines.

The modern hydro-electric station, properly designed and installed, is not difficult to operate efficiently and satisfactorily. Often, the irrigation district can handle the plant with an organization not much different from that which would be required to care for the irrigation work alone. The hydro-electric construction involves the irrigation district in larger investment and in certain risks of the business. However, the district is in better position than any one else, to use the investment to the best advantage. The risks must be taken by some one. If the right to develop power is sold, they come back to the district by lowering the consideration paid for those rights.

The Minidoka Project, in Idaho, and the Salt River Project, in Arizona, are examples of the better co-ordination that can be secured between power and irrigation, when the power is owned and generated by the irrigation interests. In each instance, the use of structures and regulation of flow have been materially modified to meet the needs for power, and to increase the revenue. Irrigation has not suffered and yet it is certain that the water users would bitterly have fought the proposal that some outside company be allowed to do the things they have done.

Generally, the best results from both economic and other standpoints will be secured where the ultimate water users themselves are directly interested in seeing the water put to the fullest beneficial use.

Markham Cheever,* Esq.—It is eminently fitting that a discussion of this paper should take place in Utah where pioneer work has been done both in irrigation and in the generation and distribution of hydro-electric energy, and where both uses of water have been co-ordinated to such a great extent as to provide a high degree of beneficial utilization of the water resources.

The early settlers in Utah were the first in the United States to practice irrigation on an extensive scale and the general condition of prosperity throughout the irrigated areas is evidence of the economic soundness with which the projects were conceived. Likewise, much valuable pioneer work in the development of hydro-electric energy from water power was done in Utah. Approximately thirty years ago construction was commenced on hydro-electric

* Gen. Supt. and Chf. Engr., Utah Power & Light Co., Salt Lake City, Utah.

plants in Provo, Ogden, and Big Cottonwood Canyons, and, in 1897, the first commercial transmission line in the country to operate at so high a voltage as 40 000 was placed in service to distribute energy from the Provo Canyon plant. Since that time, the development of water power has been on a substantial scale and an adequate supply of hydro-electric energy has been made available over wide areas for lighting cities and towns, operating irrigation pumping plants, and developing industries. It is especially interesting to note that electrical service has been made available to a larger proportion of the farms in Utah than in any other State. According to the census of 1920, which represents the latest authoritative source of information, Utah was at the head of the list with more than 34% of the farms receiving electrical service as against 7% representing the average for the whole United States.

There is in the vicinity of Salt Lake City a striking example of successful co-ordination between irrigation and power development. Bear River is the largest stream flowing into Great Salt Lake. It rises on the northerly slope of the Uintah Mountains, in Northeastern Utah, flows northward through Wyoming, enters Southeastern Idaho, and after making a turn around the northerly end of the Bear River Range flows southward into Utah and discharges into Great Salt Lake. In Southeastern Idaho it flows near, but not through, Bear Lake, a body of water having an area of 110 sq. miles. By means of canals and other extensive diversion and control works, including a pumping plant, the lake has been converted into a reservoir of capacity adequate to equalize completely the flow of the river below that point, not only during any one year, but also throughout a long series of years.

The total fall between Bear Lake and Great Salt Lake in a distance by river of approximately 200 miles is 1 720 ft. The river flows alternately through open valleys and canyon sections. The valleys are irrigated and in the canyons it has been possible to utilize for power development a substantial part of the total fall in the stream. The use of Bear Lake Reservoir has enabled the production of a large amount of firm power, and at the same time all irrigation requirements in the river basin have been met. During the exceptionally dry year of 1919 full crops were raised in the Bear River Basin, and it was estimated by a representative of the United States Department of Agriculture that in that year the value of crops saved by the release of stored water from Bear Lake amounted to between $4 000 000 and $5 000 000.

Although the vital importance of irrigation to the arid States is unquestioned, the value of an adequate and reliable supply of electrical energy must not be overlooked. In addition to the obvious advantageous use of electricity for pumping irrigation water, the widespread availability of electrical service from large interconnected systems has stimulated industries which depend on agriculture and which, in turn, create a market for farm products. Electrical energy has revolutionized industrial processes, has assisted greatly in conserving labor and has produced domestic conveniences which have now become necessities. New and enlarged uses for energy are constantly arising, and it is inevitable that the electric power industry will become of increasingly great importance in the economic development of the United States.

Difficulties in co-ordinating irrigation and power projects are in many cases imaginary rather than real. Misunderstandings arise because of lack of reliable and adequate data, or because of failure to analyze the information correctly. If, in each case, the full facts are made available and are viewed disinterestedly from the standpoint of economic practicability of the projects involved and of best results in the general development of the territory served, the solution of the problem of co-ordination will not be difficult. It should be remembered, however, that no two situations are alike in either physical or economic characteristics and no general formula can be previsioned and thereafter applied to all future problems of co-ordination if the greatest beneficial results are to be obtained from developing the water resources for both important uses.

M. C. HINDERLIDER,* M. AM. SOC. C. E.—The subject of co-operation in irrigation and power development is not of prime importance to Colorado at this time and this is largely true of the States in the Rocky Mountain region, due primarily to three factors:

First.—The wide monthly and yearly fluctuations in run-off in the streams of the Rocky Mountain region would require the use of extensive storage systems for the proper regulation of flow to meet the demands of power development or to justify expenditures for such purposes on an economical scale.

Second.—Although an extensive system of storage reservoirs with an aggregate capacity of 2 400 000 acre-ft. is in use in Colorado, such reservoirs are utilized almost wholly for irrigation and cannot be converted to power use without secondary storage which, under present conditions, would not be economically feasible.

Owing to the necessities of irrigation which is of paramount importance in the semi-arid States, stream run-off over periods of many months must be stored and held in reserve against the demands occurring later in the summer, which demands usually cover only two or three months.

Additional difficulties arise over the system of laws and administration wherein priority of claim for irrigation use must be observed regardless of where such claims occur on a stream. The time is anticipated, however, when through proper legislation present priority requirements for irrigation uses will be so modified as to remove some of the obstacles now faced by the promoter of hydro-developments.

Third.—Such developments are not more extensive in the Rocky Mountain region (1) because of the great deposits of cheap coal which are found throughout this part of the United States; and (2) because of the attendant cost of transmission over sparsely settled areas. In Colorado, for the present at least, investigations have shown that power may be supplied more economically by means of steam-generating plants than from available water power sources.

These conditions will doubtless be modified with the passing of time, when due to greatly increased density of population and to attendant demands, together with reduced cost of transmission, hydro-power possibilities, aggregat-

* State Engr. of Colorado, Denver, Colo.

ing several million horse-power, will be utilized through proper legislative provisions, permitting of a high state of co-ordination and co-operation between the dominant irrigation interests and power possibilities. Such co-ordination must of necessity come about rather slowly in order that existing corporate and individual rights may not be unduly disturbed in the process of giving way to the greater demands of the public.

C. S. Jarvis,* M. Am. Soc. C. E. (by letter).—The record of the Federal Power Commission's rulings as reported by the author goes far to prove both the need for such an authority and the benefits that have already accrued under its administration.

When irrigation and power interests are in opposition, only a non-partisan, deliberate, and independent estimate of the whole situation will lead to an equitable adjustment. It appears that many cases of litigation have been avoided by the intensive analysis of each problem with a view not only to the recognition of initiated or vested rights, but also to the ultimate beneficial use under other projects barely conceived and not yet launched.

Experience indicates that the general policy should be to promote projects for stream regulation and diversion on the head-waters concurrently with plans for similar enterprises in the intermediate and lower valleys. In no other way can there be utilized (*a*) the maximum head for hydro-electric power plants; (*b*) the maximum irrigable acreage and variety of products; (*c*) the maximum underground storage with return seepage increasing the natural flow—an important factor during years of drought; and (*d*) the full measure of potential benefits.

An excellent example of co-ordinated power and irrigation development is furnished by the Salt River Project, in Arizona. Formerly, the power plants at the Roosevelt Dam could not be operated during the non-irrigation season, because the discharge from the turbines was lost to the system. This situation has been relieved by the supplemental storage provided between the Roosevelt Dam and the intake of the main irrigation canals. This immediately replaced the intermittent power generation with constant, dependable service, brought the canal and reservoir systems into more intimate relation so that the flow at the head-gates could be varied on a few hours' notice, and made possible additional power developments nearer the place of use. As a considerable part of the demand is for pumping during the irrigation season, there is a special value in the secondary power at the lower sites.

Such a favorable solution is readily attainable where both power and irrigation interests are under the same ownership. Progress toward harmonizing the control of streams has resulted from the attitude of the Federal Power Commission to the effect that, in the last analysis, the welfare of the citizenry in each drainage basin should govern the development of water resources. This seems to be the spirit and intent of the Federal Water Power Act. Wisely administered, it should provide the unified control so essential to thorough co-ordination of power and irrigation interests, and should promote the normal activities which make for sound industrial growth.

* Care, U. S. Bureau of Pubic Roads, Washington, D. C.

WILLIAM KELLY,* M. AM. SOC. C. E. (by letter).—A few closing remarks seem to be called for by Mr. Tibbetts' discussion. The Yuba River was not mentioned in the paper because no final action had been taken on it by the Federal Power Commission at that time and, therefore, it could not be cited as an example. The Federal Power Commission has since granted the application of the Nevada Irrigation District in which Mr. Tibbetts is interested.

The District lies in the foothills of Nevada County, California. It contains about 200 000 acres, of which, according to the State Engineer's estimate, not more than 75 000 acres are suitable for irrigation. About 3 000 acres are now under irrigated cultivation. The principal industries in Nevada County up to the present have been gold mining and cattle grazing. The greater part of the land proposed for irrigation is covered with a growth of timber and brush and it is conservatively estimated that the average cost of clearing will be as much as $100 per acre. The irrigable lands are scattered over the district so that to supply them with water will require practically the same length of ditch as if the entire 200 000 acres were to be irrigated. The project could be developed to the extent of about 15 000 acres by the construction of the Scotts Flat Reservoir in Deer Creek Valley, using the run-off of the water-shed within which the District lies.

For greater development, water must be diverted from adjacent water-sheds. The project which has been approved contemplates the development of storage on the head-waters of the Middle and South Forks of the Yuba and its diversion by tunnel and conduit into Bear River and a part thence to Deer Creek.

The Pacific Gas and Electric Company has entered into a contract with the District to take the diverted water for use in existing and proposed power plants and finally to release it near the boundary of the Nevada Irrigation District. The schedule governing the release is based mainly on the power values and, therefore, only about 36% of the water supply will be delivered for use during the irrigation season. The contract is a good one for the Power Company, and the promoters of the Nevada District claim that returns from the power use of the water will pay all carrying charges on the investment required for the storage and diversion works. In other words, if the estimates are not exceeded, the District will get a small initial water supply, adequate for about 20 000 acres, at its boundaries practically without cost, except for the maintenance and operation of the mountain works. It should be noted, however, that the property owners of the District and not the Power Company assume all the risks.

Mr. Tibbetts' criticism that the engineers of the Federal Power Commission were balancing kilowatt-hours against acres is hardly justifiable. The question is not one of balancing kilowatt-hours against acres, but of balancing a possible but doubtful 75 000 acres in the Nevada District, plus a certain amount of power, against a greater irrigable acreage in the Sacramento Valley, plus about 40 000 kw. more power, plus incidental benefits to

* Col., Corps of Engrs., U. S. A.; Director of Eng., National Electric Light Assoc., New York, N. Y.

flood protection on the Yuba, Feather, and Sacramento Rivers, plus the possibility of renewing hydraulic mining on the Yuba where it is estimated that more than $50 000 000 of gold lies still unmined.

In other words, using the water from the head-waters of the Yuba in its own water-shed would increase and not decrease the acreage of land economically irrigable in California. Moreover, diversion of water from the Bowman water-shed, combined with the development of local sources, would supply all the lands that are probably irrigable in the Nevada District and leave the water of the Middle Fork to be developed in combination with the remainder of the Yuba River. It was the diversion of water from the Middle Fork to the Nevada District to which the engineers of the Federal Power Commission particularly objected.

Again Mr. Tibbetts is not correct when he attempts to point out a great difference in viewpoint between Everett N. Bryan, M. Am. Soc. C. E., and the writer. In his paper, "Hydro-Electric Power as a By-Product of Agricultural Storage,"* Mr. Bryan deals only with foothill reservoirs similar to the proposed Pine Flats Reservoir on the Kings River, described by the writer. Power at such reservoirs is and should be purely incidental to irrigation, but one of the important functions of such reservoirs is that they leave the river above them free to be developed primarily for power. Such reservoirs, when properly combined with head-water storage, accomplish the maximum use of water for both power and irrigation.

Investigation of the Nevada Irrigation District, in its relation to the Yuba River, was made jointly by engineers of the State and of the Federal Power Commission. There was no material difference of opinion between them as to physical facts or economics. The State engineers, however, operate under State laws which grant rights on the basis of priority of filing, and they could give but little regard to the broad economics of the problem, whereas the engineers of the Federal Power Commission are charged with determining whether or not any project applied for makes the fullest possible use of the water for all purposes.

In granting the Nevada District application, the Federal Power Commission certainly has demonstrated its intention to co-operate with the States to the fullest extent possible in administering the Federal Water Power Act. The Nevada District case illustrates some of the factors which the writer had in mind when he stated that practice in the Western States "sometimes sets aside economic laws". The California law, providing for the organization of Irrigation Districts, has proved itself a good one, but no law has ever been so good that it could not be used in ways not intended.

The Nevada Irrigation District was organized through the efforts of energetic and competent promoters. Its formation was made possible by the votes of many non-property owning individuals. Owners of nearly 50% of the property in the District opposed the mountain development project. The owners of property in the Lower Yuba Valley, who have perhaps a better right than the Nevada District to look to the Yuba River for water, have not

* *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 910.

organized and thus stand to lose their rights. If the Yuba water-shed and the Nevada District combined were being developed by one owner as a business proposition, looking to ultimate results as well as to earning expenses during development, it is inconceivable that the diversion of all the head-waters of the Middle Yuba to Deer Creek Valley would form the initial step.

Mr. Tibbetts' statement that "empire building in an arid section is dependent wholly on the use of water for irrigation", is rather beside the point in the Yuba controversy because, leaving aside all other factors, diversion of the head-waters of the Middle Fork to the Nevada District will result either in less land irrigated than if that water were used in its own water-shed, or in greater cost if water for the Sacramento Valley lands tributary to the Yuba is sought elsewhere.

Such a diversion may result in the gain of a valuable asset by the Nevada Irrigation District, but it will be at the expense of reduced irrigation and power development in the State of California as a whole.

Paper No. 1597

PROGRESS REPORT OF THE SPECIAL COMMITTEE ON STEEL COLUMN RESEARCH*

To the Board of Direction,
American Society of Civil Engineers:

1.—Preliminary Statement.—This Committee was authorized in August, 1923, and held its first meeting in October of that year. At this meeting, it was unanimously agreed that the first work of the Committee should be to make a thorough study of all existing data before undertaking any further tests. It was thought that it would doubtless be desirable to do further experimental work, but plans for any such work should be based on a careful study of all existing data. In order to carry out this program, it was obviously necessary to employ considerable assistance, and it was therefore arranged that M. O. Withey, Professor of Mechanics at the University of Wisconsin, should devote a large part of his time, during the year 1924-25, in assisting the Committee in this work. This plan was carried out, and the material thus brought together has been reviewed by the Committee at three meetings during the current year (1925). In addition to this review of existing data, a few preliminary tests have been made on six columns, with a view to developing the best method of testing the efficiency of lacing and other lateral connections. These tests have been made on the 1 000 000-lb. testing machine at the U. S. Forest Products Laboratory at Madison, Wis., and the University of Wisconsin has contributed to some extent in carrying on this program. These tests were made to assist the Committee in formulating any further program of experimentation. The Committee also desires to acknowledge the interest and financial assistance of Engineering Foundation in its work.

Although the Committee is not prepared to make a final report on its study of existing data, it has carried this work far enough to make it seem desirable to present some of the results in the form of a progress report.

* Presented to the Annual Meeting, January 20, 1926.

2.—Division of the Subject.—In making a thorough study of the strength of structural steel columns, it appears to the Committee that the consideration of the subject may profitably be divided into four fairly distinct parts, as follows:

(A) Strength of relatively short columns $\left(\frac{l}{r} = 30 \text{ to } 100\right)$ of good design as compared to the elastic properties of the metal, as shown by compression and tension specimen tests.

(B) Results of all tests of columns heretofore made where failure was not due to weakness of detail. These results would give information particularly on the effect of slenderness ratio and end conditions.

(C) Effect of various details, form of section, and method of manufacture, on the strength of columns.

(D) A study of the column as a part of a structure, especially with reference to end conditions and relation to columns as tested; column theories; working formulas.

The first part (A) would include the very important questions of the significance of the elastic limit or yield point or the useful limit point of test specimens; relative value and reliability of mill tests; the tension test compared with the compression test; the variation of quality of steel over the cross-section; methods of determining the proper average quality; and, to some extent, the effect of form of section and grade of steel.

The second part (B) attempts to bring together all existing data in convenient form for discussion. Even if additional tests appear to be necessary, it is thought that the Committee's study on existing data should be presented without waiting for further tests.

The third part (C) would include a multitude of questions involved in the general problem of design, such as form of section, lacing, diaphragms, thickness of unsupported lengths and widths, tie-plates, pin-plates, riveting, etc. It should be the aim of this investigation to determine the requirements necessary to produce a column which would act substantially as a unit the strength of which could be estimated closely by a suitable column formula based on integral action.

The fourth part (D) would be more or less theoretical in character, but essential to the consideration of column formulas or factors of safety. The column in the testing machine acts under very different conditions from those which obtain in most structures.

Although a discussion of the various items under these four divisions will necessarily overlap somewhat, it is thought that better progress will be made by subdividing the material in this way.

This report covers Parts (A) and (B) and some items under Part (C).

(A) Relation of Strength of Relatively Short Columns $\left(\frac{l}{r} = 30 \text{ to } 100\right)$ to the Elastic Properties of the Metal

3.—Whatever formula may be used to express column strength, it is agreed that for axially loaded columns of slenderness ratio up to 50 or 60, at

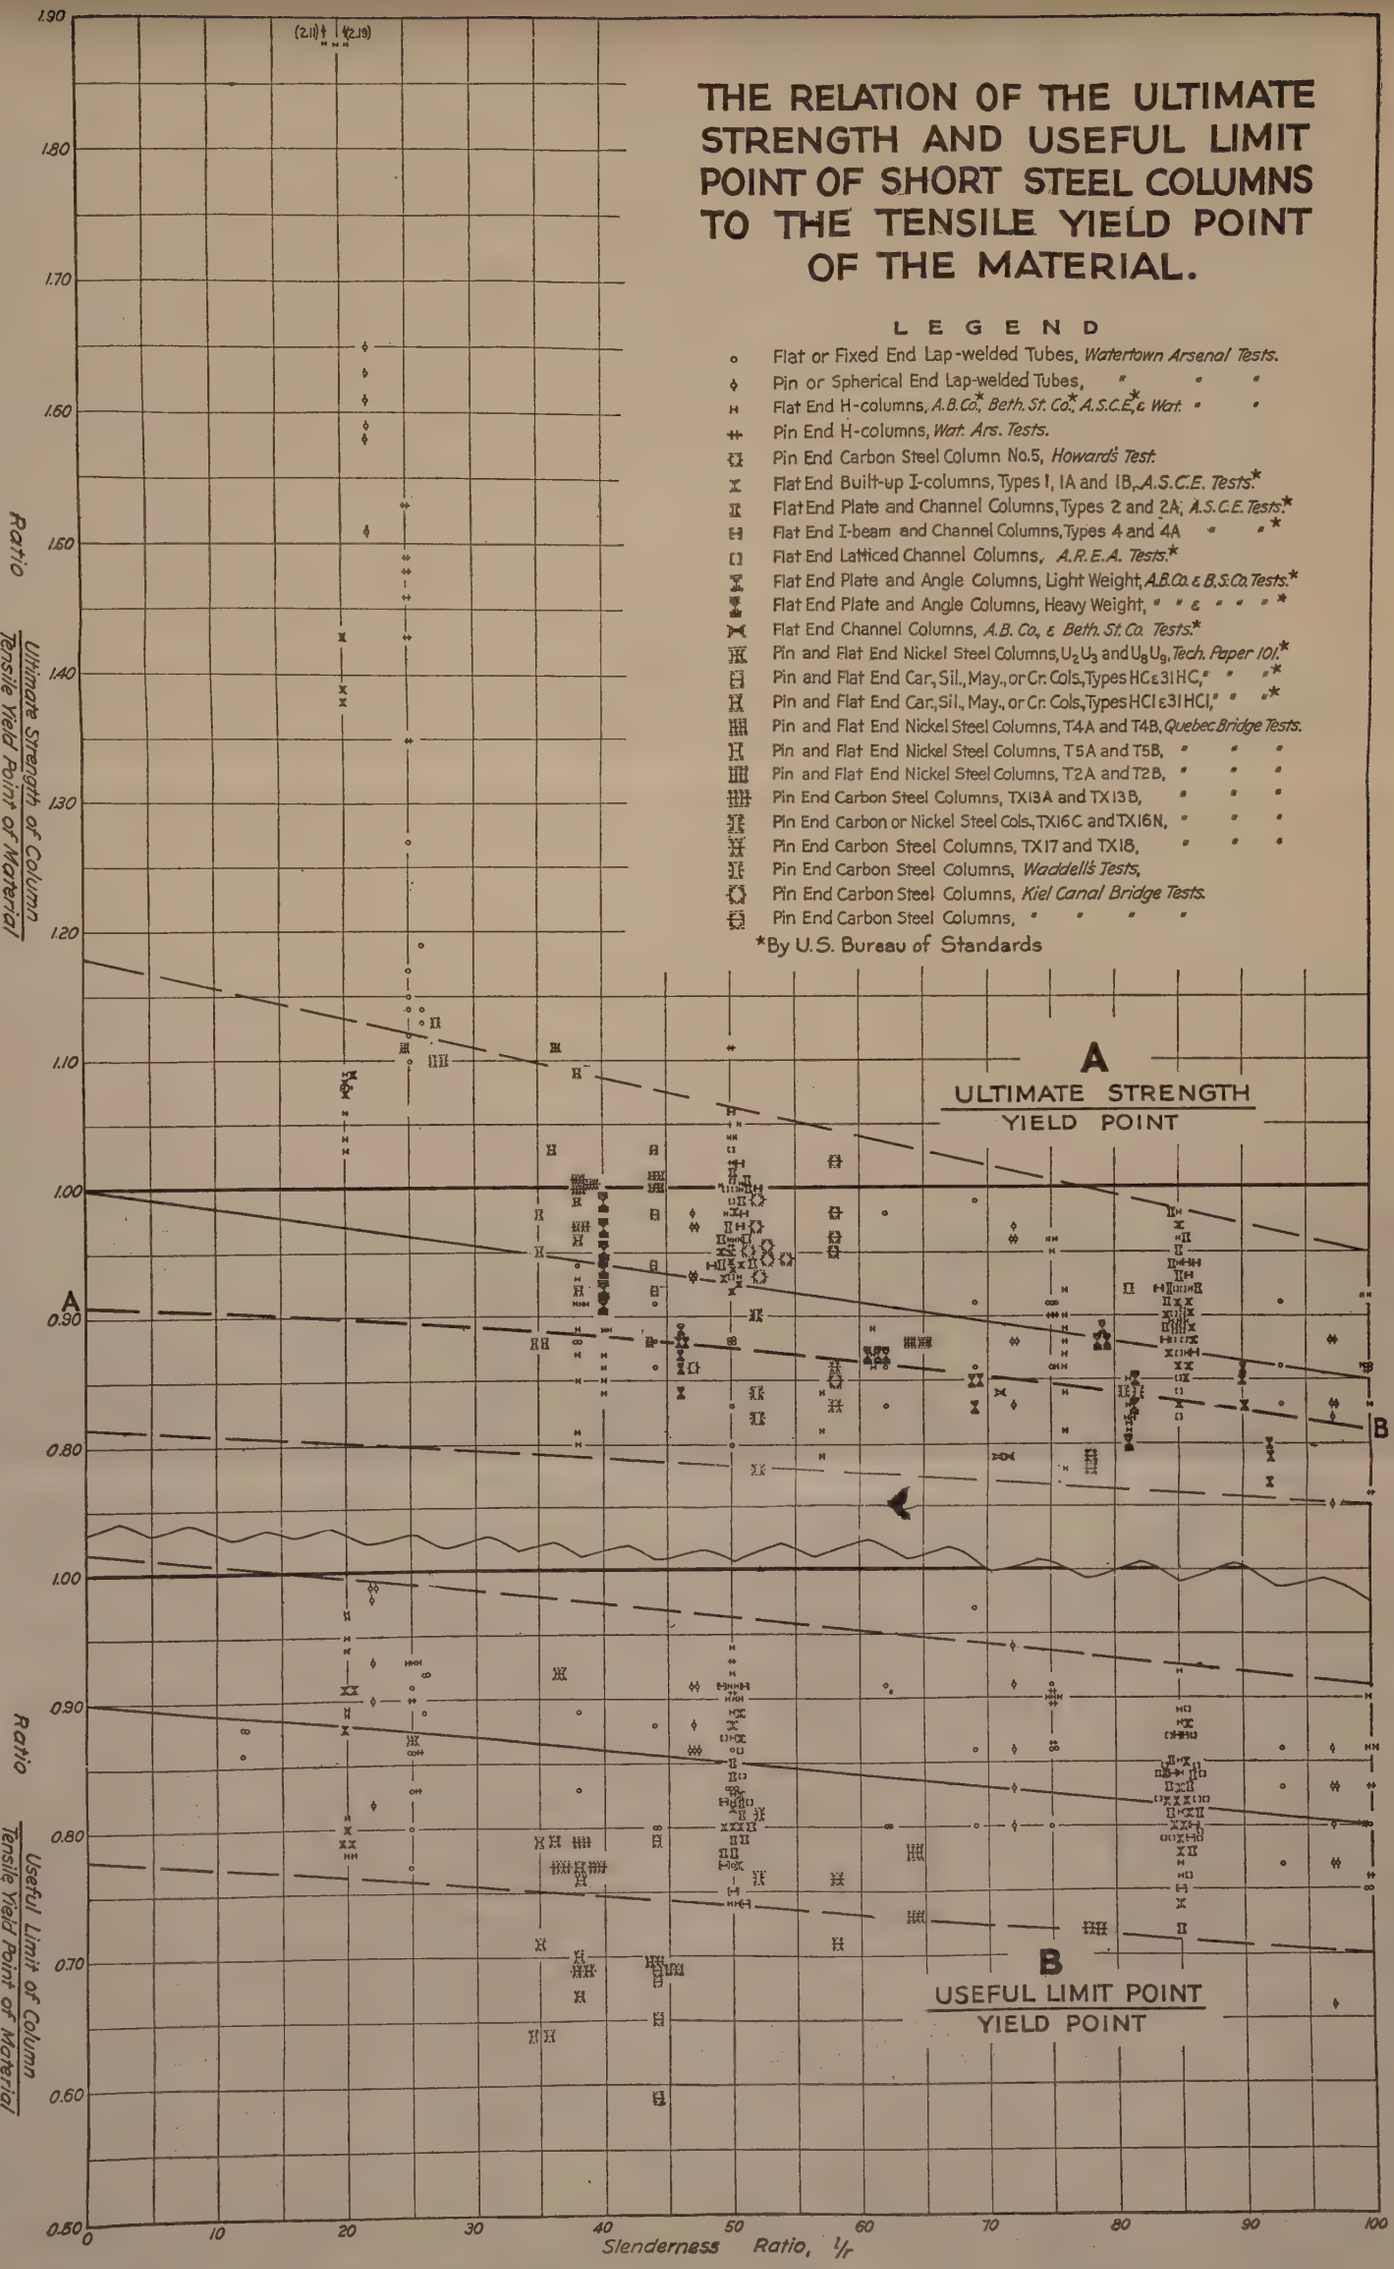

PLATE X.
TRANS., AM. SOC. CIV. ENGRS.
VOL. 89, PAPER No. 1597.
PROGRESS REPORT OF SPECIAL COMMITTEE
ON STEEL COLUMN RESEARCH.

least, the effect of length is small, and that the strength of the column, if properly designed, is primarily a function of the elastic strength of the metal. A constant value of unit stress can well be used for columns of this length, provided the character of the metal is uniform; and such value, once determined, is of much significance in arriving at the column formula needed for the greater lengths. In a study of test data with respect to this phase of the question, a great many uncertainties are confronted, especially with reference to the quality of the material. In most cases the information is inadequate, and in some cases very unreliable or given in terms of doubtful meaning. After much study, it was decided that the most useful information could be obtained by a study of the ratio of the ultimate strength of columns of different length ratios up to $\frac{l}{r} = 100$ to the tensile yield point strength of the material. The Society's Special Committee on Steel Columns and Struts made use of what was named by it the "Useful Limit Point" (U. L. P.)* as being of more significance in some respects than the ultimate strength of the column or the yield point of the material. Although there is good ground for adopting this point in the stress-deformation diagram, as the best measure of column strength, it is not practicable to adhere to this method in a study of all available data. Information does not exist to determine the U. L. P. in a great many of the tests that have been made; but nevertheless it is believed that the results of such tests are valuable and cannot be neglected. As regards the material tests, the most reliable information appears to be the values of the tensile yield point, but in many cases this information is not very satisfactory.

4.—Ratios of Ultimate Strength and Useful Limit Point of Columns to Tensile Yield Point of Material.—The Committee has examined all available tests of steel columns, and has shown in Plate X and Table 1 the results of all tests for $\frac{l}{r}$ up to 100 where failure appeared to be due primarily to a general over-stressing of the material, and where the information regarding the yield point strength of the material was fairly reliable. The results are plotted in Plate X (*A*) as ratios of ultimate strength to yield point strength. Each point represents an individual result. The legend shows what test data have been used; and it will be noticed that pin-ended columns are included, also alloy steels, as well as carbon steels. In using a simple ratio of strength of column to strength of metal, it is recognized that the slenderness ratio has some effect below $\frac{l}{r} = 100$, and, therefore, the results for the hard alloy steels are not quite comparable to the structural steel columns for the higher values of $\frac{l}{r}$; but the difference is relatively small, and it was thought desirable to use all values up to 100 in this study. Columns which failed because of some weak detail, or because of purposely eccentric loading, are omitted. The general make-up of the columns is shown by the symbols on the diagram.

The results are scattered over a rather wide range of values, the limits, except for $\frac{l}{r}$ less than 30, being indicated closely by the two straight lines shown in Plate X. The central straight line represents fairly well average values. Some of the variation in strength is due undoubtedly to the uncertainty regarding yield point of the material, and probably the high values for the tests of the Special Committee on Steel Columns and Struts* at $\frac{l}{r} = 50$ are due in part to the use of a lower value for yield point than for some of the other tests. There appears to be little effect of form of column, although most of the larger built-up columns are below the center line.

The effect of $\frac{l}{r}$ is quite marked, and is fairly well indicated by the slope of the central line. The high values for $\frac{l}{r}$ less than 30 are due to the well-known behavior of very short compression members, and are of little significance in the consideration of the ordinary column.

Plate X (*B*) gives ratios of the U. L. P. of the column to the yield point of the metal for such tests as furnished the necessary information. Here, again, the general range is well shown by two straight lines. Comparing these results with those of Plate X (*A*), an important difference is seen to be in the flatter slope of the lines, showing a less effect of $\frac{l}{r}$, and the absence of any high results for small values of $\frac{l}{r}$. Comparing the center lines of the two diagrams, it is seen that for $\frac{l}{r} = 0$, they are 10% apart; whereas for $\frac{l}{r} = 100$, they are only 5% apart. That is, for short columns there is a greater margin between the U. L. P. and the ultimate strength than for long columns. This is what would be expected, and for $\frac{l}{r}$ as great as 155 (see Fig. 6), the ultimate strength and U. L. P. values are very nearly equal.

Another noteworthy feature of Plate X (*B*) is the very low values for some of the large built-up sections, all of which come well up among the general group in Plate X (*A*). This result is due to the shape of the stress-deformation curves of these columns from which the U. L. P.'s were determined. These curves show a comparatively low proportional elastic limit, with gradually increasing rate of deformation over a wide range of stress, so that the U. L. P., as defined by the Society's Special Committee on Steel Columns and Struts is low. An explanation of this behavior probably lies in the large number of parts of which the columns were composed, a condition which is apt to result in an appreciable amount of inelastic deformation at comparatively low loads, but with little influence on ultimate strength.

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1583.

In Figs. 1, 2, 3, 4, and 5, the data shown on Plate X have been separated into groups for further study. In these diagrams, the upper and lower values are shown by the arrow-points and the average for the group by the plotted position of the column section. The sloping straight lines are the central lines from Plate X, drawn in as a guide for comparison.

Fig. 1 shows the tests of the Special Committee on Steel Columns and Struts. The ultimate ratios are rather high. Fig. 2 contains results on I and H-sections. The effect of form is hardly noticeable. Fig. 3 gives results on tubular columns. The range of ultimate values is naturally less than in the other groups on account of uniformity of material and form. There is no noticeable difference between pin and flat ends. Fig. 4 gives results for built-up latticed columns of all kinds, including the large columns reported in *Technologic Paper No. 101,* U. S. Bureau of Standards, and the Quebec Bridge tests. Here, the ultimate strength ratio corresponds well with the others; but the U. L. P. ratio is low, as previously noted. Fig. 5 includes the tests on alloy steels of high elastic limit (up to a yield point of 60 000 lb. per sq. in.). The ultimate strength ratios correspond well with the general average; the U. L. P. ratios are low. As far as these tests are concerned, it would appear that for short columns the strength bears about the same relation to the yield point of the material as in the case of ordinary structural steel. Fig. 6 gives the results of the tests of the Society's Special Committee on Steel Columns and Struts in more detail, and up to $\frac{l}{r} = 155$. The heavy lines are rough average curves. Only those types are shown for which values of yield points were closely known. All lines tend to converge for increasing $\frac{l}{r}$, as is to be expected; for the column strength for high values of $\frac{l}{r}$ is more dependent on the modulus of elasticity, E, which is practically the same for all. Type 5, the solid H-section, shows up favorably; Type 2, the narrower box section, is about the best; Type 1, the I-section, is generally the poorest; Type 7, the bulb-angle section, is also rather poor. These relations correspond in general to the deductions in Part (B) of the detailed studies on component eccentricities. For the higher values of $\frac{l}{r}$, the range of variation becomes relatively small.

Table 1 gives detailed results for all the columns used in these diagrams.

5.—The Yield Point Strength of the Metal.—The close relation between the strength of columns and the yield point strength of the material is obvious, and is well shown on the diagrams already discussed; but this relation, as shown by tests, does not appear to be as exact as it should be. This is due to several causes. One is the lack of reasonably exact information as to the material itself; and this is a very important factor in the whole problem of column strength. This kind of structural element is so sensitive to the effect of inelastic deformation, or over-strain, that it is especially important to know the practical elastic limit strength of the material out of which it is made. In the diagrams of Plate X, only those tests have been plotted for

FIG. 6.

which the tensile yield points appeared to be fairly well known. In the case of the tests of the Special Committee on Steel Columns and Struts, these values were taken from the stress-strain diagrams prepared at the U. S. Bureau of Standards, and were generally from 1 500 to 2 000 lb. per sq. in. higher than the U. L. P.'s given in the report. In other cases, the statements made in the reports were taken at their face values and doubtless did not always accurately represent the material used. It is possible that some such point as the U. L. P. used by the Society's Special Committee on Steel Columns and Struts would be a more accurate reference point than the yield point, but as no other tests give this information, it seemed best to use the yield point instead, and it is believed that the diagrams represent fairly the relations indicated.

The difficulty of securing correct information regarding the elastic properties of the material actually used is well known. The values of yield point as determined by the usual "drop of the beam" method depend largely on the details of testing; the mill tests vary largely from laboratory tests; and the material varies greatly in thin and thick sections, and at different points in the same section. The data reviewed in these studies furnish a great deal of information on some of these points, and some typical results are given in the following paragraphs.

TABLE 2.—Mill Tests and Laboratory Tests for Elastic Limit.

(Final Report of the Special Committee on Steel Columns and Struts of the Society.)

Type of column.	Average mill test, drop of beam, in pounds per square inch.	Average U. S. Bureau of Standards U. L. P., in pounds per square inch.	Average yield point from U. S. Bureau of Standards curves, in pounds per square inch
1	34 000	33 100	35 100

5	.....	37 500	38 100
5A	.....	33 300	34 700
5B	.....	22 600	25 800

6.—Mill Tests vs. Laboratory Tests.—The difficulty in using mill test data for comparative purposes is well shown in the report of the Society's Special Committee on Steel Columns and Struts. In Table 2 are shown the values of yield point (drop of beam) from mill specimen tests; the average U. L. P. from the U. S. Bureau of Standards tests; and the average yield point as calculated from the Bureau of Standards curves and as used in this report.*

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1629.

The figures in Table 2 show not only a wide discrepancy between results for material of the same column group, but also, as is well known, a large variation between light and heavy sections. There is unquestionably a very close relation between the strength of columns of moderate length and the actual yield point of the material; but to determine this relation or to utilize it in designing with any great accuracy requires more than mill test data as now ordinarily supplied.

The great discrepancy which may exist between mill test and laboratory test is also illustrated by the results obtained by the U. S. Bureau of Standards on rolled H-sections. In one case (Bethlehem H-287½ lb.), the average mill test reported was 42 900 lb. per sq. in. as compared to the Bureau of Standards' 31 700 lb. per sq. in. In the other cases, the average values were much closer, generally not more than 2 000 lb. per sq. in. apart.

The difficulty of getting a proper average value even from coupons cut from the piece is not small. This is particularly true of such forms as the H-section. This was especially studied at the U. S. Bureau of Standards, where test specimens were cut from six different zones and a variation of from 35 000 to 45 000 lb. per sq. in. in yield point was found in one case. The tests of Marburg on I-beams* showed extreme variations in elastic limit (proportional), the value for material at the root being as low as 11 000 lb. per sq. in., and in several cases as low as 15 000 to 17 000 lb. At the same time the flanges showed about 25 000 lb. The yield points varied much less, the variation being generally only 3 000 to 4 000 lb. per sq. in. Moore† gives considerable data on beams, the variation of yield point in the same beam being commonly from 3 000 to 5 000 lb., and running as high as 15 000 lb. per sq. in., the large differences being due to especially high values of yield point for the flange material. Hancock‡ gives further data on the same subject. Considering the effect of variation of material across the section, it would appear that the value of the minimum yield point would have a great effect on the strength of the column, and that perhaps a rating based on minimum yield point would be the most significant; but so far as the Committee has been able to observe, the average value is better. No doubt a very low yield point of the material making up the flange of a column would seriously affect its strength, but flange material of any form is not likely to be of a particularly low value, and the difficulty of determining the properties of the actual components of a member make it very doubtful whether anything would be gained by attempting to use minimum rather than average values.

7.—*Tensile vs. Compressive Yield Point of Test Specimens.*—In the foregoing discussion, the tensile yield point of the material has been used in all cases. It is seldom that information is given concerning the compressive yield points, and it is doubtful whether it will be found practicable to secure such information in general if the tensile yield point gives satisfactory results; but, undoubtedly, the compressive yield point is, after all, the significant thing, and it is desirable to compare the two values as far as possible. The tests of

* *Proceedings*, Am. Soc. for Testing Materials, 1909.
† *Loc. cit.*, 1910.
‡ *Loc. cit.*, 1911.

the U. S. Bureau of Standards for the Society's Special Committee on Steel Columns and Struts give some information on this point. Table 3 shows the U. L. P. from tension and compression tests of some of the material used. Average values are given in each case. The values of $\frac{l}{r}$ ranged from 12 to 20.

Considerable other information exists regarding the relation of elastic properties from tensile and compressive tests. Marshall's experiments* on mild steel show slightly higher values of elastic limit in compression than in tension, the average being about 2½ per cent. Seeley and Putnam† give the average results from a considerable number of tests shown in Table 4.

TABLE 3.—Comparison of Tensile and Compressive Useful Limit Points.
(From Final Report of Society's Special Committee on Steel Columns and Struts.)

Type of column.	Test specimen.	Average U. L. P., tension, in pounds per square inch.	Average U. L. P., compression, in pounds per square inch.	Ratio: Tension / Compression.
1	5 by 3 by 5/16-in. angle	33 300	33 100	1.006
	6 by 5/16-in. plate	32 300	29 800	1.08
1 A	5 by 3 by 5/8-in. angle	29 800	27 000	1.11
2	8 by ¼-in. plate	31 500	28 200	1.12
	6-in. channel	33 200	34 000	0.98
3	5-in. channel	34 100	35 200	0.97
	8-in. channel	34 700	36 100	0.96
4	8-in. I-beam	34 500	30 800	1.12
	8-in. channel	26 100	28 600	0.91
4 A	8-in. I-beam	28 000	28 400	0.99

Results of tests on normal and heat-treated steels with ultimate strengths from 42 400 to 138 000 lb. per sq. in. by Moore and Kommers‡ gave values for ratio of tensile to compressive yield points ranging from 92 to 116%, and averaging about 101 per cent. These included nickel and chrome steels.

TABLE 4.—Average Results from Tests on the Relation of Elastic Properties of Various Kinds of Steel.

Material.	Tension, ultimate, in pounds per square inch.	Ratio: Tensile to Compressive.		
		Proportional limit.	U. L. P.	Yield point.
Soft steel	55 400	0.784	0.933	1.04
Mild steel	54 900	0.943	.....	.....
Medium steel	78 000	0.99	1.01	0.965
Vanadium steel	109 000	0.950	0.972	0.943
Nickel steel:				
(*a*). Parallel to rolling	87 900	0.989	0.923	0.956
(*b*). Perpendicular to rolling	87 700	1.00	0.985	0.972
Chrome nickel steel	65 600	0.886	0.887	0.942

In general, it would appear that the tensile yield point is a close indication of the compressive yield point, and for the purpose in question probably as

* *Transactions*, Am. Soc. C. E., Vol. XVII (1887), p. 54.

† *Bulletin No. 115*, Eng. Experiment Station, Univ. of Illinois, 1919.

‡ *Bulletin No. 124*, Eng. Experiment Station, Univ. of Illinois. 1921

satisfactory an indication of column strength. An examination of the column test results of the Society's Special Committee on Steel Columns and Struts shows no closer relation to the compressive than to the tensile yield point.

8.—Yield Point Determined by Tests on Short Column Sections.—It has been proposed to make use of short sections of actual columns for the purpose of determining the elastic properties of the combination of shapes used and to base estimates of column strengths upon such information. This is a logical process, and should give superior results. It is doubtful, however, whether such a method is practicable in general. As a matter of fact, the results of the tests made by the Society's Special Committee on Steel Columns and Struts, when measured by the useful limit values from the tests on the very short test pieces $\left(\frac{l}{r} = 20\right)$, show a greater variation than when referred to the average yield point of the material. This is hardly sufficient evidence to condemn this method, but it throws doubt on its special value.

(B) Results of Tests on Columns of All Lengths and Showing Integral Action

9.—There have been assembled in Figs. 7, 8, and 9 the results of all available tests which appear to be pertinent to the present investigation. Tests have been excluded where failure was due to weak details, or where the load was applied eccentrically. The complete list of tests is given herewith, and for the full test data, the reader is referred to the original articles:

Steel Columns.—

American Railway Engineering Association. 30 tests. Latticed channel columns tested at the U. S. Bureau of Standards. Columns with batten-plate connections omitted. (*Proceedings,* Am. Ry. Eng. Assoc., Vol. 16, p. 636; Vol. 19, p. 789).

American Society of Civil Engineers. 99 tests. Tested by the U. S. Bureau of Standards. The following tests are omitted because of unknown or uncertain yield point of material: No. 3 heavy; No. 6; No. 6A; No. 8; No. 8A; Z-bar; No. 10 heavy; and the Carnegie H-columns; also, No. 5, extra heavy for $\frac{l}{r} = 20$. (*Transactions,* Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 1583).

American Bridge Company and Bethlehem Steel Company. 69 tests. Tested at the U. S. Bureau of Standards. Report to be published.

Watertown Arsenal Tests of H-Sections and Built-Up I-Sections. 130 tests. Two omitted on account of excessive bends. 94 tests of lap-welded tubing; 12 omitted for $\frac{l}{r} = 12$ to 22. (Report on Tests of Metals and Other Materials, 1908, 1909, 1910, 1912, 1913, 1914).

Waddell's Tests on Built-Up Channel Sections. 12 tests. (*Transactions,* Am. Soc. C. E., Vol. LXIII (1909), p. 246).

Buchanan's Tests on Built-Up I- and Plate- and Channel-Sections. 6 tests. Six omitted on account of eccentric loading or failure of details. (*Engineering News,* Vol. 58, p. 685).

Christie's Tests on Small Angle-Sections. 16 tests. Used only tests for $\frac{l}{r} = 160$ to 300. (*Transactions*, Am. Soc. C. E., Vol. XIII (1884), p. 253).

Kiel Canal Bridge. Built-Up Channel Sections. 12 tests. (*Engineering News-Record*, Vol. 88, p. 877).

Tests on Large Built-Up Columns, U. S. Bureau of Standards. 10 tests. Omitted 2 tests on account of high yield point of material and 6 tests on account of failure in details. (*Technologic Paper No. 101*, U. S. Bureau of Standards).

Quebec Bridge Tests. 18 tests. Omitted 2 tests on account of high yield point of material and others that were tested horizontally without counterpoise. (The Quebec Bridge, 1919, Department of Railways and Canals, Canada; also *Engineering Record*, Vol. 62, p. 564; Vol. 69, p. 333).

Wrought-Iron Columns.—

Bouscaren's Tests. 16 tests. Tests on Keystone and old American Bridge Company's sections omitted. (*Transactions*, Am. Soc. C. E., Vol. IX (1880), p. 447).

Christie's Tests on Small Shapes. Used results for $\frac{l}{r} = 160$ to 300. (*Transactions*, Am. Soc. C. E., Vol. XIII (1884), p. 85).

Buchanan's Tests. 2 tests. Omitted others which failed in details. (*Engineering News*, Vol. 58, p. 685).

Clark Reeves and Company. Phœnix Columns. Omitted 2, $\frac{l}{r} = 2.7$. (Report of Tests of Metals and Other Materials, 1881, p. 263).

Strobel's Tests on Z-Bar Columns. 15 tests. (*Transactions*, Am. Soc. C. E., Vol. XVIII (1888), p. 103).

Watertown Arsenal. 190 tests. Omitted 13 because of eccentric loads or failure in details. Omitted 3 because of excessive bends. (Report on Tests of Metals and Other Materials, 1881, 1882, 1883, 1884).

The results for the steel columns have been grouped as closely as practicable in Figs. 7 and 8, in accordance with the yield point or elastic limit of the material, although in many cases this could not be done very accurately. Tests on the wrought-iron columns have been grouped together in Fig. 9. These general groups will be first discussed, after which certain individual groups of tests will be considered.

10.—Tests on Steel Columns.—In Figs. 7 and 8 it will be noted that both flat-end and pin-end columns have been grouped together. This is done because a careful examination of the data showed that most pin-end columns in these tests behaved as flat-end columns up to the maximum load. A few pin-end columns, due to initial bends, acted more like round-end columns, giving a strength much less than the others, but still much higher than a truly pivoted end column. The number of such results is, however, so few, and the results are so erratic, that they have not been plotted. They will be discussed later. Figs. 7 and 8, therefore, represent results of tests on flat-end columns and on pin-end columns that were essentially flat ended. The points on the dia-

grams do not, as a rule, represent individual tests, but the average of two or three results; but in all cases the range of values above or below the average is relatively small.

In order to relate the plotted results to some basis for discussion, a Euler curve has been drawn in Figs. 7 and 8 and a horizontal straight line representing an average value for the yield point of the group. The same Euler curve has been used for the groups, namely,

$$\frac{P}{A} = \frac{900\,000\,000}{\left(\frac{l}{r}\right)^2} = \frac{4\,\pi^2\,E}{\left(\frac{1.12\,l}{r}\right)^2}$$

This is the theoretical fixed-end formula for long columns for a value of l 12% longer than the actual length. This assumes the points of inflection to be 0.56 l apart instead of 0.5 l, as required by theory. As a matter of fact, this corresponds to the observed location of the points of inflection in certain tests described later. A somewhat lower curve would apparently fit Christie's flat-end tests shown in Fig. 7 somewhat better, but a very close agreement will be noted in Fig. 9, and the curve selected will answer well enough for present purposes.

In any effort to represent these results by a formula, it is apparent that such formula, either empirical or rational, should give values for short columns closely related to the tensile yield point strength of the material, which varies with different materials, and for long columns values approaching those given by the Euler law, and which is the same for all grades of material. If the yield point strength is to be taken as the limit for $\frac{l}{r} = 0$, the simplest empirical formula is perhaps the parabola as proposed by the late J. B. Johnson, M. Am. Soc. C. E., drawn tangent to the Euler curve. Such parabolas are shown in the diagrams. They fit the tests well, but the study of short columns, as shown in Plate X, indicates that this curve may not slope rapidly enough between $\frac{l}{r} = 0$ and $\frac{l}{r} = 100$. Curves of the Rankine form are also shown in Fig. 7, arbitrarily drawn through $\frac{P}{A} = 20$ for $\frac{l}{r} = 200$. For high values of yield point, the Rankine curve appears to fall off too rapidly. This is equivalent to saying that the eccentricity (including deflection effect) tacitly assumed in the Rankine formula, increases too fast for columns of moderate length and high elastic limit. For the structural steel (36 000 lb. yield point), the Rankine curve corresponds closely to the median line of Plate X for $\frac{l}{r}$ from 80 to 100, but is considerably higher for shorter lengths $\left(95\%\text{ of yield point for } \frac{l}{r} = 50\right)$.

Probably the simplest and most logical theoretical curve is the so-called secant formula, derived by assuming a certain initial eccentricity based on results of tests, and such a curve can be drawn to fit the tests quite well. Engesser and Karman have modified the Euler formula so as to take account

of the behavior of the metal beyond its elastic limit, but they assume perfectly central loads and thus obtain relatively high results for columns of moderate length. Their curves show an upward turn for very short columns, corresponding to many test results, but this point is hardly of practical value. If the high values for very short columns are considered, the test results can be represented very closely by single straight lines intersecting or tangent to the Euler curve, and if it is desired to exclude the higher values, then two straight lines can obviously be drawn, one horizontal and the other inclined, that will represent the tests within the range of practice about as well as any curve.

It is not proposed, however, here to suggest a working formula, but only to present the test records with some comparison with well-known types of formulas. The tests shown in Figs. 7 and 8 are for flat-end conditions, and can hardly be applied to columns in structures. This subject is reserved for discussion in a later report.

11.—Tests on Wrought-Iron Columns.—Fig. 9 shows results of tests on wrought-iron columns. Here the pin-end tests show a greater variation from the flat-end tests than in the case of the steel columns, and are plotted in a separate group, and a different Euler curve is drawn. Greater differences in straightness and in pin friction are doubtless the cause of so wide a variation in results. A straight line seems to fit these results as well as any curve.

12.—Watertown Arsenal Tests on Steel Built-Up I*-Columns.**—These tests included the variables given in Table 5.

* Nickel steel.

† Where pins were used; they were placed with their axes in the plane of the column web.

‡ Based on length between centers of pins. Pins were 3 in. in diameter.

The results of these tests are plotted in Fig. 10, the points representing generally the average of three tests.

Here, again, it will be observed that the end conditions affected the strengths very little. The pin-end columns of 60 000-lb. steel with a slenderness ratio of 25, were slightly stronger than the corresponding flat-end columns; with $\frac{l}{r}$ greater than 125, the pin ends were somewhat weaker than the flat ends.

* Report on Tests of Metals and Other Materials, 1909–14.

Considering columns of 60 000-lb. steel, it appears that:

(*a*).—Flat-end columns with $\frac{l}{r} = 25$ failed by buckling of the flanges. Longer members failed by triple flexure in a plane normal to the web-plate. Sudden springing laterally occurred in tests of columns with $\frac{l}{r} = 125$, or more, when the maximum load was reached.

(*b*).—The larger sections with pin ends and $\frac{l}{r} = 25$ failed by buckling of the flanges; with $\frac{l}{r} = 50$, by triple flexure and buckling of the flanges; with $\frac{l}{r}$ greater than 50, by deflection normal to the web. The smaller sections with pin ends and $\frac{l}{r} = 19$ failed by buckling of the web and flanges; with $\frac{l}{r} = 39$ or greater, by deflection normal to the pins. Pin-end columns with $\frac{l}{r} = 100$, or greater, exhibited sudden lateral springing at the maximum load.

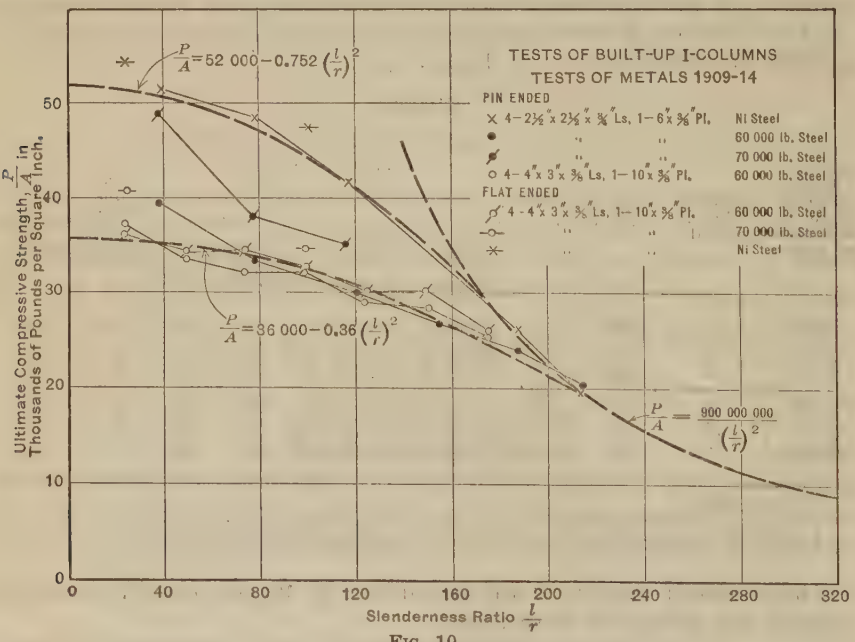

FIG. 10.

(*c*).—As in the tests on tubes and solid-rolled H-columns, so in these tests the pin friction was sufficient in most cases to prevent rotation of the ends of the columns under inherent eccentricities of load. Certain of the longer pin-end columns had initial bends which had an effect sufficient to offset the pin friction.

From the diagram (Fig. 10) it will be noted that the strength of the short lengths, $\frac{l}{r} = 25$ or less, did not run as high as in some other forms. For these short lengths, failure occurred by buckling of the flanges. The ratio of unsupported width to thickness was 10.7 : 1. For purposes of comparison, there have been drawn, on the diagram, the same Euler curve as in Fig. 7, and also tangent parabolas applicable to the 60 000-lb. steel and the nickel steel. The results on the 70 000-lb. steel are not sufficiently numerous to warrant separate consideration. The manner in which the strength of the nickel-steel column approaches that of the structural steel at high values of $\frac{l}{r}$, is quite striking.

13.—Tests on Solid Rolled H*-Columns.**—Results of tests on eighteen solid-rolled H-sections with flat ends and a like number with pin ends are given in the two reports referred to. These H-sections had flanges 6 in. wide, varying in thickness from $\frac{7}{16}$ in. at the edges to $\frac{1}{2}$ in. near the webs. They were 6 in. deep, and had webs $\frac{1}{4}$ in. thick. The area of cross-section was 7 sq. in., and the least radius of gyration was 1.54 in. Tests were made in triplicate for six lengths, ranging between 3 ft. $2\frac{1}{2}$ in. and 19 ft. 3 in. The pins were 3 in. in diameter.

Tensile tests on four specimens cut from the flanges of these members gave an average yield point of 30 140 lb. per sq. in. and an ultimate strength of 56 965 lb. per sq. in. Two web specimens gave an average elastic limit of 31 480 and an ultimate strength of 54 920 lb. per sq. in.

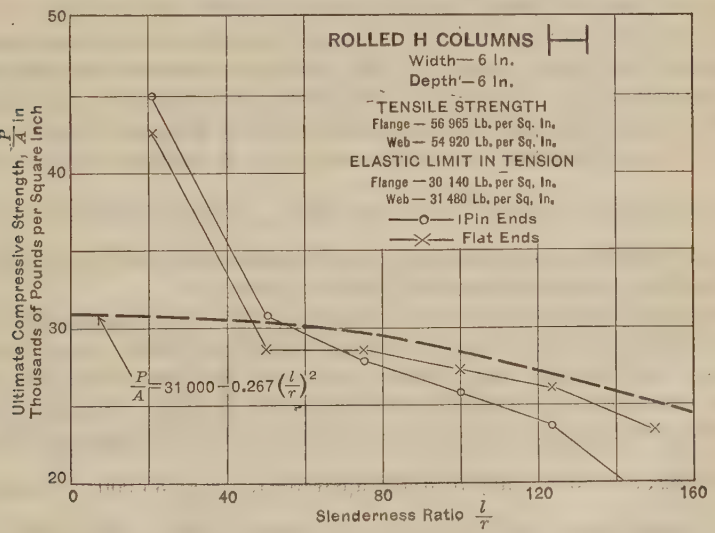

FIG. 11.

The results of these tests are shown in Fig. 11, together with a reference parabola corresponding to the yield point of the material. In this case the

* Reports on Tests of Metals and Other Materials, Watertown Arsenal, 1908–09.

strength of the pin-end columns for $\frac{l}{r} = 100$ or more was considerably less than those with flat ends. For $\frac{l}{r} = 25$ and 50, the pin ends showed the better result, probably due to a more central application of load. Several of the pin-end columns of $\frac{l}{r} = 100$ and 150 had considerable initial bends, in one case as high as 0.42 in. (omitted from the diagram), which reduced their strength materially and prevented flat-end behavior. The data on bends are discussed later. It will be noted that the values for $\frac{l}{r} = 25$ show in a marked degree the excess strength for very short columns, and quite unlike the results shown in Fig. 10. This difference is probably due in large measure to the thicker flange in the H-section, the ratio of unsupported width to the thickness being about 6, as compared to 10.7 in the case of the weaker built-up I-sections of Fig. 9.

*14.—Tests on Bessemer Steel Lap-Welded Tubing.**—One hundred and six tests on tubing, 5 in. in outside diameter, with a nominal thickness of 0.36 in., nominal area of cross-section of 5.25 sq. in., and radius of gyration of 1.645 in., were made at the Watertown Arsenal. The lengths of the specimens ranged from 1 ft. $8\frac{9}{16}$ in. to 24 ft. The slenderness ratio varied from 12.5 to 175. Most of these tubes had local bends at points along their length. Four types of end condition were used in these tests: Flat, fixed, pin, and spherical.

In the fixed-end tests, the tubing was secured at the ends in special castings which terminated in bases 18 in. in diameter, or they were clamped in the jaws of the testing machine. The radius of curvature for the spherical ends was 2.75 in.; for the seats, it was 3.00 in. The diameter of the pins used in the pin-end tests was 3.00 in.; the diameter of the seats for the pins was $3\frac{1}{16}$ in. In nearly all cases columns were tested in triplicate; six were tested in the flat-end series with $\frac{l}{r} = 25$ and with $\frac{l}{r} = 50$. Tensile tests on three specimens cut from these tubes gave an average elastic limit of 36 250 lb. per sq. in. and an average ultimate of 58 310 lb. per sq. in.

The results of these tests are shown in Fig. 12. Here, again, there is very little difference in results for different end conditions, except for the very short lengths, where the pin and spherical ends give the best results, and for the longest specimens, where the flat and fixed ends show best. Several curves are shown in this diagram: The formula (upper curve) proposed by Lilly† for steel tubing; a modified Lilly formula; a parabola, $\frac{P}{A} = 35\,000 - 0.44\left(\frac{l}{r}\right)^2$; and the same parabola and Euler curve as shown in Fig. 7. The Lilly formula is of the Rankine type with special constants. A parabola, or, within certain limits, a straight line, appears to fit these tests satisfactorily.

* Reports on Tests of Metals and Other Materials, Watertown Arsenal, 1908–09.
† *Transactions*, Am. Soc. C. E., Vol. LXXVI (1913), p. 258.

15.—Strobel's Tests on Z*-Bar Iron Columns.**—These consisted of tests on fifteen flat-end columns varying in sectional area from 9 to 10 sq. in. The average yield point of material was 34 200 lb. per sq. in. All columns failed as a unit and the results of tests in duplicate and triplicate were concordant. They are shown in Fig. 13 with the same parabola as that used in Fig. 7. Considering the relatively low yield point, the results may be regarded as rather superior to those obtained on some of the other forms.

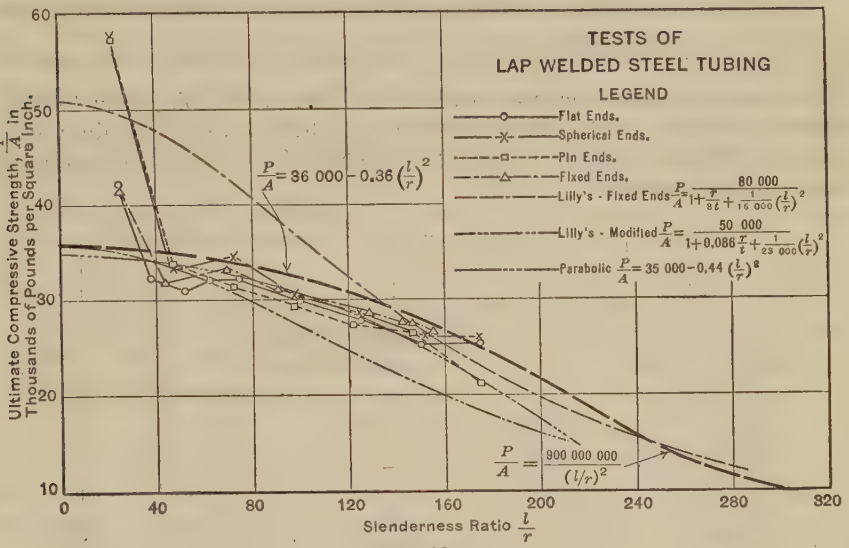

Fig. 12.

16.—Tests on Phœnix Iron Columns.†—These comprise twenty-two tests of flat-end columns of 12 to 18 sq. in. sectional area. No report on the metal composing these columns was made. The results are shown in Fig. 14 and are uniformly good.

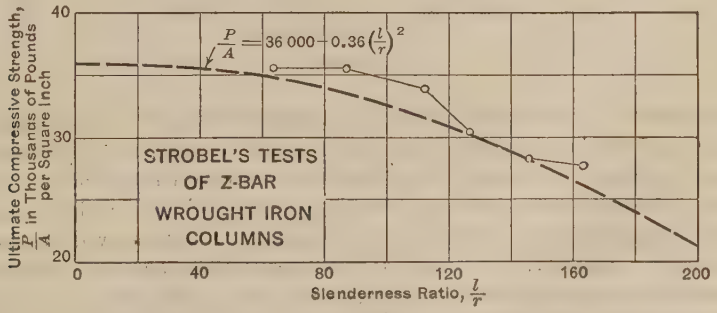

Fig. 13.

17.—Tests on 3-Inch by 3-Inch Square Wrought-Iron Columns.‡—These tests are shown by the solid circles on Fig. 9, pin-end group. The material

* *Transactions*, Am. Soc. C. E., Vol. XVIII (1888), p. 103.

† *Loc. cit.*, Vol. XI (1882), p. 1, and Report on Tests of Metals and Other Materials, Watertown Arsenal, 1881.

‡ Report on Tests of Metals and Other Materials, Watertown Arsenal, 1883.

was of rather low elastic limit (24 000 lb. per sq. in.), and the pins relatively large, $1\frac{1}{2}$ in. in most cases. The result is, for the short lengths, low values compared to other tests on wrought iron; and for the long lengths, rather high values due to resistance to turning on the pins. As a matter of fact, the group of test results can be represented very closely by a single straight line, which, however, is not of much significance in a consideration of the common type of structural column.

The effect of size of pin on the strength of the column is brought out in these tests by a series in which the pin size varied from $\frac{7}{8}$ in. to $2\frac{1}{4}$ in., and $\frac{l}{r} = 139$. The ultimate strength increased steadily with diameter of pin, from 16 300 to 22 250 lb. per sq. in., the latter value being about 92% of the elastic limit of the material. This is a good illustration of the effect of pin friction in tending to fix the ends of columns.

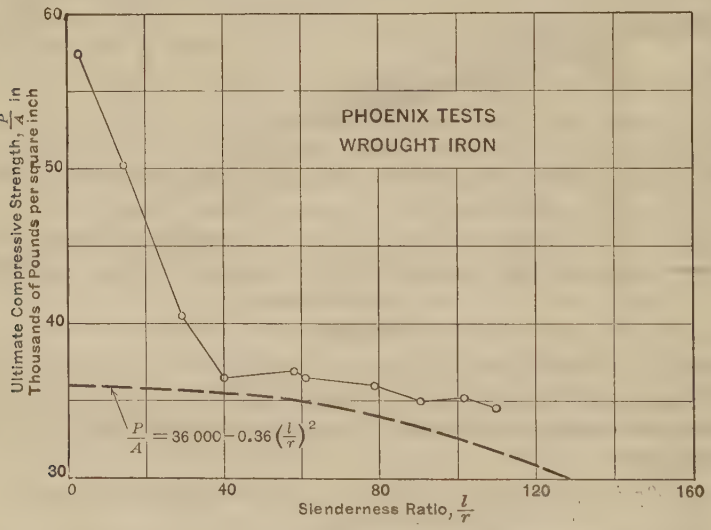

FIG. 14.

*18.—Christie's Test on Wrought Iron and Steel Struts.**—These tests were made on small shapes, generally less than 2 sq. in. in section. The ends were flat, fixed by clamps, hinged and spherical for the wrought iron, and flat only for the steel. In the diagrams of Figs. 7 and 9, only the longer lengths are used, as these are thought to be of some value in reference to failure by deflection. In the case of the longer flat-end tests, it is reported that generally the ends left their bearings at one edge before failure, and in some cases before the maximum load was reached. This action indicated a further deviation from a fixed-end condition than in the case of the tests on larger sections plotted in the diagrams. The flat-end tests, however, have been plotted on Fig. 7, and the fixed and hinged-end tests on Fig. 9. The results are relatively low except in the hinged-end group of Fig. 9.

* *Transactions*. Am. Soc. C. E., Vol. XIII (1884), pp. 253, 285.

(C) Effect of Various Details on Strength of Columns

1.—Inherent Eccentricities and Initial Bends

19.—Some information on this subject may be obtained from some of the test data, but many of the older tests give little or none except what may be inferred from the deflections produced by loads. Eccentricity may be due to bends in the column; to eccentrically applied loads; to irregularities of cross-section; or to unequal elasticity of the column components.

Where loads are presumed to be centrally applied, there may be in effect considerable eccentricity, especially in flat-end tests, where unequal bearings would have the effect of eccentric application of loads. Initial bends will also result in eccentricity of load with respect to some parts of the column. The best information available from the tests are the strain measurements made at different points along the columns, especially near the center, and considerable data to that effect are given later. These data are of some value in giving information regarding the applicability of various column formulas, but it is to be noted that in many cases the columns have been made with greater care than is required in ordinary commercial practice.

20.—Calculation of Eccentricity and Bending Moment from Strain Measurements.—Eccentricities with respect to the two principal axes have been calculated by the formulas:

$$e_m = \frac{V}{X}\frac{r_m^2}{c_m}, \text{ and } e_n = \frac{W}{X}\frac{r_n^2}{c_n} \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which, e, r, and c represent, respectively, eccentricity, radius of gyration, and distance to remotest fiber, the subscript, m, denoting the axis with respect to which the radius of gyration is a maximum, and the subscript, n, the axis with respect to which the radius of gyration is a minimum; V equals the difference in the sums of the deformations of the two sets of strain measurements at a distance, c_m, from the m-axis; W equals the same with respect to the n-axis; and X equals the sum of deformations of the four remotest fibers.

Bending moments are expressed in terms of the ratio of maximum fiber strain due to bending, to average direct strain. Assuming a constant value of E across the section, this ratio would be equal to the ratio of stresses, and has been so indicated. They have been calculated from the formula:

$$\frac{\text{Bending stress}}{\frac{P}{A}} = \frac{V + W}{X} \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

It will be noted that $\frac{V}{X}\frac{P}{A}$ represents bending stress in the direction of maximum moment of inertia, and $\frac{W}{X}\frac{P}{A}$, the bending stress at right angles.

21.—Eccentricities and Bending Stresses in the Am. Soc. C. E. and A. R. E. A. Columns.—Very careful strain measurements were made in these tests, which have been studied from various aspects. An especial effort has been made to determine effect of difference of form in the behavior of the

different columns. It is important also to study the effect of slenderness ratio. Fig. 15 gives the values of eccentricities calculated in the manner already described for a value of $\frac{P}{A}$ (average unit stress) of 15 000 lb. per sq. in., and for all the various types of columns. The light lines represent values for the light sections and the heavy lines for the heavy sections. In most cases the values represent the average of three columns. The average of all values is given in the first set of lines.

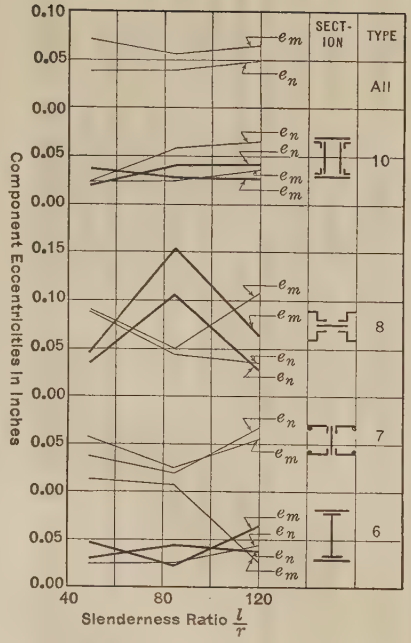
It will be noted that the value of the eccentricity at 15 000 lb. per sq. in. is not appreciably affected by the slenderness ratio. Few of the eccentricities exceed 0.1 in. Of perhaps more significance are the bending stress ratios, as these values include not only the effect of eccentricity, but also take account of variation in r and c.

Fig. 16 shows bending stress ratios averaged for each type of column. Values for all slenderness ratios of 50, 85, and 120 are averaged for this purpose, little variation being due to this factor. Results are given for $\frac{P}{A} = 15\,000$ lb. per sq. in., and also for $\frac{P}{A}$ = highest elastic load. The diagrams show no very consistent variation, although Types 2 and 5 are generally good, and Type 8 is generally poor. Type 1, which shows up rather poorly in Fig. 6, does not reveal large eccentricities. Considering the possible effects of inaccurately fitted end bearings and the relatively small bending stresses (average about 5% at $\frac{P}{A} = 15\,000$), these results are not of great significance in attempting to estimate effect of form.

22.—Eccentricity of Built-Up I*-Columns, Watertown Arsenal Tests, 1909-14.*—In this series, 33 tests were made with flat ends, and 65 with pin ends. In most cases the end conditions affected the strength but little, the pin friction being sufficient to give the effect of flat ends. In a few cases the initial deflection or bend was sufficient to offset the pin friction and greatly to decrease the strength of the column. The data (Table 6) from six columns of the same length $\left(\frac{l}{r} = 175\right)$ and section show how a rather small eccentricity affected the resistance of certain long columns of this series (60 000-lb. steel).

If the ends of the columns shown in Table 6 had been unrestrained, the Euler load which would have produced failure by lateral bending is 9 370 lb. per sq. in. (assuming $E = 29\,000\,000$ lb. per sq. in.).

These data show that an initial bend of small amount caused a marked reduction in the strength of the pin-end columns, but produced little effect on the strength of the flat-end columns. Apparently, the pin friction was sufficient to prevent Column No. 2036, which was reasonably straight, from rotating at the ends when the Euler load for unrestrained ends was applied. With the load nicely centered, it carried more than the flat-end struts of the



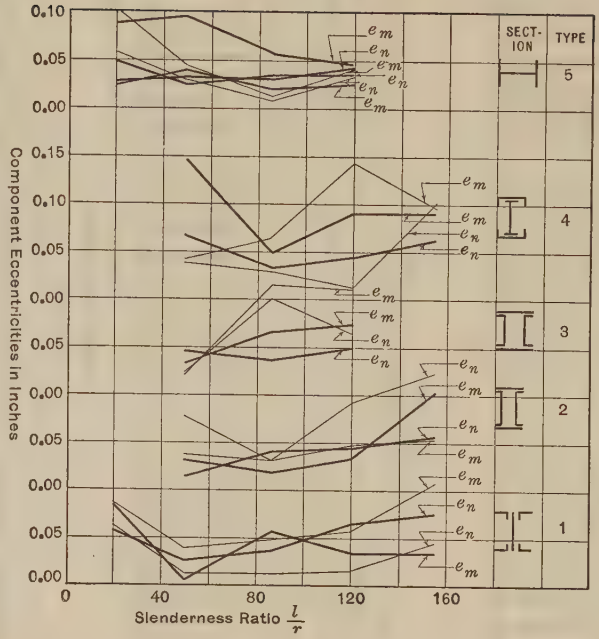


FIG. 15.

AND
AMERICAN RAILWAY ENGINEERING ASSOCIATION
SERIES AT
$\frac{P}{A}$ = 15 000 LB. PER SQ. IN.

same length and nearly three times the Euler load. On the other hand, Column No. 2035, with an initial bend of 0.15 in. (about 0.09 r), failed at a load less than one-half as large as that sustained by Column No. 2036, and only 40% larger than the Euler load.

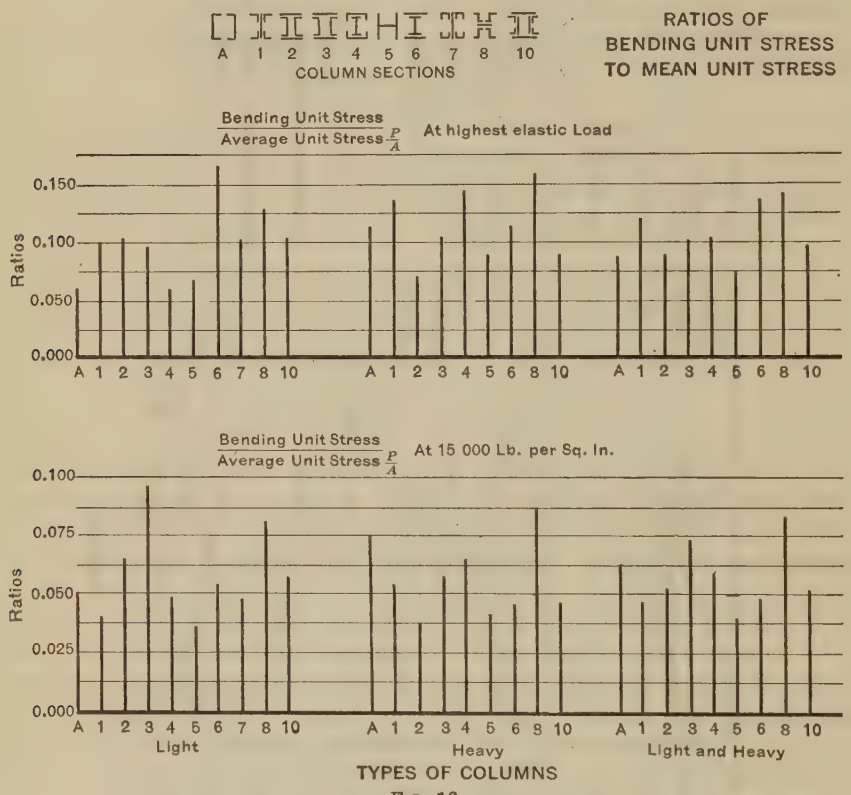

FIG. 16.

Tests of three columns—Nos. 14911-14913* (sectional area, 9 sq. in.; least $r = 1.05$ in.; $\frac{l}{r} = 186$)—are especially interesting, as strain measurements were made along the entire length of the column. The results of the gauge readings showed that two of the columns had two inflection points, the distance between these points being about 55% of the column length, corresponding closely to truly fixed-end columns. The other showed three inflection points. These gauge readings also furnished information regarding eccentricity of load throughout the column and the effect of such eccentricity upon the ultimate strength values. Table 7 gives the calculated eccentricities at the ends and center of these columns and observed deflections for loads of 12 000 and 21 000 lb. per sq. in. The values are in inches.

* Report on Tests of Metals and Other Materials, Watertown Arsenal, 1912.

It will be noted from Table 7 that the calculated eccentricities at $\frac{P}{A} = 12\,000$ are considerably greater than the actual deflections, but at $\frac{P}{A} = 21\,000$ they

TABLE 6.—Effect of Initial Bend on Column Strength.

Column No.	Kind of ends.	Deflection at Center, in Inches.				Ultimate strength, in pounds per square inch.
		Initial.		Increment in deflection under $\frac{P}{A} = 5\,000$ lb. per sq. in.		
		Parallel to pins.	Normal to pins.	Parallel to pins.	Normal to pins.	
2035	Pin	0.14	0.15	0	0.10	13 130
2037	"	0	0.15	0	0.03	23 200
2036	"	0	0	0	0.01	27 010
2032	Flat	None noted		0	0	24 730
2033	"	"	"	0	0.01	26 650
2034	"	0.12	0.10	0	0	26 720

are nearly the same. This is doubtless due to the effect of initial bends and eccentric application of load, which would have more influence in the calculated eccentricities at low loads, than in the observed deflections. In Column No. 14913, the eccentricity of 0.235 at the center gives a value of $\frac{e\,c}{r^2}$ of 0.57, which means a bending fiber stress of 57% of the direct stress, or at $\frac{P}{A} =$ 21 000, the bending stress was 12 000 lb. per sq. in. The ultimate compressive strengths of these columns were, respectively, 24 000, 26 200, and 21 500 lb. per sq. in.

* Mean eccentricities are the algebraic averages of values for Gauges 1 and 18 at the ends, and Gauges 8, 9, and 10 at the middle, of the columns.

23.—Initial Bends of H*-Sections, Watertown Arsenal Tests (1909).*—Many of the pin-end columns had initial bends of considerable amounts, the maximum being 0.42 in., several being from 0.15 to 0.20 in. In tests of columns with $\frac{l}{r} = 100$ and 150, the maximum loads per square inch and the initial deflection normal to the pins were as given in Table 8.

TABLE 8.—Effect of Initial Bends on H-Columns.

Column No.	$\frac{l}{r}$.	Maximum load, in pounds per square inch.	Initial deflection, in inches.
1986	100	24 000	0.20
1987	100	26 000	0.15
1988	100	27 000	0.08
1980	150	20 360	0.15
1981	150	17 430	0.16
1982	150	10 100	0.42

By reference to Fig. 7, it will be seen that Column No. 1988, with initial deflection of 0.08 in., gave a result not greatly below the flat-end group, but the results from the best of the columns with $\frac{l}{r} = 150$ fell much below that group. The effect of the large deflection of 0.42 in. is evident in the low value for the ultimate of 10 100 lb. per sq. in. Applying the secant formula for eccentric loads to the column,

$$S = \frac{P}{A}\left(1 + \frac{e\,c}{r^2}\sec\left(\frac{l}{2\,r}\sqrt{\frac{P}{A\,E}}\right)\right)$$

and using $\frac{P}{A} = 10\,100$ lb. per sq. in., $e = 0.42$ in., $c = 3$ in., $E = 30\,000\,000$ lb. per sq. in., and $r = 1.54$ in., the value, $S = 38\,200$ lb. per sq. in., is derived as the extreme fiber stress, with an average load of 10 100 lb. per sq. in.—a value about equal to the yield point of the material. The additional deflection at failure was 1.74 in., giving a central eccentricity of $1.74 + 0.42 = 2.16$ in., and,

$$S = \frac{P}{A}\left(1 + \frac{e\,c}{r^2}\right) = 37\,700 \text{ lb. per sq. in.}$$

a close agreement with the secant formula. The theoretical Euler load on this column for hinged ends is 13 000 lb. per sq. in. It is seen, therefore, that whereas this large initial deflection of 0.42 in. greatly weakened the column as compared to straighter columns, the reduction below the theoretical Euler load for strictly hinged-end columns was not nearly as great. This illustration shows clearly the restraining effect of pin friction in the normal pin-end columns.

24.—Eccentricities of Columns Reported in Technologic Paper No. 101.—Strain gauge readings in this series of tests give some information on the eccentricities observed in testing large columns. Table 9 gives calculated

values of eccentricity, e, and eccentric ratio, $\frac{e\,c}{r^2}$, for several of these columns, and at an average stress of 30 000 lb. per sq. in. All these columns were of symmetrical cross-section, consisting of built-up I or channel-sections connected by a central web and lacing.

As shown in *Technologic Paper No. 101,* of the U. S. Bureau of Standards, the eccentricities in general decreased with increasing load up to 30 000 lb. per sq. in., at least, thus showing that the eccentricities were primarily due to imperfect bearings in the testing machine rather than to bends or inherent eccentricities. The eccentric ratios correspond to the proportionate bending fiber stress, the maximum value of which in Table 9 is 19%, the next highest being 10 per cent. These values range about the same as in the series of tests made by the Society's Special Committee on Steel Columns and Struts.

25.—Other Studies of Eccentricity.—Several studies have been made of the question of eccentricity of loading and that due to bends and irregularities in section, value of E, etc., by many investigators. These studies are concisely summarized by Salmon,* and show a great variety of results, most of them much larger than those found from a study of the latest experimental results determined by strain gauge measurements. The values given are, in general, what may be called inferred eccentricities, determined in some cases by deflection measurements, in others by fitting curves from eccentric-load column formulas to results of tests; and in still others by a detailed consideration of practical conditions in manufacture. The total combined eccentricity due to all causes, expressed as the eccentric ratio, $\frac{e\,c}{r^2}$, ranges from as high as 0.60 to as low as 0.06. Morris† calculated values from deflections in Buchanan's tests of $\frac{e\,c}{r^2}$ from 0.01 to 0.20, averaging 0.07 (perpendicular to

* "Columns", by E. H. Salmon, pub. by Frowde and Hudder & Stoughton, London, England.

† *Engineering News,* Vol. 66.

pin) and much larger values parallel thereto. Prichard* suggests a value, $\frac{e\,c}{r^2} = 0.1 + \frac{l}{700\,r}$, and Basquin† suggests a value, $\frac{e\,c}{r^2} = 0.1 + \frac{l}{1000\,r}$, but this is based on existing column formulas, and not on tests. Salmon has plotted values of initial deflections, or bends, of many test columns, and shows that very few have bends greater than $e = \frac{l}{750}$. These suggested values are considerably greater than those calculated from strain gauge measurements given herein. Comparing them with the values for H-columns mentioned in Paragraph 23, Basquin's formula would give for $\frac{l}{r} = 100$, $\frac{e\,c}{r^2} = 0.20$, or $e = 0.16$ in., and for $\frac{l}{r} = 150$, $\frac{e\,c}{r^2} = 0.25$, or $e = 0.20$ in. Salmon's suggestion for initial bends would give for $\frac{l}{r} = 100$ ($l = 154$ in.), $e = \frac{154}{750} = 0.20$ in., and for $\frac{l}{r} = 150$ ($l = 230$ in.), $e = \frac{230}{750} = 0.30$ in.

26.—Eccentricities Shown by Relation of Ultimate Strength to Yield Point of Relatively Short Columns.—If the average yield point strength of the material is taken as a basis, some information can be deduced as to equivalent eccentricities from the data in Plate X. Taking no account of the effect of deflection on the stress, the maximum reduction of strength is 25% for $\frac{l}{r} = 100$. This would correspond to an increase of fiber stress due to eccentricity of $\frac{25}{100 - 25} = 33\frac{1}{3}\%$, or $\frac{e\,c}{r^2} = 0.33\frac{1}{3}$ per cent. However, at this length, the effect of deflection is considerable. The line, AB (Plate X), represents the result of applying an eccentric load formula in which $\frac{e\,c}{r^2}$ is taken at $0.1 + 0.001\,\frac{l}{r}$, and the maximum stress, S, at 36 000 lb. per sq. in. Comparatively few results lie below this line, and none of the tests made by the American Railway Engineering Association or the Society's Special Committee on Steel Columns and Struts. As far as these test results go, such a value, therefore, appears to be conservative, even for built-up members of many elements, and includes necessarily the effect of bends, eccentricity of load, variation in value of E, and all other factors. It represents rather a near approach to a maximum than an average effect.

27.—General Conclusion Regarding Eccentricities.—In the eccentricities calculated by the different methods, the various factors have in effect been lumped together in one result. In the case of flat-end tests, an important element is the adjustment of the specimen in the testing machine, or, as it may be called, eccentricity of loading. This information is an aid in judging the significance of test results, but is of little practical value in estimating

* *Transactions*, Am. Soc. C. E., Vol. LXI (1908), p. 174.
† *Journal*, Western Soc. of Engrs., Vol. 18, p. 543.

eccentricities in the column as used in the structure. Eccentricity of the actual loading, at least for any but pin-ended columns, must be determined by a study of the structure and not from testing machine results.

The other principal causes of eccentricity—crookedness and variation of size and elasticity of the elements—are important, and the tests can be considered as giving some information on this point, if indeed somewhat negative in character. That is, the combined effects of these factors can hardly be greater than the total as shown by the tests, as this would be the result with loads perfectly centered. Referring to Fig. 15, it will be seen that the value of e is seldom more than $\frac{1}{10}$ in., and is little affected by length. Considering this to be due entirely to initial bends, it would correspond, (considering the column as fixed) to a bend of 0.2 in., a considerably smaller value than that indicated by most estimates. These columns, however, were fabricated with especial care and were doubtless straighter than the average column.

Of all the factors contributing to eccentricity in the column in most modern structures and inherent in the column itself, it would appear that crookedness is the most important and the only element capable of direct determination. On this subject, information is very scarce, and what is available relates mostly to columns built for testing purposes. It would appear quite possible and feasible to obtain valuable information on this point by numerous careful measurements made in structural shops and on existing structures. This is a line of work well worth consideration. Eccentricity of load on riveted and flat-ended columns is a function of the entire structure, and has little relation to testing machine eccentricity. The column test can give useful information on the effect of crookedness, variation in material, form, and details, and for this purpose, it would appear that the loading should be applied centrally, or with a definite known eccentricity. From such tests, column formulas can be derived suitable for centrally applied loads, or for a certain assumed eccentricity as determined by a study of the action of the column as a part of the structure.

2.—The Unsupported Length of Column Components

28.—Sources of Information.—Although there is no comprehensive series of tests dealing with the effect of the unsupported length of components on the strength of built-up columns, considerable information concerning this subject is obtainable from the tests on wrought-iron columns of the box type reported in Tests of Metals and Other Materials (1881 and 1884), also, from the tests of Bouscaren, Buchanan, the American Railway Engineering Association, Talbot and Moore, and *Technologic Paper No. 101,* U. S. Bureau of Standards. These tests give some information relating to the effect of the unsupported length of cover-plate in channel-plate columns and the unsupported length of channels or ribs; also, some data concerning the effect of unsupported length in segmental columns of the older types.

29.—Unsupported Length of Cover-Plates.—Table 10 has been prepared from tests of wrought-iron columns reported in Tests of Metals and Other Materials (1884). As the pin diameters were 3½ in. and the deflections normal

to the pins at maximum loads were small, it was assumed that frictional restraint at the pins was sufficient to prevent rotation. The maximum fiber stresses given in Column (6) of Table 10 were calculated from the deflections recorded in the reports on the assumption of fixed ends. Ratio of rivet pitch to thickness of plate is given in Column (9), and Column (11) shows the behavior of the column at failure, *B* indicating buckling of the cover-plate and *D* indicating general deflection of the column. An examination of this information shows little difference in the behavior of columns of the various plate thicknesses or ratios, $\frac{p}{t}$. In all cases except two, the shortest columns of each group showed plate-buckling at failure, and the longer columns a failure by general deflection. Only one column of $\frac{l}{r}$ exceeding 50 $\left(\frac{l}{r} = 75\right)$ showed a buckled plate at failure. The average maximum fiber stress (Column (6)) for the columns with $\frac{1}{4}$-in. cover-plates was 33 700 lb. per sq. in.; for those with $\frac{5}{16}$-in. plates, it was 35 400 lb. per sq. in., and for those with $\frac{7}{16}$-in. plates, it was 35 300 lb. per sq. in. The ratio of the unsupported length to thickness, $\frac{p}{t}$, for the $\frac{1}{4}$-in. plate was about 24, and for the thicker plates about 20 and 12, respectively. The smaller average maximum stress sustained by the $\frac{1}{4}$-in. plates may be taken as some evidence of too great an unsupported length for these plates. This group shows also four values below 33 000, which was the lowest of the other group. Furthermore, four of the columns of the first group of $\frac{l}{r} = 74$ and $\frac{l}{r} = 87$ showed buckling of plates "after considerable deflection under maximum load."

It seems obvious that in the case of columns of small slenderness ratio, such as 40 or, perhaps, 50, a failure of the column at a load approximately equal to or perhaps greater than the average yield point of the material will be accompanied by a buckling of outside plates or outstanding flanges. Such a column is too short to fail by deflection without wrinkling the component parts on the concave side, that is, the material on the concave side will be strained somewhat beyond its yield point at maximum load, and if not held in place will wrinkle or buckle. This over-strain is well illustrated by the fact that columns of $\frac{l}{r}$ less than 30 quite generally carry loads greater than the yield point strength of the material. It would seem, therefore, that buckling of plates in the case of the shortest columns of this series is not to be taken as evidence of too great unsupported length; the most important factor is whether or not the rivet spacing was sufficiently close to develop the full yield point stress in the material before buckling. Judging by the results obtained with the thicker plates, this was probably not accomplished in the case of the thinner plates with $\frac{p}{t} = 24$, but was accomplished with $\frac{p}{t} = 20$,

or less. As far as these tests are concerned, they indicate that current practice in this regard is conservative.

Considering the plate between rivets as a flat-ended column, its value of $\frac{l}{r} = 3.46 \times \frac{p}{t}$ and for $\frac{p}{t} = 20$, $\frac{l}{r} = 70$. Reference to the values of column strength given in Plate X indicates that the strength of an ordinary column of such slenderness ratio is likely to be 10 to 15% below the yield point strength of the material; but in effect the unsupported length of the plate is considerably less than the rivet pitch so that the effective slenderness ratio is much less than 70.

Respectfully submitted,

F. E. TURNEAURE, *Chairman,*

MEMOIRS OF DECEASED MEMBERS

GEORGE HENRY BENZENBERG, Past-President, Am. Soc. C. E.*

DIED MAY 31, 1925.

George Henry Benzenberg was born in New York, N. Y., on May 31, 1847. One year later, his parents removed to Detroit, Mich., where he received his early education. He was graduated as Bachelor of Science in Civil Engineering at the University of Michigan in June, 1867.

Following his graduation, Mr. Benzenberg was engaged for two years on the primary triangulation of the Great Lakes, and from 1870 to 1873, he was employed on the location and construction of the Milwaukee Northern Railroad, from Cedarburg to Green Bay, Wis.

From 1874 to 1899, he served the City of Milwaukee, Wis., as Assistant City Engineer, City Engineer, and President of the Board of Public Works. He also served as Consulting Engineer and, in connection with their waterworks or sewerage systems, as a member of several engineering commissions for the following cities: Cleveland, Ohio, Kansas City, Mo., New Orleans, La., Omaha, Nebr., Toledo, Ohio, Racine, Wis., and a number of smaller cities, and completed the water filtration plant of Cincinnati, Ohio.

From 1904 to his death, Mr. Benzenberg served as a Trustee of the Northwestern Mutual Life Insurance Company. As Chairman of the Building Committee of the Trustees, he supervised the building of the home of this Company in Milwaukee, which is the outstanding building in that city and cost about $3 000 000. In 1910, he retired from all professional activities, except those connected with the supervision of the construction of the Insurance Company's building.

With the exception of the first six years, Mr. Benzenberg devoted his professional career to municipal work, many monuments of which indicate his outstanding ability as a resourceful engineer.

While building the water intake tunnel under Lake Michigan, a distance of 6 000 ft., for the City of Milwaukee, numerous blow-outs caused its temporary abandonment. The work was finally completed successfully under Mr. Benzenberg's direct charge.

After the intake water tunnel, crib, and shaft for the water-works of the City of Cleveland had been lost, he took the work under his immediate direction, and recovered them.

His plan for keeping the waters of the Milwaukee and Kinnickinnic Rivers free of sewage pollution by means of fresh lake water pumped into them near the city limits, was a bold undertaking and was condemned by many prominent engineers as impracticable. Mr. Benzenberg built the works and they have been eminently successful. To no other man is the City of Milwaukee so much indebted for its excellent water, sewer, and street improvements, all of

* Memoir prepared by the following Committee: John W. Alvord, M. Am. Soc. C. E., *Chairman*, C. F. Loweth, Past-President, Am. Soc. C. E., and T. Chalkley Hatton, M. Am. Soc. C. E.

which he originally planned, no material changes in these plans having since been found necessary.

In 1911, the University of Wisconsin awarded him the degree of Doctor of Science. In 1893 and 1894, he was President of the American Water Works Association, and, in 1895, became the first President of the American Society of Municipal Improvements.

In addition to his very active professional work, Mr. Benzenberg was quite as active in Masonic circles in which he was widely known throughout his own State and the country. He was a member of all the Masonic organizations, in many of which he had served in official capacities. He received his Thirty-third Degree in 1886 and, at the time of his death, was one of the three active members of the Supreme Council from Wisconsin.

On December 16, 1879, Mr. Benzenberg was married to Allie Wolfrum who survives him; his daughter, Mrs. May Benzenberg Mayer, of New York, N. Y., also survives him.

Throughout his life, Mr. Benzenberg was one of those engineers who, having broadness of vision, bold initiative, and high ideals, commanded the respect and confidence of the community in the improvement of which he took such an active part, and of those with whom he came in contact.

Mr. Benzenberg was elected a Member of the American Society of Civil Engineers on May 2, 1883. He served as Director of the Society from 1895 to 1897; as Vice-President in 1901 and 1902; and as President in 1907.

CHARLES HINCKLEY BAKER, M. Am. Soc. C. E.*

DIED APRIL 18, 1924.

Charles Hinckley Baker, the eldest of the five children of William Taylor and Eliza (Dunster) Baker, was born on November 30, 1864, at Chicago, Ill. His parents were natives of the States of New York and New Hampshire, respectively, and were both of English descent. Henry Dunster, the founder of the Dunster family in America, was the first President of Harvard University.

Charles Hinckley Baker was graduated with honors from Cornell University in 1886 with the degree of Bachelor in Civil Engineering. After one year of work on railroad construction in Dakota for the Chicago Northwestern Railway Company, he accepted a position in Seattle, Wash., in the same kind of work, with the Seattle, Lake Shore, and Eastern Railroad Company.

After three years Mr. Baker resigned from this position and opened a private engineering office in Seattle, and soon developed a contracting business for the construction of railroads and water-works. In 1891, he built, by contract, the Third Street and Suburban Electric Railway, in Seattle, and an electric light and power plant in connection therewith. Later, he was appointed Receiver of the Merchants National Bank of Seattle.

In 1898, he planned and constructed at Snoqualmie Falls the first hydro-electric power plant in the Northwest and organized the Snoqualamie Falls Power Company (later, the Seattle Tacoma Power Company), of which he was President, General Manager, and Chief Engineer until the end of 1904. This plant was, and still is, extremely novel for the reason that the power-house consists of a cavern hewn in the rock about 300 ft. below the bed of the river. The Niagara Plant had just been constructed with the turbines placed in the shaft underground, and Mr. Baker carried his work even further than that at Niagara by placing the whole plant underground.

In 1904, he moved to New York, N. Y., and was one of the organizers of the Muscle Shoals Hydro-Electric Power Company and the Alabama Interstate Power Company and, as Engineer, made the first surveys and plans for the Muscle Shoals Project. He also organized and served as Vice-President of the American Cyanamid Company. He was largely interested in reclaiming about 100 000 acres of land in the Everglades District in Florida, on which tract the City of Moorehaven is now located.

Mr. Baker's principal professional interest was in the development of new, original, and unusual projects. The fact that these enterprises were carried through to a successful conclusion is due in large measure to his clearness of vision and careful organization.

Four children survive him, namely, William T. Baker, Leslie D. F. Baker, Mrs. Dorothy Baker Calhoun, and Ruth Baker.

Mr. Baker was elected a Member of the American Society of Civil Engineers on June 4, 1902.

* Memoir compiled by C. B. Wing, M. Am. Soc. C. E., with the assistance of H. L. Gray, M. Am. Soc. C. E., William W. Best, Esq., of Seattle, Wash., and H. R. Hoffeld, Esq., of Buffalo, N. Y.

WILLIAM JAMES BALDWIN, M. Am. Soc. C. E.*

DIED MAY 9, 1924.

William James Baldwin, the son of Captain John and Giovanna Caterina (San Giovanni) Baldwin, was born on June 14, 1844, on shipboard, and his birth was recorded at Waterford, Ireland. He was educated in the schools of Boston, Mass., and of Charlottetown, Prince Edward Island.

In 1862, he entered the office of his father who was a Naval Architect and Surveyor for Lloyds (British), to study naval architecture, including navigation, drawing, engineering, and physics.

In order to acquire a practical knowledge of the details of ship construction, Mr. Baldwin, in 1864, accepted a position in the iron shipyard of Donald McKay, at East Boston, Mass., where he was engaged for two years on the construction of three monitors and the conversion of several blockade runners into cruisers. In 1866, he was made Assistant under Stephen Gates, Civil Engineer, in the construction and repair of iron ships at East Boston, but, in 1868, on account of the decline in iron shipbuilding, he turned his attention to general machinery. From 1870 to 1874, he served as Manager and General Superintendent of the Detroit Novelty Works, in charge of about 100 men, in the foundry, forge, and finishing shops.

From 1874 to his death, Mr. Baldwin engaged in professional practice as a Consulting and Designing Engineer, principally in connection with the construction and design of engineering plants for large public buildings, which included boilers, engines, elevators, pumps, small water-works, and ventilating and heating systems. Many of these buildings are of prominence in New York, N. Y., where he had established his headquarters, for example, the College of Physicians and Surgeons, the Vanderbilt Clinic, Sloane Maternity Hospital, and the old Tribune Building. He also installed engineering plants in many apartment houses; a department store; the Government buildings on David's Island in New York Harbor; the New York State Reformatory, Elmira, N. Y.; the Insane Asylum, Wilmington, Del.; Clayton Block, Denver, Colo.; and the elementary schools at Honesdale, Pa. In the State of Michigan, he installed engineering plants in the State Prison at Jackson, the prison at Ionia, the State School at Coldwater, and the State Insane Asylum at Kalamazoo. Altogether, the number of boilers designed and set under his supervision exceeded five hundred.

He was also Consulting Engineer for the Department of Health, City of New York; Consulting Engineer and Designer for the United States War College at Washington, D. C.; for the United States Immigrant Station in New York Harbor; and for the United States Soldiers' Home in Tennessee; as well as the New York Telephone Company and the Empire City Subway Company.

From 1880 to 1889, Mr. Baldwin was Associate Editor of *Engineering Record* in its Department of Sanitary Engineering. He also served as Lecturer

* Memoir compiled from information on file at the Headquarters of the Society.

and Professor of Thermal Engineering at the Brooklyn Polytechnic Institute, Brooklyn, N. Y.

He was an Honorary Member of the American Society of Heating and Ventilating Engineers; a Member of the American Society of Mechanical Engineers and the Telephone Pioneers of America; and a Life Member of the Brooklyn Chapter of the American Institute of Architects. Mr. Baldwin was also a member of the Committee of the American Society of Mechanical Engineers that formulated standard pipe threads (known as the "Briggs formula"), for the United States and Canada in 1886, and of the Special Committee for Electric Screw-Thread Standards, as well as of the International Committee for the Formulation of an International Standard for Pipes and Fittings.

He was the author of a number of books, of which the following have been published: "Steam Heating for Buildings" (1881); "Hot Water Heating and Fitting" (1887); "Baldwin on Heating" (1890); "Data for Heating and Ventilation" (1897); "An Outline of Ventilation and Warming" (1899); and "The Ventilation of the School Room" (1901). He was also a contributor to the Dictionary of Architecture and Building.

Mr. Baldwin was elected a Member of the American Society of Civil Engineers on September 5, 1888.

FRANK VALENTINE ERHARD BARDOL, M. Am. Soc. C. E.*

DIED APRIL 9, 1925.

Frank Valentine Erhard Bardol was born on June 12, 1869, at Erie, Pa. He received his early education in the public schools of Buffalo, N. Y., where his parents moved when he was a child. At the age of 16 he entered Cornell University as a student in Civil Engineering and was graduated with the degree of Civil Engineer in 1889.

In July, 1889, Mr. Bardol began his engineering career as Draftsman and Principal Assistant Engineer with the Lehigh Valley Railroad Company, at Buffalo, N. Y., under Division Engineer, S. T. M. B. Kielland, M. Am. Soc. C. E., where he was engaged in terminal improvements, including the construction of docks, warehouses, and yards at Buffalo, as well as at Duluth, Minn., and Chicago, Ill. He remained in the service of the Lehigh Valley Railroad Company until the end of 1891.

In January, 1892, he was appointed to and accepted the position of Assistant Engineer in the Bureau of Engineering, Department of Public Works at Buffalo, in direct charge of the construction and maintenance of bridges, street pavements, and also of general surveys and other miscellaneous work in the Bureau. He held this position until the end of 1897.

In January, 1898, at the age of 29, Mr. Bardol was appointed City Engineer of the City of Buffalo, and in this capacity was Chief Engineer of the Bureau of Engineering, Department of Public Works, in charge of the supervision of all construction and maintenance of public work in the city, except water. During his term of office as City Engineer, he was confronted with a number of the city's municipal problems, among which were the increase of the navigability of the Buffalo River; the solution of the railroad terminal problem for the city's various incoming lines; the Hamburg Canal nuisance; and various harbor improvements, which he was instrumental in obtaining through his efforts before the River and Harbors Committee at Washington, D. C.

On the expiration of his term of office as City Engineer of Buffalo at the end of 1901, Mr. Bardol retired from public service and immediately opened an office in Buffalo as Consulting Engineer and afterward as Construction Engineer. The years that followed in his comparatively short life were eventful in the extreme; his natural gifts along many different lines were outstanding not only in the formation of successful construction companies, but also as a keen investor which enabled him in a few years to become a multi-millionaire.

In 1902, Mr. Bardol formed the Eastern Construction Company, and as its President built a number of asphalt streets in Buffalo and adjacent towns. This Company was dissolved at the end of two years. In 1904, he organized the Eastern Concrete Steel Company, and as President built many structures, among which were a number of bridges, viaducts, and subways along the line of the New York Central and Hudson River Railroad; also similar structures

* Memoir prepared by F. J. Tresise, M. Am. Soc. C. E.

for the Lehigh Valley and Delaware, Lackawanna and Western Railroads, the State Normal School in Buffalo; the Buffalo City Hospital; and many other large buildings for Cornell University; Syracuse University; the Eastman Kodak Company, of Rochester, N. Y.; and the Larkin Company, of Buffalo.

In 1911, he became associated with the Rock Asphalt and Cement Corporation of Buffalo, and as Vice-President and General Manager was in charge of the construction of many millions of dollars of public improvements throughout the city. He was engaged in this capacity until his death.

In 1916, Mr. Bardol added to his many other interests the Erie Beach Amusement Park. In connection with the ownership of the Park, he purchased the Niagara Ferry and Transportation Company, operating between Buffalo and Fort Erie, Ont., Canada, across the Niagara River; the Buffalo and Fort Erie Railway Company, operating between Fort Erie and the Park; and a steamship line operating summer excursion boats from the foot of Main Street, Buffalo, to the Lake Dock at Erie Beach Park. This large enterprise, which for years had continued as a failure was, through his executive ability and business acumen, put on a highly paying basis within the nine years of his ownership and personal management, and enlarged and improved to such an extent that at the time of his death it ranked second to none in the United States.

In describing the career of Mr. Bardol the editor of a local paper stated:

"Frank V. E. Bardol was a most successful, if not conspicuous figure in the life of Buffalo. As Vice-President and General Manager of one of the two large local Paving Companies, he had the spending of millions of the taxpayers' money in the course of 25 years, but the politics inevitably connected with such a business he apparently left to his associates.

"Mr. Bardol was a thoroughly practical engineer with a keen business mind, and was one of those men who could make money out of his hobbies for he made a hobby of operating the Erie Beach, which he bought out of the Bankruptcy Court."

He was married to Katharine M. Bott, of Buffalo, on May 11, 1910, who, with three children, Franklin V. E., Robert George, and Edgar John, survives him.

Mr. Bardol was of a kindly disposition, and was eager to help those who were worthy of assistance. This was fully shown in his $250 000 endowment for scholarships in the University of Buffalo, and many other smaller gifts.

He was a member of the Buffalo Club; Buffalo Athletic Club; the Rotary Club; Buffalo Orpheus; Washington Lodge, F. and A. M.; the Buffalo Consistory; Ismailia Temple; and the Buffalo Fraternal Order of Eagles.

Mr. Bardol was elected a Member of the American Society of Civil Engineers on May 2, 1900.

GUION VICTOR BARRIL, M. Am. Soc. C. E.*

DIED APRIL 17, 1924.

Guion Victor Barril was born in New York, N. Y., on December 25, 1879. His paternal grandfather, John Joseph de Barril, came from Madrid when a young man, as Spanish Consul to Baltimore, Md., and remained in the United States, where he was well known in diplomatic and business circles. His maternal grandfather, William H. Guion, of the old "Guion Steamship Line," was one of the pioneers of the fast-going ocean steamers.

Mr. Barril was graduated from St. Francis Xavier College in New York, in 1898, and began his professional career as Rodman, with the City Surveyor of Baltimore, Md., remaining in this position approximately one year. From 1899 to 1901, he served as Rodman, Transitman, and Resident Engineer on preliminary and location surveys and on grade reduction for the Baltimore and Ohio Railroad Company.

In 1901, he held the position of Transitman and Chief of Party on grade reduction surveys for the Southern Railroad Company, and, in 1902, acted as Chief of Party on location surveys for the Baltimore and Ohio Railroad Company. From 1902 to 1904, he was Assistant to the Chief Engineer on general construction work for the Northampton Portland Cement Company, and for a few months served as Topographical Draftsman with the Erie Railroad Company.

On July 19, 1904, Mr. Barril went to the Isthmus of Panama as a Civil Engineer with the Isthmian Canal Commission. He was first engaged on general engineering work and, later, was made Assistant in Charge of Street Improvement and other municipal work in the City of Panama.

Leaving the Canal Zone in 1909, Mr. Barril spent one year in private practice in New York and vicinity, and from 1910 to 1911, served as Assistant Superintendent on double-track construction for the New York, Ontario, and Western Railroad, for the MacDonald Construction Company of New York. He devoted the next three years to railway construction work in Brazil. Returning to the Panama Canal in 1914, he was associated with the Engineering Staff of the Fortification Division, and was in direct charge of the construction of some important works.

In November, 1921, Mr. Barril left the service of the Panama Canal to take charge of the Panama Construction Company, in the Republic of Panama. He served as Chief Engineer of that Company which was engaged on the construction of about 50 km. of highway for the Republic. While on this work Mr. Barril showed extreme tact and resourcefulness in dealing with a class of labor unfamiliar with the various phases involved in the construction of a first-class highway.

On the completion of the highway contract, Mr. Barril became associated with the United States Army on the Canal Zone, where he was engaged on miscellaneous construction projects until his death on April 17, 1924.

* Memoir prepared by E. S. Randolph, Assoc. M. Am. Soc. C. E.

He was one of the pioneer builders of the Panama Canal, having arrived when the sanitary conditions were appalling and before modern science had dealt with the fevers and other diseases which are so prevalent in tropical countries. The improvements which have been wrought during the last twenty years, and have made the Canal Zone a winter resort visited by many tourists, are an enduring credit to, and an undeniable proof of, the efficacy of science, and much credit is due Mr. Barril for lending his assistance at a time when it was so greatly needed.

In August, 1900, Mr. Barril was married to Virginia Alexander, of Winchester, Va. He is survived by his widow, a son, John J. Barril, and his mother, Mrs. Benton Gauldre-Boilleau, of Washington, D. C.

He was an able constructor, a diligent student, and very thorough in planning and keeping records of his construction work. He was prominent in his community, a member of the Panama Rotary Club, of the Engineers Club of the Canal Zone, of the Knights of Columbus, and of the Society of the Incas, the latter being composed only of pioneers in the construction of the Panama Canal.

Mr. Barril was elected a Member of the American Society of Civil Engineers on July 11, 1921.

EDWARD ADAM BECK, M. Am. Soc. C. E.*

DIED OCTOBER 18, 1925.

When Edward A. Beck, City Manager of Lynchburg, Va., died in that city on October 18, 1925, the profession to which he had dedicated his life lost one of its ablest and most successful members. Although he was only forty years of age at the time of his death, his accomplishments were already conspicuous in the field of municipal administration, and he had reached the position where he was regarded as a leader in this important branch of modern city government.

Edward Adam Beck was born on January 19, 1885, in Peru, Ind., the son of John Henry and Catherine Magdelan (Silberman) Beck.

After attending the local elementary schools, he entered Purdue University, from which he was graduated in 1913 with the degree of Bachelor of Science. In 1917, he received the degree of Civil Engineer.

From 1906 to 1914, prior to and during his college course, Mr. Beck was engaged on engineering work, ranging from preliminary surveys for local electric lines to the construction of important railroad terminals. During five years of this period he served as Division Engineer of the Wabash System and had supervision of the location and construction of the important terminal at Detroit, Mich., including the negotiation for municipal franchises, a valuable training for the profession which he afterward adopted, and in which he was a real pioneer.

In 1914, he was called to the Borough of Edgeworth, Pa., as Borough Manager. He was the first to hold such a position in Pennsylvania and was able to do so only under a very liberal construction of the then existing laws. The experiment was, however, so successful, that general laws were promptly enacted by the State, permitting the adoption by municipalities of the manager form of government. During 1917, he was also Manager of Sewickley, a borough contiguous to Edgeworth. It is doubtful whether this unique distinction of serving two cities in such capacity at the same time has been enjoyed by any other City Manager.

When Mr. Beck resigned these positions, he was elected, from among a large number of aspirants, to the position of City Manager of Goldsboro, N. C., being the first official in this position for that city. During the period of approximately two years that he served in this capacity, he displayed marked ability as an administrative officer, and gained much valuable experience in the conduct of municipal affairs.

In 1918, he resigned his civil position to enter the Army during the World War. Commissioned first as Captain in the Sanitary Corps, he was later promoted to the rank of Major in the Engineer Reserves of the United States Army and was placed in charge of water supply, sewage disposal, and mosquito control, at Camp Shelby, Miss. He was under orders for overseas service when the Armistice was signed.

* Memoir prepared by R. W. B. Hart, M. Am. Soc. C. E.

After his discharge from military service Mr. Beck again entered the field of municipal management and was elected as City Manager of Auburn, Me., where he also held the position of Chief Engineer of the Water and Sewer District. So marked was his success in this position that the municipal authorities of Lynchburg, Va., after a careful survey of the entire field, of available candidates, elected him as its first City Manager. He entered upon the duties of his office in Lynchburg on September 1, 1920, and continued in this service until his death, which was caused by pneumonia, following an operation.

Mr. Beck brought to the administration of the affairs of Lynchburg an experience that peculiarly fitted him for the tasks there presented, having displayed such unusual ability, untiring energy, and genius for organization and management that he won the entire community to the ardent support of the new plan of government, although a number of its citizens had at first bitterly opposed the change. His record of accomplishment in Lynchburg not only gained recognition from the citizens of that community, but attracted the attention of those interested in city government in all parts of the United States, and he became definitely established as a distinguished leader in this new profession.

At the time of his death Mr. Beck had just completed the preliminary work necessary for the immediate rebuilding of Rivermont Bridge in Lynchburg. The work involved the change from an iron structure to one of reinforced concrete. The idea was his own and resulted in the saving of many thousands of dollars to the city. Because of the unusual height and length of the viaduct it is, perhaps, the most monumental work of this character ever undertaken and has attracted the interest of engineers in all sections of the country. In grateful recognition of the valued services of its first City Manager, and as a tribute that will most appropriately perpetuate his memory, the City Council has formally designated this structure, "Beck Bridge," and on its completion a suitably inscribed tablet will be unveiled with appropriate public ceremonies.

Mr. Beck was noted for the thoroughness of his knowledge of all the details incident to the administration of municipal affairs. He was, therefore, a man of prompt decision and of unusually sound judgment. The City Council soon learned that it could with confidence follow his recommendations in all matters with the assurance that they had been most carefully and intelligently considered by him.

He was a man of unfailing courtesy and consideration, and of absolute fairness. The humblest citizen could always gain access to him and receive an attentive hearing. The most influential person could not secure a privilege or a concession that he did not deem fair and just to all.

Possessing vigorous mentality and dauntless moral courage, he could maintain his conclusions with forceful ability in any forum, for he was a strong debater. He was often called on to address audiences interested in civic affairs and his utterances were controlled by a lofty conception of the true ideals of citizenship and public service.

Mr. Beck found a most congenial atmosphere in Lynchburg and frequently stated that he hoped to spend his life among its people. Such a pur-

pose was itself proof of the sincere affection in which he was held by them, and it was further attested when the news of his untimely and unexpected death shocked the city, for the whole community was grief-stricken and expressions of personal sorrow were heard from those in every walk of life.

Business was suspended throughout the city during the funeral ceremonies, and when his body was borne to its last resting place in Spring Hill Cemetery, it was laid in a grave that was banked with beautiful floral designs, tributes from nearly every organization in the city and from hundreds of individuals, while throngs of people assembled to share in this expression of a common sorrow for a great loss.

Although young in years, his life had been rich in service and filled with the joy of worth while achievement. On the people of every community in which he had lived, he left the impress of a clean and exemplary life devoted to the highest ideals. The influence of such an example never dies; no man can leave a richer legacy to posterity.

On June 26, 1907, he was married to Hazel Maude Locke, of Peru, Ind., and is survived by her and one son, Edward Adam Beck, Jr., as well as by a sister Mrs. Catherine Dilly, of Cleveland, Ohio, and a brother, Albert J. Beck, of Indianapolis, Ind.

Mr. Beck was a man of rare personal charm and one who delighted in the intimate associations of his fellows. He was a member of the Masonic Fraternity, having been a Thirty-second Degree Mason, a Knight Templar, and a Shriner. He was also an Elk and a Rotarian and was very active in the latter organization.

Mr. Beck was elected an Associate Member of the American Society of Civil Engineers on May 6, 1914, and a Member on November 26, 1918.

EDMUND HAMILTON BOWSER, M. Am. Soc. C. E.*

DIED MAY 8, 1925.

Edmund Hamilton Bowser was born at Louisville, Ky., on January 13, 1856. His father was John W. Bowser, formerly of Baltimore, Md., and his mother before her marriage was Anna Culver, of New Orleans, La. She was gifted as a poetess and wrote a prize-winning poem for the Nashville Centennial.

Mr. Bowser received his engineering education at Vanderbilt University, Nashville, Tenn., which he attended from 1878 to 1882. At the time of his graduation he was awarded a scholarship for the highest standing in the engineering class. For a year after graduation he remained at the University as Physical Instructor.

In 1883 he entered the service of the Cincinnati Southern Railway Company as Assistant Engineer, and continued in this position for two years. For three years thereafter he was in Florida, engaged in general engineering work. On April 15, 1888, he entered the service of the Newport News and Mississippi Valley Railroad Company as Assistant Engineer. This railroad later became the Chesapeake, Ohio, and Southwestern, and is now a part of the Illinois Central System. While with the Chesapeake, Ohio, and Southwestern Railroad Company he was stationed at Louisville, Ky., with the title of First Assistant Engineer, and was in charge of the work in the Bridge, Building, and Track Departments.

In 1898, a year after the Chesapeake, Ohio, and Southwestern Railroad was incorporated with the Illinois Central System, Mr. Bowser was made Roadmaster, with headquarters at Memphis, Tenn. He resigned this position in July, 1899, to become Assistant Engineer with the Louisville and Nashville Railroad Company, with headquarters at Pensacola, Fla. While in this position he had charge of several large dock projects. In October, 1903, he left the employ of the Louisville and Nashville Railroad Company to become General Manager of the Southern Creosoting Company, at Slidell, La.

On August 1, 1907, Mr. Bowser re-entered the employ of the Illinois Central Railroad Company as Chief Timber Inspector and on January 1, 1912, was promoted to the position of Superintendent of the Timber Department. On January 1, 1922, he became Superintendent of Ties and Treatment, which position he held until his death.

He was an active member of the American Railway Engineering Association and the American Wood Preservers' Association. He had served as a member of the Committee on Wood Preservation of the American Railway Engineering Association for about fifteen years, having been Vice-Chairman in 1912, 1913, and 1914. In the last report of this Committee,† Mr. Bowser contributed a paper entitled "The Effect of Preservatives on the Inflammability of Wood." He was a recognized authority on wood preservation and his papers on the subject attracted wide attention. For more than twenty years

* Memoir prepared by A. L. Dabney, M. Am. Soc. C. E.

† *Bulletin 270*, Am. Ry. Eng. Assoc., October, 1924.

he made a close study of wood preservation, and it is largely due to his efficient and conscientious work that the present high standard of wood treatment has been attained.

Mr. Bowser was a Charter Member of the Engineers Club of Memphis, a member of its first Board of Directors, and during 1922 served as President. Under his guidance the Club was inspired with a new enthusiasm and grew in membership and influence. At the close of his administration he delivered an address which is notable in the Club's history. It was immediately ordered published for distribution, and has the distinction of being the only paper that the Club has put into print. The following quotation from this address has, since its utterance, appeared on every *Bulletin* of the Club:

"The true Engineer is one who sees visions, and following his visions beyond the beaten path of common practice, does something that has not been done before, or does it in a better way."

From his boyhood Mr. Bowser had been an active member of the Unitarian Church. For five years he was President of the Board of Trustees of the of the Memphis Church, and was Chairman of the Building Committee for the new church building erected in 1923.

He was married to Alice Fairfax Smith, daughter of Judge James Power Smith and Julia Robert Smith, of Chattanooga, Tenn., on June 20, 1889. He is survived by his widow, three nephews, Allen F. Owen, of Chicago, Ill.; and Wilfred and David Bowser, of Anchorage, Ky., and two nieces, Miss Ethel Owen, of Washington, D. C., and Mrs. Helen Owen Lee, of Pasadena, Calif.

Mr. Bowser was drowned with the sinking of the Steamer *Norman* in the Mississippi River, near Memphis, Tenn., on May 8, 1925. He had with him a great-nephew, a boy ten years old. A small power boat came to the aid of the *Norman's* passengers, and Mr. Bowser swam to the side of this boat and placed the boy in it, but refused to get in himself until the women and weaker swimmers were saved. He swam away to assist others and was not again seen alive.

His sincerity, optimism, enthusiasm, and geniality won and held his fellow engineers who had for him a strong esteem and genuine affection.

Mr. Bowser was elected a Member of the American Society of Civil Engineers on June 1, 1904.

THOMAS PETTUS BRANCH, M. Am. Soc. C. E.*

DIED MAY 28, 1923.

Thomas Pettus Branch, the second son of Franklin Addison and Margaret Antonia Branch, was born at Tallahassee, Fla., on May 20, 1864. His father and grandfather were both Methodist ministers.

After completing his public school education he entered Vanderbilt University in September, 1881, and was graduated from that institution as a Civil Engineer in June, 1885.

In September, 1885, Mr. Branch assumed the duties of Professor of Mathematics and Engineering in the State Agricultural College at Corvallis, Ore., to which position he had been elected on the recommendation of Chancellor Garland of Vanderbilt University. At the end of his first year the ownership of the institution changed and the entire faculty resigned. Professor Branch served the Northern Pacific Railroad for the next three years, surveying and locating line and superintending the building of track through the mountains.

In 1889, he returned to Georgia and taught school for a few months in Meriwether County. Then, with a college friend, he surveyed and platted several towns in Tennessee, including Harriman. Between 1890 and 1894, he was in the service of the Savannah, Americus and Montgomery Railroad (now the Seaboard Air Line Railroad) and, as Field Engineer, built twenty miles of the line between Americus and Savannah, Ga. On the completion of this work, he entered the service of the Louisville and Nashville Railroad and was Resident Engineer at Guntersville, Ala., but his health having failed, he had to give up active field work.

In September, 1894, Professor Branch took charge of the Shellman, Ga., Public School and served in that position for one year.

In September, 1895, he became associated with the Georgia School of Technology as Adjunct Professor of Mathematics, and until his death was in charge of the Civil Engineering Department. For many years during this period he served as Secretary of the Faculty and Registrar. In 1920, the University of Georgia conferred on him the degree of Doctor of Science.

Dr. Branch had high ideals and lived a clean Christian life. He was an active member and for many years an officer in the Methodist Episcopal Church. Devotion to duty and loyalty to principle were the outstanding traits of his character. His long years of service in educational institutions developed in him a clear and balanced judgment of human nature, which, combined with a kindly and friendly personality, compelled the confidence and admiration of his associates and students.

At the Georgia School of Technology he shares the credit of having inaugurated the Co-Operative Educational Courses, and no member of its Faculty

* Memoir prepared by the late Paul H. Norcross, M. Am. Soc. C. E.

deserves more praise for its growth and influence. Dr. Branch's life was one of intensive and unselfish service. His influence on the undergraduates and their subsequent careers during the twenty-eight years that he was connected with the Georgia School of Technology is reflected in the admiration with which his name is held by those who knew him. He lived and died beloved by all.

In 1895, he was married to Mary Susie Pharr who died in 1907. In 1909, he married Mina Pharr Thweatt who, with a son, Thomas Pharr Branch, and a daughter, survives him.

Dr. Branch was elected an Associate Member of the American Society of Civil Engineers on February 5, 1902, and a Member on May 5, 1915.

FRED AZDELL BRYAN, M. Am. Soc. C. E.*

DIED JULY 23, 1924.

Fred Azdell Bryan, a prominent citizen and one of the leading business men of South Bend, Ind., died suddenly, of septic poisoning, on July 23, 1924. Although he was but little past middle age, he had achieved a remarkable record and left a considerable sphere in the world better for his having lived in it.

Fred Azdell Bryan was born in Mechanicstown, Carroll County, Ohio, on December 21, 1867, the son of John and Anna Azdell Bryan, the latter of Columbiana County, Ohio. He attended the common schools and High School in Wellesville, Ohio. In 1886, he entered the Pennsylvania State College, from which he was graduated in 1890, as a Civil Engineer. As a student he was diligent, bright, and prompt, and his sunny disposition and staunchness of character endeared him to a circle much larger than his own class. He was never ostentatious, nor would he seek to gain favor or preferment through rivalry with his peers and associates. Friendship was to him above all considerations of personal advantage. Unselfishness was an outstanding trait of his beautiful character; and, for such a personality, a useful and successful career was to be foretold during his student days. His whole life was singularly free from those antagonisms and personal animosities which men of affairs so commonly encounter in conducting large business enterprises.

Soon after leaving college, in 1890, Mr. Bryan was engaged as an Assistant in an engineering party with the Pennsylvania Railroad Company. During the next two years he was employed as a Draftsman and Transitman with the Denver and Rio Grande Railroad Company. From 1893 to 1896 he was with the Edison General Electric Company, as Engineer and Superintendent of Construction in the building of approximately 75 miles of city and interurban electric railroads. During the next five years, 1896-1901, he served as Assistant Engineer with the Michigan Central Railroad Company and was stationed at Niles, Mich. In this connection his work had to do with extensive improvements and relocation of tracks for reduction of grades and curvature, bridge renewals, etc., carried out by the late Augustus Torrey, then Chief Engineer of the Michigan Central Railroad.

About this time (1901) Mr. Charles A. Chapin, owner of the South Bend, Ind., Electric Company, undertook the promotion of an extensive scheme of hydro-electric power development on the St. Joseph River, to supply energy for electric lighting, electric railway operation, and general power purposes throughout the river valley. After searching for an engineer qualified by training and experience to take charge of this work, Mr. Chapin selected Mr. Bryan, and made him General Manager of the South Bend Electric Company, with headquarters at South Bend.

Mr. Bryan at once took charge of the design and construction of two dams and hydro-electric plants on the St. Joseph River, costing approxi-

* Memoir prepared by the late Walter Mason Camp, M. Am. Soc. C. E.

mately $1 500 000, followed by the construction of a steam plant, in South Bend, costing $250 000, to take the peak of the load. In addition, he had charge of the operation of two hydraulic plants and another steam plant, of similar capacity, already constructed and supplying power to South Bend.

These extensive power developments for the operation of varied public utilities comprised hydro-electric plants at Twin Branch, Elkhart, Ind., Buchanan and Berrien Springs, Mich., with a power distribution extending from Michigan City, Ind., and St. Joseph and Benton Harbor, Mich., on the west, to Ligonier, Ind., on the east—a densely populated and manufacturing district approximating 2 000 sq. miles in area—and constituting one of the largest electrical utilities of the Middle West.

So faithfully and successfully did Mr. Bryan prosecute the purposes of this public utility enterprise that he remained with it as engineering and executive head for twenty-two years. In 1908 the South Bend Electric Company became the Indiana and Michigan Electric Company, with Mr. Bryan as its President. It was through his vision, initiative, and executive ability that the original plant of the South Bend Electric Company was expanded to cover the additions previously mentioned.

In 1923 the controlling interest in the Indiana and Michigan Electric Company was sold to the American Gas and Electric Company. The new organization desired Mr. Bryan to retain the management of the property, but, largely owing to the condition of his health, he declined. Close application to the exacting requirements of multitudinous affairs had worn upon him, and he decided to seek relief in travel, with a view of engaging later in a business that would permit more time for recreation than he had previously been able to enjoy.

Early in 1923, shortly after severing his connection with the Indiana and Michigan Electric Company, Mr. and Mrs. Bryan started on an extended tour of the Orient. They visited Hawaii and Japan and traveled far into the interior of China. While in China, Mr. Bryan received a cablegram offering him an important position as a Consulting Engineer with the Studebaker interests, to serve in an advisory capacity with the Harris Trust and Savings Bank, of Chicago, Ill., which was financing the Studebaker enterprises, consisting of traction, gas, and water utilities in Illinois and Missouri. He accepted this offer, and on his return to the United States in the fall of 1923, became actively engaged in his new occupation, with an office in South Bend, spending a part of his time, more or less regularly, in Chicago. He was thus engaged at the time of his death.

In his civic activities Mr. Bryan was hardly less distinguished than in his engineering and executive achievements. His admirable qualities of character, taken with his trained intellect and genius for organization, made him a splendid type of public-spirited citizen. Besides being a Director in the Citizens National Bank, of South Bend, he was a member of the Chamber of Commerce, the South Bend Country Club, the Knife and Fork Club, the Indiana and University Clubs, the Phi Gamma Delta Fraternity, and of the Union League and the Indiana Society in Chicago. He also served as President of the South Bend Boy Scouts' Council, to which he gave much of

his time and energy, and as a Director of the City Reserve Mission, and was a member of the First Presbyterian Church.

During the World War Mr. Bryan was placed in charge of the Third Liberty Loan for Northern Indiana, and the alacrity with which his district subscribed its full quota was credited to the executive ability and good will which he brought to bear upon this very pressing and indispensable financial project of the nation.

It is exceptional that the life of one engaged with as many business affairs as Mr. Bryan could be occupied so largely with the public enterprises of the community in which he lived. His masterful organization and management of the Boy Scout movement won for him not only the love and veneration of the boys but the admiration of the general public. In South Bend, with a population of about 80 000, the proper rearing of children has been studied as one of the most serious social problems of the community, and the zeal which Mr. Bryan put into this work was greatly appreciated and commended. His efforts in this service, in which he became so eminent, may have been prompted by recollections of the early years of his own life, or by the fact that he himself was childless. He had, by nature, a warm spot in his heart for boys. It is said, further, that he was constantly on the lookout for worthy boys ambitious for an education but lacking opportunities to acquire it; and that, in many instances, he found ways and means to place such young men in a position to realize their objective without letting them know their benefactor. It is deserving of all commendation that in his will he provided a substantial trust fund the income from which was designed to meet the cost of constantly maintaining four young men in college, the favored ones to be selected from among worthy boys of South Bend identified with the Boy Scout organization.

It would have been incompatible with Mr. Bryan's success as a public utility executive and leader in social service had he not been a man of independent opinions on public questions and policies. Although he was habitually frank and outspoken in the expression of his views, yet his manner of address was always so considerate and kindly that he seldom, if ever, offended. This can be said notwithstanding that there often fell to him the difficult task of conducting negotiations with State commissions, municipal councils, and other civic authorities regarding matters of franchise rights or rate adjustments. He had a way of presenting his case that seldom failed to carry conviction. An open manner and conservative habit of statement, a conspicuous sense of fair dealing, a direct method of getting to the point of a question were characteristic of Mr. Bryan and accomplished for the interests that he represented what most men of affairs would not attempt to carry through without the employment of qualified legal talent. His willingness to consider broadly the rights of others and a dignified manner of dealing were the criteria of his business methods.

In his social life, as in his business career, Mr. Bryan always held to high ideals and his tastes were cultural. He was married on June 9, 1896, to Estelle M. McVicker, of Lisbon, Ohio, who survives him.

Mr. Bryan was elected a Member of the American Society of Civil Engineers on December 1, 1908.

ENRIQUE BUDGE, M. Am. Soc. C. E.*

DIED JUNE 2, 1924.

Enrique Budge was born in Valparaiso, Chile, on November 15, 1844, the son of Robert Forbes Budge, a native of Scotland, and Mercedes Prats y Urizar. Robert Forbes Budge was an *ex*-officer of the British Navy, who after the surrender of Napoleon Bonaparte retired from the service. He made two voyages to Chile, the first in 1818 and the second in 1820. He then remained in that country and, after a few years, married Mercedes Prats, the daughter of the Postmaster-General of Chile. Enrique Budge was the seventh son of a family of ten. He began his education at the English school of Messrs. Bloom and Goldfinch in Valparaiso, specializing in mathematics.

Mr. Budge began his technical career in 1863 at the Victoria Foundry and Iron Works of Messrs. Henderson, Flynn and Company, of Valparaiso, where he acquired a practical knowledge of structural engineering that was of great assistance to him in his subsequent work. In 1864, he joined the forces of the Valparaiso and Quillota Railway, then under construction by the renowned English engineer, George Lloyd. In 1865, he was appointed by the Chilean Government as Assistant Engineer on the San Fernando and Curico Railroad and, in 1867, undertook the work of turning the course of the Rio Teno near Curico. This river, due to extraordinary freshets, had inundated the neighboring farms, and Mr. Budge opened a new course for its flow by cutting the railway embankment, thereby completely isolating the railway bridge. This work was most successful.

From 1867 to 1869, he was Resident Engineer of the work at Paso Hondo, on the Valparaiso and Santiago Railroad. This work included difficult alignment of the track, which crossed the Paso Hondo River five times in a distance of 800 m. It also included the construction of heavy embankments, cuts, and tunnels to obtain the most economical layout which called for a single bridge and a tunnel to cross the stream, at a consequently low maintenance cost, which was the end desired. As the old bridges had been built ten years previously of timber with arched spans and were of different sizes, a serious difficulty was encountered because of the enormous expense entailed, including the delay of traffic. The new location, therefore, was accepted as a solution inasmuch as it did not interfere with the traffic. Having completed this work, he was appointed in 1869 as Resident Engineer of the Valparaiso and Santiago Railroad.

From 1870 to 1872, as Resident Engineer, Mr. Budge surveyed and constructed the Los Vegas and San Felipe Railroad, a branch of the main line from Valparaiso to Santiago, Chile, and from 1872 to 1874, he extended that branch line 45 km. to Los Andes, Chile, the starting point of the Chilian Transandine Railway to Argentina through the Cordillera de los Andes, *via* Mendoza. This railroad completed, he was again in charge, as Resident Engineer, of the Valparaiso and Santiago Railroad, including the Los Andes Branch.

* Memoir prepared by Edward B. Budge, M. Am. Soc. C. E.

In 1875, the Chilian Government awarded by contract the construction of the Curico and Angol Railroad and the Chillan, Concepcion and Talcahuano Railroad, a total length of 425 km. Technical and financial difficulties began with the contractors and the bankers who were to provide the funds for the work, and, consequently, with the Government itself. Mr. Budge, whose sound judgment and knowledge of railway construction had already greatly helped the Government on similar occasions, was proposed as Chief Engineer and Controller of Finances of the enterprise, and was immediately accepted in this capacity by mutual agreement of the three parties concerned. Work on this part of the Chilian Railway System was most difficult and expensive, as the railway extends to the southern part of the Republic and crosses all the rivers of the country, which flow from east to west and are subject to heavy freshets in winter. Moreover, as the large bridges included in the contract were to be temporary on account of the cost involved and the time required for permanent structures, and yet had to be of sufficient strength to withstand the traffic during the winter, the contractors were at a loss as to how to comply with the Government requirements; but, fortunately, Mr. Budge's perseverance and sound advice overcame all difficulties.

In 1878 and 1879, he was commissioned by the Chilian Government to study the construction and working of railroads in Europe and the United States, but on account of the war with Peru and Bolivia, he was obliged to return to Chile before finishing his commission, having visited only European countries. He was again appointed Resident Engineer of the Valparaiso and Santiago Railroad in 1880, and in 1881 he was appointed Chief Engineer and Director of the new Government mole at Valparaiso, a very important and complicated work which required a foundation of fifty-three caissons, from 20 to 100 ft. long, and 11½ ft. in diameter, sunk by the pneumatic process and filled with mortar. On this foundation iron bridge girders were anchored, and a system of smaller girders supported a concrete pavement laid on steel buckle-plates. In this pavement were embedded the tracks for the heavy hydraulic cranes used for unloading material directly from the ships, and also tracks for hauling loaded and empty cars. A 60-ton hydraulic crane was erected for handling extra heavy loads. This mole has stood as a monument to Mr. Budge's enterprise, for neither storms nor the great earthquake of 1906 did the least damage to the solid foundations of this unique structure. During these years, he also studied and carried out plans for the water-works systems of the Towns of Curico, San Felipe, and Los Andes.

In 1884, he was called upon by the Chilian Government to take charge as Engineer in Chief of the whole plan for Government railways from Valparaiso to Talcahuano and Angol. He, therefore, undertook the work of reconstructing all the important temporary bridges, which, having been built under economical conditions, were actually a great hindrance to railway traffic, particularly as in winter heavy freshets were sure to destroy some of the bridges and embankments. Among many others, he reconstructed the Nuble Bridge, the Laja Bridge, and the Bio-Bio Bridge, each 500 m. long, in 50-m. spans. The abutments and piers were built by the pneumatic process because these rivers

carry such a volume of water that no other form of foundation was considered satisfactory.

Mr. Budge continued his connection with the Chilian State Railways until 1894, and, during that time, he served as Director-General of the State Railways in 1885, 1891-92, and 1894. His work on these railways was of the utmost importance, and involved, in addition to the construction of bridges as previously mentioned, new lines, stations, etc., making improvements in accordance with the latest engineering practice.

He had been a member of the Sociedad de Fomento Fabril (an organization of merchants and manufacturers formed to promote Chilean business interests), since 1883, and served as Counselor in 1889; Vice-President in 1898; and President from 1902 to 1908. Due to his important and long service he was nominated in 1909 as Honorary President, which office he held until his death. During his term of office, he organized three technical schools in Santiago, and one in each of the following towns: Talca, Chillan, Concepcion, Valdina, Serena, and Iquiquè.

In 1901, Mr. Budge undertook the work of preparing an exhibit to be entered by the Chilian Government at the Pan-American Exposition, at Buffalo, N. Y., and was given charge of this task as General Commissioner for Chile. It was due to his unfailing energy and propaganda in favor of this plan that his country was able to hold a most merited and flattering position in that World's Fair.

In 1904, he was again appointed by the Government to take charge of the Chilean National Exposition, which was carried out principally by the Sociedad de Fomento Fabril and was a great triumph for Chilean industries. The thanks of these industries were tendered Mr. Budge who had devoted all his experience to the success of the undertaking.

He acted as Consulting Engineer to Messrs. Clarke Brothers who had concessions from the Chilean and Argentina Governments for building the Transandine Railway to Argentina. When the proposed plans were submitted to him, he at once offered a complete modification of them. In order to use the common steam locomotive to reduce the general gradient of 8%, the proposed plans had included a series of costly loops and tunnels. Mr. Budge at once recommended the higher grade and the use of the Abt rack system. The contractors immediately grasped the idea and accordingly new plans were drawn using a grade of 8%, with rack line, which resulted in great economy in cost and time of construction. This line crosses the Andes at a height of 10 500 ft., through a tunnel 3 144 m. long.

Mr. Budge acted on behalf of the Government as Consulting Engineer to report on the proposal for the construction of the graving dock at Talcahuano; he also reported on the construction of wharves and quay walls for the Port of Iquique and a mole for Pisagua.

The terrible earthquake at Valparaiso in August, 1906, which destroyed this and neighboring cities and resulted in enormous losses through death and fires caused by falling houses, introduced a most serious problem as regards the reconstruction of the city. Mr. Budge was called on by the Government to undertake this work which required an experienced engineer.

New plans had to be laid out, new grading from hills to the sea-front, new outlets for the streams, new streets—in short, a new city had to be designed with modern causeways and footpaths, with an expenditure of £3 000 000 gold.

Having completed this work of reconstruction, Mr. Budge was nominated in 1910 as Inspector General of Materials to be furnished to the Chilean Government by European and North American firms. He devised a sound method of financial accounting for materials provided to the railways and Government contractors, including those used in the construction of quay walls and breakwaters at Valparaiso, by the firm of S. Pearson and Son, Limited. He held that office until 1920, during which time he visited the principal manufacturing establishments of Europe and the United States.

On his return to Chile, Mr. Budge was appointed Director of various industrial corporations, which positions he held until his accidental death. In his endeavor to pass through a crowd in one of the banks in Santiago, he fell into a deep trench recently opened for the layout of electric cables, striking his chin. This blow caused concussion of the brain which gradually developed into paralysis and subsequent death.

Mr. Budge was very active, never tiring of any work that he undertook. He was the first President of the Portland Cement Factory, "El Melon", the only factory of its kind in Chile, and placed it on a sound financial basis. It can be truly said of him, that up to 1910 no engineering plan was carried out by the Government of Chile or by Chilean contractors without his endorsement, so that his name is connected with almost all the public works constructed in Chile during the last fifty years.

Mr. Budge is survived by his widow, Mrs. Carolina Zañartu de Budge, and three children, Olga, wife of Augustin Edwards, Chilean Minister to Great Britain, Carlos, and Enrique.

He was elected a Member of the Institution of Civil Engineers of Great Britain and also a Member of the Institution of Mechanical Engineers in 1879. He was a faithful member of the Roman Catholic Church.

Mr. Budge was elected a Member of the American Society of Civil Engineers on February 1, 1882.

WALTER MASON CAMP, M. Am. Soc. C. E.*

DIED AUGUST 3, 1925

Walter Mason Camp, the son of Treat Bosworth and Hannah A. (Brown) Camp, was born at Camptown, Pa., on April 21, 1867. He came of Colonial ancestry; his earliest paternal American ancestor was Nicholas Camp, who came from Essex County, England, in 1631, with the Rev. John Elliott, and settled in Massachusetts. Both his paternal and maternal ancestors served in the Revolutionary War. His father who was an insurance surveyor and the author of insurance literature, served as Captain of Company F, 52d Pennsylvania Infantry, during the Civil War and was once confined in Libby Prison.

Mr. Camp received his preliminary education by winter attendance at the public schools in Wyalusing, Pa. At the age of nine he was employed as a fireman in a planing mill at Wyalusing and, later, for four years, he worked on farms and at lumber camps. From 1882 to 1887, he was with the Lehigh Valley Railroad Company as Trackman, Chainman, and Rodman on preliminary and location surveys, and double-track construction, and, later, on extensive river surveys for bridge location. During this time he acquired also a working knowledge of telegraphy.

In 1887, Mr. Camp entered Pennsylvania State College, from which he was graduated in 1891 as Civil Engineer. For a few months following his graduation he served as a Surveyor with the San Joaquin Valley Railway Company, at Fresno, Calif., and as Draftsman in the office of the Chief Engineer of the Southern Pacific Company, at San Francisco, Calif. From 1892 to 1894, he was Engineer and Superintendent of the Rainier Avenue Electric Railway, Seattle, Wash., which extended eight miles into the suburbs; he had full charge also of the location and construction of an uncompleted part of the road. He designed and built rolling stock for heavy freight traffic, repair shops, station buildings, and wharves for the steamers operated in connection with the railway and also designed and rebuilt a counterweight system for operating electric cars on a 17% grade.

Mr. Camp was with the Seattle, Lake Shore, and Eastern Railway Company as Engineer in charge of building spur-tracks into lumber camps in 1894 and 1895. His work here consisted in relocating and rebuilding parts of the main line, widening cuts and embankments, and reballasting parts of the roadbed. He served also as Work Train Foreman, Surveyor, and Section Foreman. In 1895, in addition to other work, Mr. Camp studied as a post-graduate student in electrical and steam engineering at the University of Wis-

* Memoir compiled from information on file at the Headquarters of the Society.

consin, and, in 1896, taught for a short time in the National School of Electricity in Chicago, Ill. He then accepted the position of Receiver and Inspector of Materials for construction, and served as Superintendent of Construction, for the Englewood and Chicago Electric Railway Company (a storage battery road), in Chicago. He also had charge of building the counterweight system for this Company in Morgan Park, Ill.

In the spring of 1897, Mr. Camp became Engineering Editor and, later, Managing Editor of the *Railway and Engineering Review* (now the *Railway Review*), in Chicago. He served also as Consulting Engineer to the Englewood and Chicago Electric Railway Company, with reference to the operation of the counterweight system and in repairing it.

He acted as Consulting Engineer to capitalists investigating the cost of construction, operation, and traffic possibilities of an electric railway for Towanda, Pa., in 1898, and, in 1899, to the Automatic Rail Joint Spring Company of Chicago in reference to track fastenings and the manufacture of concrete ties. In 1900, he was consulted by the Kobu Railway Company of Japan in the matter of the selection of track materials.

Mr. Camp was admired as a writer by members of the railroad fraternity because of the clear and forceful presentation of his opinions. He was particularly well versed in matters relating to track maintenance and automatic train control. On learning of his death, one of his associates remarked: "He was the best-informed man I ever knew". His published works, excluding his editorials, comprise "Notes on Track," which is used as a textbook in colleges having Railroad Departments; "Life of Samuel F. Patterson"; and "Railroad Transportation at the Universal Exposition, St. Louis 1904". He was also the author of numerous papers published by engineering and historical associations. No one was ever in doubt as to the exact meaning of his editorials, which were based on thorough investigation and sound knowledge. He understood railroad conditions thoroughly.

Although devoted to the work of his profession, Mr. Camp was a man of varied interests. He was fond of outdoor life and owned and operated a farm at Lake Village, Ind., where he became a successful farmer. He also had a quiet retreat in the Michigan woods. He was a student of Indian life, customs, and history. He spoke a number of Indian languages and dialects and had made a study of their wars with the white man from the standpoint of the Indian. His vacations were often spent in research work on their reservations in the West where he was a welcome visitor, and it was not unusual to see a group of Indians in his office seeking advice. Mr. Camp was also a student of Astronomy and was interested in the question of whether or not the planets are inhabited. In his will he provided a fund which is to be used by the Northwestern University to carry on research work to investigate this problem.

He was greatly concerned in the welfare of young men, many of whom profited by his kindly counsel. His cabin in Michigan and his farm were always at their disposal. He was married, at Blue Island, Ill. on May 2, 1898, to Emeline L. F. Sayles, who survives him.

He was a member of the American Railway Engineering Association; American Railway Bridge and Building Association; Roadmasters' and Maintenance-of-Way Association; Society for the Promotion of Engineering Education; Permanent Way Institution (Great Britain); Railway Signal Association (now Signal Section of the American Railway Association); Mississippi Valley Historical Association; Western Society of Engineers; Chicago Engineers Club, and others.

Mr. Camp was elected a Member of the American Society of Civil Engineers May 1, 1901.

CHARLES EDWARD LAW BALDWIN DAVIS, M. Am. Soc. C. E.*

DIED JUNE 4, 1925.

Charles Edward Law Baldwin Davis, the son of Charles S. A. and Mary Jeanette (Downs) Davis, was born at New Haven, Conn., on February 16, 1844. After spending one year in the Academic Department of Yale College in 1861-62, he was appointed a Cadet at the United States Military Academy, at West Point, N. Y., on July 1, 1862. He was graduated from West Point on June 18, 1866, and commissioned a Second Lieutenant of the Corps of Engineers, United States Army. He was promoted to the rank of First Lieutenant, Corps of Engineers, on March 7, 1867; Captain on September 12, 1877; Major on April 7, 1888; Lieutenant-Colonel on May 3, 1901; Colonel on October 10, 1905; and Brigadier-General U. S. Army, on January 29, 1908.

Lieutenant Davis served on various military duties at Willets' Point and West Point, N. Y., and as Assistant Engineer in the construction of fortifications at Boston, Mass., Harbor, from 1866 to 1872. He was Assistant Engineer on the improvement of the mouth of the Mississippi River, from December 9, 1872, to May 1, 1876, and of Galveston Harbor, Texas, from 1876 to 1881. Captain Davis was then assigned to duty with the Light House Establishment, as Engineer of the Tenth Lighthouse District (1882), and afterward of the Eleventh District (1882 to 1886), and was also in charge of the improvements of the rivers and harbors of the Milwaukee, Wis., Engineer District, from 1882 to 1892.

From 1892 to 1896, Major Davis was on duty at Washington, D. C., in charge of the defensive works of the Potomac River, of certain river and harbor improvements in Maryland and Virginia, of the construction of a sewerage system at Fort Monroe, of the reconstruction of the Washington end of Long Bridge, of repairs to the Aqueduct Bridge across the Potomac, and of a survey and plan of a bridge across the Eastern Branch of the Potomac at the foot of South Capitol Street, Washington. He was also, during this period, a member of the Board of Officers to report on the various types of disappearing carriages for seacoast fortifications, and, from 1895 to 1896, was in charge of increasing the water supply of Washington, D. C.

From 1896 to 1902, Colonel Davis was stationed at San Francisco, Calif., in charge of the fortifications in that locality and in the Hawaiian Islands, as Engineer of the Twelth Lighthouse District. He also served as member of the California Débris Commission to regulate hydraulic mining. During part of this time he had charge of the improvements of the harbors of Wilmington, San Diego, and San Luis Obispo, Calif., as well as of the construction of the breakwater at San Pedro, Calif.

From 1902 to 1904 he was Division Engineer of the Philippine Division, and was in charge of the designing of fortifications and of military map-making in the Philippine Islands. From 1904, until his retirement from active service, on February 16, 1908, General Davis was in charge of the improvement of the channels connecting the waters of the Great Lakes, between Chicago,

* Memoir prepared by C. McD. Townsend, Col., U. S. A. (*Retired*), M. Am. Soc. C. E.

Ill., Duluth, Minn., and Buffalo, N. Y., his work including the design and commencement of the construction of the third lock in the canal at Sault Ste. Marie, Mich., the enlargement of the channel of St. Marys River, and the construction of the Livingston Channel.

In 1907 and 1908, he was also Division Engineer of the Lakes Division, Detroit River. After his retirement from the military service, General Davis was employed in 1910 and 1911, as United States Agent in charge of fortifications and river and harbor work in the San Francisco District.

General Davis had a most pleasing personality, and, although he never posed as a specialist in any particular branch of engineering, he had executive ability which enabled him to accomplish successfully the numerous and varied duties to which he was assigned during his professional career.

His fame as an engineer will be perpetuated by the inauguration of the lock which bears his name at Sault Ste. Marie. The Davis Lock is a concrete structure, 1 350 ft. long, between miter sills 80 ft. wide, and has 24½ ft. of water on its miter sills at low water, with a lift varying from 17 to 21 ft., dependent on the varying stages. With its companion, the Sabine Lock, which has recently been constructed, it is one of the largest lift locks in the world, being exceeded only by those of the Panama Canal.

General Davis was elected a Member of the American Society of Civil Engineers on July 12, 1877. He was also a member of the Army and Navy Club of Washington, D. C.

GEORGE DEVIN, M. Am. Soc. C. E.*

DIED MAY 28, 1925.

George Devin, the son of M. L. and Amanda J. Devin, was born in Macon County, Illinois, on February 27, 1847. The family afterward removed to a farm near Des Moines, Iowa, where he attended the public schools.

In June, 1864, Mr. Devin enlisted in Company B, 48th Regiment, Iowa Infantry, and served until he was mustered out in the following October. In 1871, he entered Cornell University, from which he was graduated in 1873, with the degree of Bachelor in Civil Engineering.

Following his graduation, Mr. Devin was employed on construction work by the firm of T. B. White and Sons, of New Brighton, Pa. (afterward the Penn Bridge Company, of Beaver Falls, Pa.), and served as Superintendent of Shops for that firm.

He was afterward a member of the firm, and Manager, of the Pittsburgh Bridge Company, of Pittsburgh, Pa. Among his associates in the organization of this Company was Mr. John A. Nichols, formerly Master Mechanic of the Keystone Bridge Company. One of the notable works of that firm was the reconstruction of the Railway Suspension Bridge at Niagara Falls. In 1881, he engaged in independent contracting for bridges in connection with the Delaware Bridge Company, of Athens, Pa., of which Charles Macdonald, Past-President, Am. Soc. C. E., was then President.

During practically all his subsequent work, Mr. Devin was engaged in the design and construction of bridges, in contracting in connection therewith, or in a consulting capacity. He was identified at different times with the Wrought Iron Bridge Company, of Canton, Ohio, as Assistant Superintendent; the King Bridge Company, of Cleveland, Ohio, as Engineer; the Atlanta Bridge Company, of Atlanta, Ga., as Superintendent of Erection; with the late Theodore Cooper, M. Am. Soc. C. E., of New York, N. Y.; the Pottsville Bridge Company, of Pottsville, Pa., as Chief Engineer; the Penn Bridge Company, of Beaver Falls, Pa.; the American Bridge Company; the Kansas City Terminal Company, Kansas City, Mo., etc. He also was engaged in private practice as a Consulting Engineer in Chicago, Ill., New York, N. Y., and St. Louis, Mo.

On July 25, 1876, Mr. Devin was married to Emma R. Lowry, of New Brighton, Pa., who died in St. Louis, Mo., in 1922.

Shortly after his wife's death, Mr. Devin retired from active work and, later, became an inmate of the National Home for Disabled Volunteer Soldiers at Sawtelle, Calif., where he remained until his death. He was buried in the Home Cemetery with full military honors on June 1, 1925.

* Memoir prepared by T. Sidney White, M. Am. Soc. C. E.

He was the eldest of six brothers, only one of whom, James Devin, of Des Moines, Iowa, and a sister, Mrs. Sarah D. Clarke, of Redwood City, Calif., survive him.

Mr. Devin had a great liking for mechanical problems, and took much pleasure in mathematical calculations, investigations, and analyses, and, also, in studies of stresses in iron and steel structures.

He was a man of absolute integrity, considerate of others, and possessed of a strong sense of loyalty to and affection for his friends.

Mr. Devin was elected a Member of the American Society of Civil Engineers on September 7, 1887.

JOHN HOFFMAN DUNLAP, M. Am. Soc. C. E.*

DIED JULY 29, 1924.

John Hoffman Dunlap, son of George Harlan and Mary Catherine (Folger) Dunlap, was born in Harrisville, N. H., on September 9, 1882. He was educated in the public schools of Concord, N. H., and in Dartmouth College, from which he received the degree of Bachelor of Arts in 1905, and the degree of Civil Engineer from the Thayer School of Civil Engineering in 1908. Between 1905 and 1908, besides doing the work for his engineering degree, he served with the United States Reclamation Service, in Nevada, and for a time with the Pennsylvania Lines West, in Columbus, Ohio.

During the summer of 1908, Mr. Dunlap was Field Instructor in the Thayer School, and in the fall of that year he was engaged as Instructor of Descriptive Geometry and Drawing by the College of Applied Science of the State University of Iowa, with which institution he remained until his appointment as Secretary of the American Society of Civil Engineers, in 1922. He was made Instructor in Civil Engineering in 1909, Assistant Professor of Hydraulics and Sanitary Engineering in the Department of Civil Engineering in 1911, Associate Professor in 1917, and Professor in 1920.

During his stay in Iowa Mr. Dunlap was engaged in engineering work, as time permitted, was for seven years Secretary-Treasurer of the Iowa Engineering Society, and for one year its President, and he wrote and published more than twenty-five papers on various engineering matters, principally in the field of sanitary engineering practice.

He was also active in the formation of the Iowa Section of the American Society of Civil Engineers and was its President for one year.

Mr. Dunlap was a member of the Society for the Promotion of Engineering Education, the New England Water Works Association, the American Water Works Association, the American Public Health Association, the Proportional Representation League, Gamma Alpha, Phi Beta Kappa, Sigma Xi, and of the Sigma Nu Fraternity. During the later years of his residence in Iowa City, he was President of the Social Service League of Iowa City, and a member of the Executive Committee of the Boy Scout Council.

On June 29, 1910, in Franklin, Vt., he was married to Fanny Maria Gates. She and three sons, George Spaulding, Richard Folger, and Clark Gates, are living.

Mr. Dunlap's death resulted from injuries sustained in a railroad wreck near Chicago, Ill., on June 30, 1924, as he was returning from the Annual Convention of the Society that had been held in Pasadena, Calif. He was buried in Franklin, Vt., on July 31, 1924.

Mr. Dunlap was elected an Associate Member of the American Society of Civil Engineers on April 17, 1917, and a Member on June 6, 1921. He was elected Secretary of the Society on June 19, 1922.

* Memoir prepared by Anson Marston, R. W. Crum, and the late William G. Raymond, Members, Am. Soc. C. E.

As almost all Mr. Dunlap's professional life was lived in the State of Iowa, it seems fitting to record first something of the position he won for himself there.

A session of the Iowa Section of the American Society of Civil Engineers was held in Iowa City on October 7, 1924, to honor his memory. At this session addresses were made by C. S. Nichols, M. Am. Soc. C. E., Professor at Iowa State College, and Past-President of the Iowa Section, Lloyd A. Canfield, Assoc. M. Am. Soc. C. E., a former student under Mr. Dunlap and Secretary of the Iowa Engineering Society, Anson Marston, M. Am. Soc. C. E., Dean of Engineering, Iowa State College, then Vice-President of the American Society of Civil Engineers, and the late William G. Raymond, M. Am. Soc. C. E., Dean of the College of Applied Science of the State University of Iowa. Excerpts from the addresses of Professor Nichols and Dean Raymond will indicate Mr. Dunlap's position in the State as an engineer, as a teacher, and as a citizen.

Professor Nichols spoke, in part, as follows:

"We are gathered here to-night, a company of loyal friends, with hearts and minds in perfect harmony, to pay honor to a departed comrade. How empty must sound any words we shall utter in our feeble attempts to express our admiration for and appreciation of John Dunlap. Much more appropriate would be a session of silent meditation together, mentally building him into our midst once more, and reviewing in retrospection the pleasant and profitable association we have had with him.

"John Dunlap was first of all a man, a Christian man whose every activity was in keeping with his noble principles and high ideals. He was an engineer, true, but only because through this profession he found the best opportunity to use his talents for service. To this end he became the best engineer possible. This was to him but natural, because it was fundamentally essential to insure a full measure of usefulness.

"He looked well to his tools, both as to manufacture and condition, and he became proficient in their uses. In his tool chest were some most valuable pieces of equipment. If we were to pick them out, one by one, we would probably choose first of all his Refinement of Thought. Who could ever forget his masterful address at Sioux City, in 1922, as President of the Iowa Engineering Society, on 'The Engineer's World', and this earnest appeal to his fellow engineers: 'Shall we not each of us dedicate ourselves, our lives, our training, our property, all that we have and are, in order that we may serve as good citizens of a noble country, and of a world growing steadily better, because it is an engineer's world in which each engineer is playing his part, with a firm and steadfast faith that the soul of civilization is not meat and raiment, but life and spirit.' Then and there he probably as nearly as ever bared his soul to his fellow men. This took courage, indomitable courage, because it was a radical departure from the ordinary, and it was only because he was sound personally that he could say those things.

"And right there he showed the handiwork of another important tool, Definiteness of Purpose. Never, under any circumstances, could John Dunlap be swerved from the line of duty which he had set up for his life. Even as he pioneered, he kept the line straight, his compass in his hand. He had the courage to speak his convictions even though he stood alone.

"Did any of you ever fail to understand him when he spoke to you either in public address or in private conversation? I cannot conceive of it. He was master of those exceptional tools, Clearness of Thought and Clearness of Presentation. He had a wonderful ability to integrate ideas and impressions

and to rationalize them into concrete expression, whether in speech, in illustration, or in construction. Through these characteristics he gained the finest confidence of those with whom he dealt.

"Diligence also was his constant aid, and explains in large part his wonderful capacity for accomplishment. Most things did not come easy for him; he worked as probably few of us ever will know how.

"Of him it can be said truthfully that he accepted Personal Responsibility for his every action. There was no passing of responsibility by John Dunlap. If he made mistakes, he acknowledged them, and made amends so far as it was physically possible. He was thoughtful and deliberate in his preparations, but when the time came to act there was brought into play an irresistible force for accomplishment. But his zeal for accomplishment and his earnestness in putting things through were ever tempered by an abundance of Consideration of Others. Even his opponents in controversy considered him a clean and honorable fighter for the principles he championed.

"Above all we like to recall his Cheerful Disposition and his saving Sense of Humor. Of his perplexities he kept us in complete ignorance, except as they were common to a considerable group and called for group discussion. Always bright and happy, his presence added joy to any gathering, large or small.

"These are the things which made him a man among men, and, coupled with native ability, made him a good engineer. We are but incidentally interested in the details of his professional work, as they contributed to his success only in the experience they afforded, and the opportunity they offered for contact with men and for the rendering of personal or community service. It is of interest, however, to follow through the high points of his work, and catch the point of view throughout.

"It was while acting as Field Instructor in the summer of 1908 at his Alma Mater that he saw the large opportunity for service in the intimate contacts which are possible between instructor and student, and decided to devote himself to educational work. He joined the Engineering Faculty of the State University of Iowa, where he rose in rank and influence until his call to the executive leadership of our National Society.

"During the summer of 1915, while engaged in a water-works survey for the Extension Division of the State University, he caught his first real perspective of conditions surrounding the administration and operation of municipal utilities, and saw the opportunity of and great need for those improvements which only the experienced engineer can direct properly. It was then that his personal opportunity and duty became plain. During that summer he visited about forty of our best Iowa cities, and while employed only to gather data for a report, he was diligent in his efforts to assist the local officials in remedying their difficulties. The full value of this voluntary advice and personal service will never be known, but there is much evidence that through his report and recommendations there resulted not only local improvements in many of the towns visited, but State legislation as well, which through the years to come will safeguard the interests of both municipal and private water-works companies.

"During the summer of 1916, he was Engineer in charge of the construction of the Sewage Treatment Plant for the State Hospital and Colony for Epileptics at Woodward, and there became impressed that an engineer's work was not complete until he had provided adequately for the future operation of the plant by the layman operator. He made a remarkably clear perspective sketch of this plant, showing every operating detail, accompanied by detailed instructions for its operation, and had them framed and hung in the plant. He also spent hours of his own time in providing for satisfactory supervision and maintenance.

"The summers of 1917 and 1918 were spent under the auspices of the State Board of Health inspecting sewage treatment plants in all parts of the State. In this capacity, he rendered the same valuable service to the municipalities that had characterized his work two years before in connection with the water-works plants. Ever on the outlook for methods of making improvements, he formulated excellent recommendations for more complete supervision and control by the State Board of Health of the design, construction, and operation of municipal sanitary works.

"He was one of the most ardent supporters of the annual conferences of sewage treatment plant operators and contributed much to their success.

"In his consulting practice he invariably rendered his clients a service of high character. The esteem of a man by his own townspeople usually tells the true story. One instance in the case of John Dunlap will suffice. In 1915, a controversy arose between the Iowa City Water Company and the City as to water rates. The City retained John Dunlap as its engineer, and after investigation and consultation a satisfactory rate was agreed upon. For various reasons this rate continued throughout the World War period, although during this time the company is reported to have sustained a considerable loss. With continued high prices, therefore, some adjustments in the rate became necessary, and the Company chose John Dunlap to make a complete valuation of its properties and determine a proper rate for water service. As a result of his study and recommendation a rate was established satisfactory to both parties. Here was the case of a man who could serve either party to a controversy and satisfy both. Why was it? Because he was fair and square, and both sides knew that his decision would be rendered purely on the basis of what was right. And, of course, there was no question as to his technical ability.

"Several years ago, while in a large hospital, he watched a patient in the use of a drinking fountain. What he saw caused him to watch others, there and elsewhere. As he turned over in his mind these facts of observation he became convinced that elements of danger existed in the usual type of vertical jet drinking fountain because of lip contact with the jet spindle and the possibility of pathogenic bacteria remaining in the water column, much as a ball can be balanced on a vertical column of air. Examination proved his fears to be well founded, and inquiry through State boards of health revealed the fact that suspicion was arising elsewhere. He gathered all the information he could and presented a paper before the Iowa Section of the American Water Works Association, recommending the appointment of a committee to thoroughly investigate this problem of public health. The committee was appointed, Mr. Dunlap was made Chairman, served for three years, made a thorough investigation, enlisted the support of various agencies, gathered all available information and substantiating evidence on the subject, and submitted constructive recommendations for the adoption of a specific principle in drinking fountain design which would eliminate all possibility of disease transmission in the manner mentioned. These recommendations were published in the *Proceedings* of the American Water Works Association, have been commented on very favorably by sanitary authorities, and will result in much improvement in this important matter.

"How many of us watching the apparently little things and after turning them over in our minds assign to them a proper valuation? That was what John Dunlap was doing all the time. His mind carried over from a demonstration or experiment in physics to the drinking fountain jet of water, and he saw there an element of danger.

"Many of the substantial things which have been accomplished in this State could be traced back to their initiation in the mind of John Dunlap. He was an inspiring and a directing genius, but in his characteristic quiet way. In many instances others received the credit that should have gone to

him. We have been wont to claim credit for the passage of the Engineers' Registration Law, but we should not forget that John Dunlap was the quiet director of our efforts and to him should go a very large measure of credit for the creation of a Board of Engineering Examiners which will justify itself in the years to come after the trying early years have passed.

"John Dunlap was an example of the best type of engineer. He was active and able in the profession; he gave to his fellow engineers the benefit of his experience and observations through papers and otherwise; he entered heart and soul into the activities of those technical societies with which logically he should affiliate; he was a worker in public undertakings for the benefit of society, whether local, State, or National; he took active part in all the worth-while local affairs of his community; he was a pillar in his church; and, above all, he was loyal and true to his home and his family.

"What more can we say of John Dunlap than that he was a real man, a real engineer, and a real friend? He left us while yet a young man and his work but nicely started, yet the place he filled will long be vacant. The lesson he left us is this: Engineering provides an excellent opportunity for service of the highest type, if we but have the point of view. May we not all make honest endeavor to get more nearly the point of view which John Dunlap had, to the end that we may make our profession nobler and worthier of universal respect."

The late Dean Raymond spoke of Mr. Dunlap's work as a teacher and a citizen of Iowa City, saying:

"Mr. Dunlap was one of those teachers who are keenly alive to the desirability of improving curricula and teaching methods, particularly to the desirability of so improving them as better to develop the man in the student, by giving him breadth of vision and wholesome example. Clean in his living before these students, conscientious in his preparation for his appearances before them in the classroom, sympathetic, generous, and sound with his counsel as they came to him with their personal problems, or their problems of class, or general student activities, interested in their sports as well as in their work, Mr. Dunlap was an invaluable influence for good in the college.

"In the University organization, too, he was recognized to be one of the most useful of men, holding positions on the more important committees. Uniformly courteous even when differing radically with his colleagues, always finding good in the weakest of human beings, the right arm of his pastor in the work of his church, leader in the social service work of the community, John Dunlap unconsciously exerted an influence in University and community life that rarely is contributed by any one man. Not soon will he or his work in Iowa City and the University be forgotten."

In the brief period that Mr. Dunlap was permitted to serve the American Society of Civil Engineers as its Secretary, he made a most remarkably favorable impression on the Board of Direction to which he was immediately responsible, and gave evidence of a real vision of future Society usefulness, to the realization of which he was giving of the best that he had.

One who was familiar with his work as Secretary has this to say of him:

"Fresh from the activities of university life, enthusiastic for his new work, Mr. Dunlap threw himself into the service of the Society. There he found an outlet for his utmost efforts. For two short years he gave all his energies to the many-sided tasks that confront the Secretary of a National engineering organization. Wherever it extended, the Society work felt the impetus of his dynamic energy. This resulted in improvements in the internal machinery of the Soceity, in the quickening of the Society in its relations

with its members, and in the furthering of its external co-operation with other activities.

"It was at Mr. Dunlap's suggestion that comprehensive sub-committees of the Society's Committee on Technical Activities and Publications were established. He felt that thereby this important technical work would gain the interest, the counsel, and the assistance of a widespread membership. On his recommendation the Board of Direction adopted changes in the method of handling membership applications. These improvements included the establishment of local membership committees to secure more effective assistance in determining the qualifications of applicants, the revision of the application form, and the classification of applicants for action by the Board, whereby the unquestioned cases were approved more expeditiously and the intermediate to doubtful cases could thus receive a more careful attention.

"Following Mr. Dunlap's suggestion, a questionnaire was sent to members of the Society to learn their special engineering interests. When these forms were catalogued they served to indicate the direction and extent of the major activities of the membership and to provide useful lists of individuals to serve the Society in their particular fields.

"Perhaps his external relations—with Local Sections, Student Chapters, and individual members—were even more successful in their results. For example, he visited every Local Section; in some cases he was enthusiastically urged to return for the second and even the third conference. Similarly, he talked to the Student Chapters, with which his long teaching experience stood him in good stead. Mr. Dunlap's theory was that the administrative office of the Society, its individual members, and the Local Sections, could best co-operate as they knew each other better and appreciated the other's problems; that he could take the Society to the Local Sections and, in return, bring back timely suggestions for its improvement, thus cementing the two parts of the work through mutual understanding and interchange of ideas. These visits had the further effect of strengthening the Society before the public through the favorable presentation of its ideals which he made as an effective speaker.

"Finally, Mr. Dunlap's efforts were marked by a cordiality in the Society's relations with other organizations. Early in his official work he evinced a warm interest in the efforts of the Engineering Societies' Employment Service. He regarded this as a most potent force for assisting engineers and for improving the standards of engineering employment. At a critical period in the existence of this activity, he won over for it the Society's continued support. Even before his death the recovery of the Employment Service had vindicated his judgment.

"Another co-operative effort from which Mr. Dunlap expected great things and to which he gave much study was the Joint Conference Committee (comprising the Presidents and Secretaries of the Founder Societies) formed to consider important matters of common interest to the four National Societies. During its first year, Mr. Dunlap, as Secretary of this Committee, was active in formulating policies under which it has since continued to prosper.

"In still another direction—engineering education—he played an important part. From its inception he was closely connected with the investigation of engineering colleges and curricula carried on by the Society for the Promotion of Engineering Education: First, as a member of the Development Committee of that Society, which formulated the project; then, as a member of its Board of Investigation and Co-ordination, which superseded in the actual conduct of the work; and, finally, as an *ex officio* representative of the American Society of Civil Engineers on the Board of Educational Councillors, a committee of the National Engineering Societies co-operating in the investigation. Thus, in his dual capacity, he was of invaluable help to the work, forming a

strong point of official contact between engineering teaching and engineering practice.

"In all Mr. Dunlap's official relations—with his confrères at Headquarters, with other officers, with members or students, with outside organizations—his motto was 'Service'. Whether it was a fundamental policy of the Society or a courtesy to a single distant member, the matter received his closest attention. He gave his all, without stint; this service was not only the last, but the greatest of his life—great in its conceptions and great in its accomplishments."

On August 1, 1924, the Executive Committee of the American Society of Civil Engineers adopted resolutions, as follows:

"Whereas, it has pleased Almighty God to take from us our beloved Secretary,

JOHN HOFFMAN DUNLAP

"Be It Resolved: That the President and the Executive Committee, in behalf of the Board of Direction and the members of the American Society of Civil Engineers, express their sense of the great loss which the Society and the Engineering Profession of the United States has suffered by the death of our Secretary, who by his labors in our behalf; by his faithfulness, efficiency and courtesy; by his advocacy of the highest ideals for the advancement of the Profession; by his unselfish efforts to serve every member of the Society; and by the example he set us as a Christian citizen, has made a lasting impression in our hearts.

"Be It Further Resolved: That our heartfelt sympathy be extended to his family, that his family be furnished with a copy of this resolution, and that it be spread upon our records, printed in the *Proceedings* and *Transactions,* and that copies be furnished to the technical press and to other Engineering Societies."

It seems to be fitting to close this memoir with a repetition of the inspiring words of Mr. Dunlap spoken as he retired from the Presidency of the Iowa Engineering Society and quoted by Professor Nichols in his address before the Memorial Session of the Iowa Section of the American Society of Civil Engineers:

" 'Shall we not each of us dedicate ourselves, our lives, our training, our property, all that we have and are, in order that we may serve as good citizens of a noble country, and of a world growing steadily better, because it is an engineer's world in which each engineer is playing his part, with a firm and steadfast faith that the soul of civilization is not meat and raiment, but life and spirit.' "

CHARLES WELLS EDDY, M. Am. Soc. C. E.*

DIED JUNE 18, 1925.

Charles Wells Eddy was born on November 8, 1875, at Brunswick, N. Y. He was of Pilgrim stock, having been a descendant of Samuel Eddy, who came to America in 1630, and Kenelm Winslow, who came in 1629, both joining the Pilgrim Company at Plymouth, Mass. He was also a descendant of Robert Collins, of Sandown, N. H., who served as Captain of the New Hampshire Volunteers in the Revolutionary War.

In 1884, Mr. Eddy moved with his parents to Simsbury, Conn., where he received his early education at the public schools and McLean Seminary. He then entered the Connecticut Agricultural College and was graduated in the Class of 1893.

From 1893 to 1900, he was engaged in land surveying and in surveying for and inspection of State roads for various towns of Connecticut. From November 14, 1900, until his death, on June 18, 1925, with the exception of about a year, Mr. Eddy was employed by the City of Waterbury, Conn., in the Bureau of Engineering. During 1900 and 1902, he was engaged as Surveyor on the completion of the Wigwam Reservoir of the Waterbury Water Supply. In 1906 and 1907 he served as Resident Engineer in charge of the construction of the dam of the Coe Brass Company, at Torrington, Conn.

From 1908 to 1916, Mr. Eddy was engaged in preliminary surveys for, and was Resident Engineer in charge of, the construction of a dam for the Morris Reservoir which forms a 2 000 000 000-gal. storage reservoir for the City of Waterbury. Following this engagement he was employed in other water supply work and in making preliminary surveys for the 7-mile tunnel which the City of Waterbury is now constructing to enlarge its present water system, and also in designs for future controlling works for this system. At the time of his death, he was Resident Engineer at Thomaston, Conn.

Mr. Eddy was always loyal and keenly interested in his work, never sparing himself when it required unusual attention.

That he was willing to devote some of his time for the benefit of others is shown by the fact that besides being a member of the Society, he had also been a member of the Connecticut Society of Civil Engineers since January, 1900, having been its President at the time of his death. He was also a member of the New England Water Works Association, and of the American Society for Municipal Improvements; Director of the Thomaston Water Company; President of the Thomaston Sewer Company, the Thomaston Business Men's Association, and of the Masonic Temple Corporation of Thomaston.

Mr. Eddy was a member of the Congregational Church of Thomaston, and a Thirty-second Degree Mason.

He was married at Simsbury, Conn., on July 31, 1901, to Gertrude Holcombe, who survives him.

Mr. Eddy was elected an Associate Member of the American Society of Civil Engineers on March 2, 1909, and a Member on June 24, 1914.

* Memoir prepared by R. A. Cairns, M. Am. Soc. C. E.

MARTIN RYERSON EVERETT, M. Am. Soc. C. E.*

DIED FEBRUARY 4, 1926.

Martin Ryerson Everett was born at Frankford Township, near Branchville, N. J., on August 21, 1867. He was the son of Martin Ryerson and Julia (Roe) Everett, both of whom died before he attained the age of ten. He attended the public schools of Branchville and, after graduating, entered the employ of one of the merchants of that town.

In 1890, becoming dissatisfied with the limited opportunities of a rural community, Mr. Everett went to New York, N. Y., and accepted a clerical position with the Jackson Architectural Iron Works. While thus employed he met many civil and mechanical engineers and after learning of their achievements became so interested that he decided to become an engineer. He immediately entered the evening sessions at Cooper Union and received the degree of Bachelor of Science in 1898. At this time he was in charge of the Structural Shop of the Jackson Architectural Iron Works.

In 1900, Mr. Everett went to Newark, N. J., to be Shop Manager and Designer of Steel Structures for Cooper and Wigand, Contractors and Engineers. After receiving the degree of Civil Engineer from Cooper Union on May 28, 1904, he became connected with the Cooper-Wigand-Cooke Company.

From 1906 to 1908, Mr. Everett was General Manager of the Cooper Iron Works, of Newark. Resigning from this position he engaged in private practice as a Contractor and Engineer, continuing as such until 1910, when he became Vice-President of the Hedden Iron Construction Company, in charge of operation. After serving as Vice-President with this Company for two years he resigned and again engaged in private practice.

In 1914, he incorporated the Company known as the Martin R. Everett, Incorporated, Engineers and Contractors, with headquarters in Newark, and served as President until his death from a lingering illness on February 4, 1926.

Mr. Everett had a wonderful and unique personality, made many friends, and was a favorite with those whose good fortune it was to know him well. Always interested in sports and athletics as a young man, he was an enthusiastic supporter of them throughout his life and was never happier than in witnessing some big game.

Mr. Everett had resided in East Orange, N. J., for twenty-five years. He was an active member of the Arlington Avenue Presbyterian Church of that city, and was also a member of many fraternal and community organizations.

He is survived by his widow, Lillian Robertson Everett, his son, Martin Ryerson, Jr., and his sister, Miss Jennie H. Everett, of Bayonne, N. J.

Mr. Everett was elected a Member of the American Society of Civil Engineers on April 14, 1919.

* Memoir prepared by Victor Graff, Pres., Martin R. Everett, Inc., Newark, N. J.

GEORGE THOMAS FORSYTH, M. Am. Soc. C. E.*

DIED AUGUST 31, 1925.

George Thomas Forsyth, the son of Elizabeth and Jonathan Forsyth, was born in Providence, R. I., on January 19, 1876. In his early childhood his parents moved to Salinas, Calif., where his boyhood was spent and where he received his public school education.

In 1895 he entered Leland Stanford, Jr., University. There he pursued a special engineering course until the spring of 1899, when he accepted a position with the Union Iron Works at San Francisco, Calif., where he was engaged until December, 1900, in ship-fitting and the erection of marine engines.

In January, 1901, Mr. Forsyth entered the service of the Southern Pacific Company at San Francisco, as Draftsman in the office of the Engineer of Bridges. This was on the eve of the great physical development which was to take place in that railroad and in other lines then being associated with it by the late E. H. Harriman. In 1903, Mr. Forsyth was promoted to the position of Chief Draftsman, in which capacity he was in direct charge of bridge and miscellaneous structural and mechanical design. He remained in this position until 1905, during which period he took an important part in the preparation of the common standard plans of the Harriman System. These plans touched almost every physical detail of railroad construction and maintenance, and their value is evidenced by the fact that most of them are still in use on the Union Pacific and Southern Pacific Systems. Perhaps his most effective efforts were directed to the standard bridge designs, in which he showed ingenuity and clearness of thought that seemed sometimes to approach genius.

In 1905, Mr. Forsyth was appointed Bridge Engineer of the Oregon Railroad and Navigation Company and of the Oregon Lines of the Southern Pacific System. In the great program of extensions and improvements which had just begun, and during the next eight years, he was continuously occupied with the design and construction of many bridges, but he also found time to devote himself to power-plant and wood preservation problems. His most important work in this period was in connection with a large double-deck lift-bridge over the Willamette River, at Portland, Ore., which was constructed under his supervision, and to the design of which he contributed largely.

In 1913, Mr. Forsyth decided that better opportunities existed outside of railroad service, and with the regret and good wishes of his associates he joined the Union Bridge Company of Kansas City, Mo., and later the contracting firm of Diecks and Diecks. In these engagements he successfully carried to completion a number pneumatic caisson and subaqueous tunnel projects.

* Memoir prepared by S. Murray, M. Am. Soc. C. E.

In 1920, Mr. Forsyth returned to Portland, Ore., where he opened an office and engaged in independent practice. Early in 1924, he was called to take charge of a tunnel beneath the Duwamish River at Seattle, Wash., in the construction of which difficulties had developed that appeared to be insurmountable. Under his direction, this project, which had seemed palpably a failure, was carried to a swift and successful completion. This was his last important work.

Mr. Forsyth was a brilliant mathematician and a leader in bridge design and construction. Loyal and steadfast, he was a man of independent thought and of original and whimsical humor. His passing leaves a gap which his friends and associates can never fill.

He was married on June 16, 1902, to Florence Ligon, who, with one son, George Thomas, Jr., survives him.

Mr. Forsyth was elected a Member of the American Society of Civil Engineers on October 1, 1912.

HENRY FOX, M. Am. Soc. C. E.*

DIED JUNE 8, 1925.

Henry Fox was born at Troy, N. Y., on September 12, 1864, and was educated at the Baraboo, Wis., High School.

He entered the service of the Chicago and Northwestern Railway Company in the spring of 1885, as Rodman, and remained in that position during the construction of the Northern Illinois Railway. In 1886, he was employed as Levelman, on the survey and construction of the Maple River Railway, at Onawa, Iowa. During 1887, he was in camp in the woods of Northern Michigan, while in charge of a division of the Iron River Railway then being built between Iron River and Watersmeet.

In 1889, Mr. Fox entered the University of Wisconsin as a Special Student, changing in the Sophomore year to the Mechanical Engineering Department, and was graduated in 1892 with the degree of Bachelor in Mechanical Engineering. During his summer vacations he was employed by the Chicago and Northwestern Railway Company, on general maintenance-of-way work. As soon as he left the University, he was engaged as Inspector by the Chicago and Northwestern Railway Company, during the erection of the Hall System of automatic block signals on the Galena and Wisconsin Divisions. In 1893, he became Mechanical Draftsman at St. Joseph and Hermann, Mo., with the Missouri River Commission.

In 1895, Mr. Fox was employed on the Illinois and Mississippi Canal (Hennepin Canal) and the Chicago and Northwestern Railway, and in 1896, served as Resident Engineer on railway construction for that Company at Gillett, Wis. From 1896 to 1897, he served as Assistant Engineer for the Railway Company at Manitowoc, Wis., in charge of the construction of tracks, buildings, docks, and car-ferry slips. From 1898 to 1900, Mr. Fox was employed as U. S. Inspector for the Illinois and Mississippi Canal, in charge of the construction work of the Second Division, Eastern Section.

From 1900 to 1902, he held the position of Locating Engineer on the Choctaw, Oklahoma and Gulf Railroad, at Hartshorne, Okla.; and from 1902 to 1905 that of Junior Engineer with the U. S. War Department, on field work, in charge of secondary triangulation on seven deep waterway surveys on the Illinois and Des Plaines Rivers from Lockport to Grafton, Ill., a distance approximating 300 miles. On the completion of this work, he was transferred from Chicago, Ill., to Baltimore, Md.

From 1905 to 1909, Mr. Fox served as Assistant Engineer in the U. S. Engineer's Office at Baltimore in local charge of river and harbor improvement and fortifications, as well as ship channels in the Chesapeake and Patapsco Rivers, leading to Baltimore. From 1909 to 1915, he was connected with the Maryland Dredging and Contracting Company (now the Arundel Corporation of Baltimore), as Superintendent and Engineer of general river and harbor improvement work along the Atlantic seaboard, and was engaged

* Memoir prepared by the Misses Pearl C. and Esther Fox, Baltimore, Md.

in construction work at Buzzards Bay and on the Cape Cod Canal. He also supervised the contract work on the New York State Barge Canal, and on bridges, locks, and dams on the Mohawk River.

From 1916 to 1917, he held the position of U. S. Assistant Engineer at Little Rock, Ark., in charge of field parties for the survey of the Arkansas River, from Little Rock to the mouth of the river, a distance of approximately 150 miles. In 1917, he was relieved from duty and ordered into active military service as Captain of Engineers and served during the World War until 1919.

During the latter part of 1919 and part of 1920, Captain Fox was employed with the Baltimore and Ohio Railroad as Assistant Engineer to the District Engineer of Construction, on new tracks, bridges, and engine terminal facilities, such as roundhouses and machine shops, at Grafton, Fairmont, and Clarksburg, W. Va.

In 1920, he returned to the U. S. Engineer Department as Assistant Engineer on construction, Division No. 1, Wilson Dam, Muscle Shoals Project, on the Tennessee River at Florence, Ala. When this work was discontinued on May 1, 1921, he entered the State Highway Department of Florida at Tallahassee, as Location and Construction Engineer, and built concrete bridges and 20 miles of State Highway No. 8.

During 1922, Captain Fox was employed as Engineer with Trammell and Holway, Engineers, on the Spavinaw Water Project for the City of Tulsa, Okla., and located 55 miles of 54 and 60-in. conduit lines at Spavinaw Dam and Tiawah Tunnel. In 1923, he accepted a position with the Walbridge-Aldinger Company, Contractors for the Spavinaw Water Project, at Tulsa, for which Company he constructed 55 miles of standard-gauge railway.

During 1924, he entered the State Highway Department of Oklahoma as a Federal Engineer in charge of field parties in the northern part of the State, which position he held at the time of his sudden illness and death on June 8, 1925.

On October 18, 1893, he was married to Pearl Irwin Clark, of St. Louis, Mo. He is survived by a son, Henry Clark Fox, a student in Civil Engineering at the University of Maryland, and two daughters, Pearl C. and Esther Fox, of Baltimore.

Captain Fox had been a member of the Western Society of Engineers since 1900, and of the American Association of Engineers (Washington, D. C., Chapter), since 1921. He was also a member of Lodge 34 A. F. and A. M.; of Lodge 49, of Baraboo, Wis.; a Thirty-second Degree Mason; and a Member of Zamora Temple and Alabama Consistory, of Birmingham, Ala.

Captain Fox was elected a Member of the American Society of Civil Engineers on July 1, 1909.

STEPHENSON WATERS FOX, M. Am. Soc. C. E.*

DIED MAY 8, 1925.

The unfortunate sinking of the Steamer *Norman* in the Mississippi River below Memphis, Tenn., on May 8, 1925, took a large toll from the membership of the Society. Of this number was Stephenson Waters Fox, of Paducah, Ky.

"S. Waters" Fox, as he preferred to be known, was born in Natchez, Miss., on August 3, 1856. He was graduated from the Rensselaer Polytechnic Institute, Troy, N. Y., in 1876 as a Civil Engineer. Previous to and following his graduation, Mr. Fox, like many young engineers of that day, obtained his early experience on railroad surveys, these engagements being on several railroads in Southern Indiana, Kentucky, and Tennessee.

In 1876, he was for a short period with the Snead and Company Iron Works, of Louisville, Ky., as Computer. In 1878, he became an Assistant to the late Brig.-Gen. Charles R. Suter, U. S. A. (*Retired*), M. Am. Soc. C. E., then Major, Corps of Engineers, U. S. A., and was engaged on improvement work on the Mississippi River. He remained as an Assistant Civil Engineer with the U. S. Corps of Engineers, until 1903. During this period he had a large degree of responsibility for the design and construction of many important river improvements, principally of revetments for the protection of caving banks and levees, and the control of the Mississippi and Missouri Rivers and their tributaries, including works at Choctaw Bend, Mississippi River, and at Glasgow, Cedar City, St. Charles, St. Joseph, Kansas City, Mo., and other points on the Missouri River.

In 1903, Mr. Fox resigned from the Government service and opened an office at Kansas City, Mo., as a Consulting Engineer, specializing in river improvements, the construction of levees, and land reclamation. In this capacity he served, with much credit, several railways, municipalities, and other corporations, on difficult projects of considerable magnitude and also designed several large suction dredges. During this period, he was for several years Chief Engineer for the Union Terminal Railway Company, of St. Joseph, Mo. Later, he moved to St. Louis, Mo., where his engineering activities were of similar character.

In 1917, when the United States entered the World War, Mr. Fox was commissioned a Major in the Engineer Reserve Corps, and served with credit in the Division of Inland Waterways of the United States Railroad Administration as Engineer of Contracts and Construction. After the close of the war Major Fox became associated with Cox and Stevens, Marine Engineers, of New York, N. Y., and while with this firm designed a new type of boat for use on the Erie Canal.

In 1922, he became Consulting Engineer for the Joyce-Watkins Company, large producers of railroad ties, telegraph poles, etc. This engagement necessitated his removal to Paducah, Ky. In addition to the questions of timber

* Memoir prepared by Charles F. Loweth, Past-President, Am. Soc. C. E.

treating and of transporting ties and poles by river, he had presented to him many new and novel problems, such as the design of special machines and floating equipment for handling a special product. To these he brought to bear those qualities of patient, thorough, and open-minded investigation which were characteristic of him and which had contributed largely to his success and had won for him the hearty commendation of many employers. His zeal and interest in new and novel, yet always practical, problems kept him much younger than his years.

Major Fox was considered an authority on levees, bank protection, and other kindred problems relating to the control of the Missouri River, to which he had given much careful and enthusiastic study. In 1905, he presented to the Society a noteworthy paper entitled "Technical Methods of River Improvement as Developed on the Lower Missouri River, by the General Government, from 1876 to 1903."*

Outside his professional work, Major Fox always found time and interest for many worth-while activities and lent his assistance to many enterprises that promised good to the community. Although a resident of Paducah for only three years, he was, at the time of his death, President of the local Lions Club; he had been for some time a member of the City Planning Commission and had been appointed its Chairman within a month of his unfortunate death. For many years he was an active member of the Presbyterian Church.

Major Fox was a man of culture and appreciation, fair-minded, broad, and kindly. He had a genial and happy disposition and made and retained many friends. If one may be judged by his aspirations and ideals, as well as by his accomplishments, the sentiments in the following verses, a typewritten copy of which was found on his remains, reflects in some degree the measure of the man:

"Carve your name high o'er the shifting sands,
Where the steadfast rocks defy decay.
All you can hold in your cold, dead hand
Is what you have given away.

"Count your wide conquest o'er sea and land,
Heap up your gold, hoard as you may.
All you can hold in your cold, dead hand
Is what you have given away.

"Build your pyramids, skyward, let them rise,
Stand gazed at by millions, cultured they say.
All you can hold in your cold, dead hand,
Is what you have given away.

"Silver and gold and jewels, all so grand,
King of the solon, a mart, a day.
Yet all you can hold in your cold, dead hand
Is what you have given away."

The great river on whose banks Major Fox was born and spent his boyhood days, and near which most of his life was spent, finally claimed him

* *Transactions*, Am. Soc. C. E., Vol. LIV (1905), p. 280.

as its own; but the works in the design and construction of which he had so large a share, built to control the river, are yet unconquered by it.

He is survived by his widow, a son, Burton C. Fox, of Portland, Ore., and three daughters, Mrs. Jett Blackburn, of Portland, Ore., Mrs. Cleveland X. Hening, of San Francisco, Calif., and Mrs. Harvey J. Schmelzer, of Kansas City, Mo.

Major Fox was elected a Junior of the American Society of Civil Engineers on July 7, 1880, and a Member on October 6, 1886.

MILTON HARVEY FREEMAN, M. Am. Soc. C. E.*

DIED MARCH 24, 1925.

Milton Harvey Freeman was born at Crary Mills, St. Lawrence County, N. Y., on October 12, 1871. He was the son of the late Noel O. Freeman whose family came from Vermont, having settled there in Colonial days. His mother was Mary E. Harvey, whose family on the maternal side settled at Gill, near Northfield, Mass.

Mr. Freeman was graduated from the Potsdam Normal School, at Potsdam, N. Y., in June, 1895, and for the next two years, taught in district schools in New York State. In September, 1897, he became principal of the Heuvelton Union Free School at Heuvelton, N. Y., where he remained until June, 1899. In the fall of that year, he entered the University of Michigan, with the idea of specializing in mathematics and physics for the purpose of teaching these subjects. While at college, his interests were directed toward engineering as a profession, and he was graduated from the University in June, 1903, with the degree of Bachelor of Science in Civil Engineering.

Immediately after his graduation, Mr. Freeman was employed by the Michigan Central Railroad Company as Assistant Engineer in charge of party, locating branches for logging, double-tracking the main line, laying out freight yards, and maintenance-of-way work. He continued in this position until September, 1905, when he returned to the East and was employed by the Pennsylvania Tunnel and Terminal Railroad Company on the East River Section of the Pennsylvania Tunnel, where he remained as Inspector of shield tunnels until 1907. From 1907 until May, 1909, he served as Assistant Engineer in charge of a shift on shield-driving, building iron lining, and placing the concrete lining in four tubes westward from the Long Island City Shaft.

In May, 1909, Mr. Freeman accepted a position with the Board of Water Supply of New York as Inspector in rock tunnel and in charge of a shaft field party at the Rondout Siphon, where he continued until December of that year, when he was made Assistant Engineer in the Designing Department on studies of reinforced concrete. In March, 1910, he became Assistant Engineer-Chief Inspector on placing concrete tunnel lining. He was engaged in this work until March, 1911, when he became Section Engineer at the Rondout Siphon in charge of concreting and grouting the tunnel lining, which included tests and experimental work in grouting porous rock. He continued at this work until April, 1914, when he was made Section Engineer on the Narrows Siphon in charge of experimental work on the flexible watertight joint for the 36-in. cast-iron pipe.

In September, 1914, Mr. Freeman entered the employ of the New York State Public Service Commission for the First District as Resident Engineer on the Brooklyn side of the Old Slip-Clark Street Tunnel, from mid-river

* Memoir prepared by James F. Sanborn and Ole Singstad, Members, Am. Soc. C. E.

to the Brooklyn Approach. These were shield-driven tunnels under the East River and the streets of Brooklyn and were to be included in the Rapid Transit Railroad System of New York. In December, 1916, he became Resident Engineer in charge of the entire River Section and Manhattan Approach of the 60th Street, New York-North Jane Street, Long Island City Tunnels, where he remained until the completion of excavation in October, 1918. He was then made Resident Engineer on the Manhattan shore of the 14th Street Eastern-North 7th Street Brooklyn Tunnel, and was employed on this work until June 30, 1919. During the latter period, he was also busy devising grouting methods and was in charge of the field work of stopping leakage at the Canal Street Station of the Brooklyn Rapid Transit Company in New York.

On July 1, 1919, he was appointed Resident Engineer to the New York State Bridge and Tunnel Commission and the New Jersey Interstate Bridge and Tunnel Commission under the late Clifford M. Holland, M. Am. Soc. C. E., Chief Engineer. He served with Mr. Holland and his associates in the work of investigation and preliminary design, and on January 1, 1921, became Division Engineer. On July 1, 1921, he was promoted to the position of Engineer of Construction, and remained in active charge of the construction work until the death of Mr. Holland, whom he succeeded as Chief Engineer on December 1, 1924.

The construction of The Holland Tunnel, formerly known as the Hudson River Vehicular Tunnel, is a monument to the high talent and painstaking ability of Mr. Freeman as a subaqueous tunnel engineer. Under Mr. Holland, Mr. Freeman had personal charge of construction on this pioneer project which far exceeds in proportions any tunnel built under similar conditions. The successful driving of five shields of a diameter of 30 ft. 4 in. and one of 31 ft. in itself suffices to mark him as a great engineer. The difficulties encountered in shield-driving, together with the problems of sinking five large shafts, one—the New York River Ventilation Shaft—surpassing in size any similar construction; the water-tightness of these enormous tubes; and the intricate concrete work on the inner lining, were problems that called for his best efforts. The success attained in these various branches of the work stand out as distinct accomplishments of high engineering ability.

Weakened by close application for many years to the numberless details of the work under his charge, his career was prematurely ended. He died at his home in Valhalla, N. Y., on March 24, 1925, of pneumonia after an illness of eight days.

Mr. Freeman was noted for a thoroughness in his knowledge of every detail and for his integrity of purpose and judgment in the solution of the intricate problems which were his responsibility. His devotion to his professional activities was intense and no labor was too great for him to give to the correct solution of whatever problem might be presented to him. He had a fine sense of justice and was noted for his consideration in never doing anything to hurt the feelings of his associates or subordinates. He had high ideals and was fearless in carrying through his purpose with standards of action that marked him among men. His influence was keenly felt by

those who came in contact with him, and his death leaves with them a sense of irreparable loss. With his ability was an unusual modesty which always marked his relations with others. One of the outstanding accomplishments of his professional career was the success that attended his work in stopping the leakage at the Canal Street Station of New York's Rapid Transit System. He prepared a paper on this subject, which he read before the Brooklyn Engineers' Club on April 15, 1920, and for which he was awarded the Alfred T. White Prize by the Club.

In 1917, Mr. Freeman was married to Gertrude Vandermark, of Stone Ridge, N. Y., who survives him.

The New York State Bridge and Tunnel Commission and the New Jersey Interstate Bridge and Tunnel Commission, of which Commissions Mr. Freeman was the Chief Engineer, adopted unanimously by a rising vote the following resolution as a mark of respect to the memory of their late Chief Engineer:

"Again the New York and the New Jersey Bridge and Tunnel Commissions meet in special session with a vacancy in the office of Chief Engineer. Milton H. Freeman, Chief Engineer to the Commissions, answered the final summons on Tuesday, March twenty-fourth, nineteen hundred and twenty-five, midway in the fifty-fifth year of an active, useful life. Appointed Chief Engineer December 1, 1924, to succeed the late Clifford M. Holland, he brought to the office eminent qualifications of education, trained judgment and wide practical experience. It may be said that he gave himself too unsparingly to the building of the Holland Tunnel. His service was intensive and untiring, his ways so quiet and unobtrusive, his words so considerate and his manner so courteous as to inspire respect and affection, making every member of our Commissions sensible of a personal loss and of the loss to the great undertaking in which we are engaged."

He was a member of the Brooklyn Engineers' Club and the University of Michigan Club of New York.

Mr. Freeman was elected an Associate Member of the American Society of Civil Engineers on July 1, 1909, and a Member on September 9, 1919. He served as a representative of the Society on the Joint Committee on Specifications for Concrete and Reinforced Concrete.

FRANKLIN IDE FULLER, M. Am. Soc. C. E.*

DIED DECEMBER 16, 1925.

Franklin Ide Fuller, the son of Leonard F. and Mary I. Fuller, was born on May 29, 1858, in Providence, R. I., of an old New England family. He attended the public schools, afterward becoming a student of civil engineering while working in the offices of the City Engineer of Providence. He spent four years in this office, winning several promotions, and mastering much of the technique of his chosen profession. At the end of his term, he entered the railroad service and was engaged in location and construction work on the New York, West Shore and Buffalo Railroad.

In 1883, Mr. Fuller went to Oregon and there was connected with railway work as representative of the Northern Pacific Terminal Company. The failure of the Northern Pacific Railway Company and the cessation of railroad construction in the Northwest at that time forced him to enter the contracting business in which he continued for four years, devoted largely to railway and heavy timber work. The next three years were spent with the Oregon Iron and Steel Company at Oswego, Ore., first, as Assistant to the Manager and, later, as Manager of the Company. Following this engagement he devoted a year to the real estate business.

In 1892, he became connected with the Portland Cable Railway Company, and remained with this Company and its successors, through several consolidations and mergers, until his death. He was active in the transportation development of the city, having done more perhaps to increase street-car lines in Portland than any other man. When the Cable Company became the Portland Traction Company, Mr. Fuller was made Manager and continued in this office until the Company was merged with the Portland Railway Company, when he was made General Manager.

By his forethought and hard work he saved his Company from failure during the panic of 1893. Banks, stores, hotels, and all lines of business were being closed. It was the blackest hour of Portland's history. Mr. Fuller at once put the line on as low an operating basis as possible. In order to get sufficient cash to keep it going, he sold books of street-car tickets among the business houses, even taking them into the residence districts and selling them from house to house. In 1904, came the amalgamation of the Portland Railway Company and the City and Suburban Railway Company, forming the Portland Consolidated Railway Company. Mr. Fuller was General Manager for a year, then the properties were purchased by the Clark and Seligman interests of Philadelphia, Pa., and New York, N. Y., and the Portland Railway Company was re-organized with Mr. Fuller as President.

The incorporation of the Portland Railway, Light, and Power Company came in 1906, with the addition of the lines and other property of the Oregon Water, Power, and Railway Company. Mr. Fuller became Vice-President in charge of the railways of the Corporation.

* Memoir prepared by J. P. Newell and D. C. Henny, Members, Am. Soc. C. E.

One of the monuments to his engineering ability and progressiveness is the Portland Heights Street Car Line. At the time it was projected, it was said to be impossible, and impracticable, but his professional eye saw the way clear to the fulfillment of his plan, and for years this was the most scenic city street-car line in America.

At the time of his death, Mr. Fuller was the oldest official in electric transportation work on the Pacific Coast, both in length of service and in age. He was active in the affairs of the Chamber of Commerce, at times serving as Director. He was also a member of the Woodmen of the World, Modern Woodmen of America, Royal Arcanum, Arlington Club, and Multnomah Club. He was a Director of the Lumbermen's Trust Company and of the Oregon Portland Cement Company.

On April 14, 1886, he was married to Anna Jessie Parrish, of Portland, who survives him, with one son, Leonard F. Fuller, Chief Engineer of the Thompson Radio Corporation, of Ridgewood, N. J.

The outstanding feature of Mr. Fuller's professional career was his work as an executive, with the task of administering the intricate affairs of a great public utility. In this position the many-sidedness of the man was apparent. In the settlement of the innumerable controversies which arise between city officials and a street railway company, Mr. Fuller's word was always conclusive. Whatever he promised he performed.

The esteem in which he was held by the City Council of Portland was expressed in the following resolution:

"On account of his long service in this community and his intimate knowledge of local transportation and traffic problems, the counsel of Mr. F. I. Fuller was always valuable in assisting us to arrive at a fair and reasonable solution. He was a man of exceptional ability, sound judgment, and high moral character, always patient and considerate of the rights of others. Even in the face of strenuous objections he was always calm, deliberate, and courteous in presenting his views, or in pressing the claims and wishes of the large utility he represented. We voice our deep regret at his passing, because we realize that Portland has lost a valuable citizen, and the profession of engineering an honorable and worthy member."

Modern conditions of employment offer many opportunities for friction with subordinates, but the character of Mr Fuller's relations with his men is best evidenced by their spontaneous tribute in a memorial addressed to Mrs. Fuller, in which they stated, in part:

"In the passing of Franklin Ide Fuller, we, his co-workers in the Portland Electric Power Company, feel keenly the loss of a faithful, sympathetic friend who was ever ready to advise and help us.

"His high sense of honor and loyalty to us and to the Company he so generously served have been an inspiration to all with whom he came in contact. We know no act of his life that does not express kindness, tenderness, and generosity.

"Any one who could occupy, with such gentle humility, the position he has so long and honorably filled is an example of the highest type of Christian character and is indeed a great man."

The esteem in which Mr. Fuller was held by his associates was voiced by the President of his Company as follows:

"He was well known and admired for his staunch qualities and rugged character by many thousands of citizens in all walks of life. He was quick to realize the needs of Portland and he always endeavored to serve his city and his fellow-men to the best of his ability.

"During the many years in which I have been associated with Mr. Fuller, his calm serenity, sure poise, and good judgment in the face of perplexing problems have always been a source of deep inspiration to his associates in our company. I have never known a more faithful friend, a more lovable companion or a more conscientious, loyal business associate."

The Directors of the Lumbermen's Trust Company expressed their sorrow in a memorial which is, in part, as follows:

"In the passing of Mr. Franklin Ide Fuller, the Lumbermen's Trust Company and its affiliated corporations have suffered the loss of a valued adviser, who, by reason of his broad acquaintanceship, his acute analysis of problems, his matured judgment and his unwavering integrity, has contributed largely to the material progress of our institutions. Beyond and above this his unselfishness, cheerfulness, modesty of character and boundless faith in his fellow men have endeared him to each one of us and have left to us a loving memory which we will always retain."

Mr. Fuller's whole life was permeated by principles to which his pastor and intimate friend, Dr. H. L. Bowman, bears testimony:

"Mr. Franklin I. Fuller during his residence in Portland was associated with the Church and with Christian work. In 1909 his membership was placed in the First Presbyterian Church with which he was actively affiliated. For the last thirteen years of his life he was a member of the Board of Trustees of the Church and for the last two years its President. He gave generously and loyally of his time and interest to the work of the Church.

"But Mr. Fuller's life was not one in which Christian character simply showed in Church activity. His life was an outstanding instance of the principles of the Master interpreted in terms of practical business life. In the beautiful and considerate fellowship of the home, in devoted friendship, in the sterling integrity of business conduct, in unselfish consideration of coworkers, in the activities of citizenship Mr. Fuller revealed the rich fruitage of Christian character. His was a life in which religion was woven so thoroughly as to become instinctive; with no impulse for display his life was yet a vocal testimony of the value of Christian ideals in building character and enriching personality.

"Such a life so mastered by the spirit of Jesus Christ becomes in memory as it was in fellowship a summons to the noblest life."

To the members of his profession Mr. Fuller's conspicuous success as an executive was a source of pride, his cordiality and kindness a constant encouragement, his fine public spirit an example, and his upright life an inspiration.

Mr. Fuller was elected a Member of the American Society of Civil Engineers on January 6, 1886. He was one of the first Presidents of the Portland Section of the Society.

JOB ROCKFIELD FURMAN, M. Am. Soc. C. E.*

DIED SEPTEMBER 7, 1925

Job Rockfield Furman, the son of John M. and Virginia Holmes Furman, was born in Westchester, N. Y., on June 21, 1865. His early schooling was received at the Friends School in New York, N. Y. He then entered the Stevens Institute of Technology at Hoboken, N. J., from which he was graduated in 1885 with the degree of Mechanical Engineer.

After a brief experience in the rebuilding of marine engines, in 1887, he entered the employ of Otis Brothers and Company, manufacturers of elevators and hoisting machinery. Working first as a Draftsman, he early acquired a considerable knowledge of elevator apparatus and was generally assigned to take charge of elevators of an unusual character.

In 1888, he went to Paris, France, as Resident Engineer in charge of all work in foreign countries. There he was in charge of the erection of the two elevators in the Eiffel Tower. This undertaking, at a time when prevailing low, brick-walled buildings did not call for any long lifts, presented a unique problem, since the Eiffel Tower elevators ascend 420 ft., with a load equal to 50 persons.

Mr. Furman remained in Paris during the time of the Exposition in 1889 and then returned to the United States where he took an important part in the development of high-pressure hydraulic apparatus, which was in vogue at that time. As Assistant Engineer, he co-operated in the design of three 25 000-lb. passenger elevators, as well as towers and viaducts, for the Weehawken Viaduct at Weehawken, N. J., and superintended its erection. About this time he was also engaged on the Catskill Mountain Incline. In 1891, he assumed full charge of the Engineering Department of Otis Brothers and Company with headquarters in New York.

In 1894, Mr. Furman again crossed the ocean, this time to Glasgow, Scotland, where, as Resident Engineer, he superintended the installation of twelve high-pressure 15 000-lb., vehicle elevators for the Glasgow Harbor Tunnel, the most powerful lifts attempted to that date.

In 1896 he severed his connection with Otis Brothers and Company to become Secretary and Treasurer of the C. F. Parker and Company until 1898. During this time, in addition to other works, he was in charge of the deepening of 6½ miles of the Erie Canal. He then went to London, England, where he engaged in professional engineering work as a Consulting and Contracting Engineer. As Consulting Engineer to the Sprague Electric Elevator Company, he designed forty-eight 17 000-lb. electric passenger elevators for the $15 000 000 London Central Railway and supervised their installation.

In 1904, Mr. Furman again became associated with the Otis Brothers Elevator Company as Assistant Chief Engineer and was placed in charge of the installation of the 170 electric lifts in the new London Underground Railways. He laid out the twelve large elevators installed in the Elbe Tunnel

* Memoir prepared by Theodore V. Purcell, Vice-Pres., The Peoples Gas Light & Coke Co., Chicago, Ill.

at Hamburg, Germany, and shortly afterward left the Otis Company to join the well-known architects, D. H. Burnham and Company.

With this firm, which later assumed its present name of Graham, Anderson, Probst, and White, Mr. Furman remained until his death. As Chief Mechanical Engineer he assisted in the design of many large buildings for which the firm acted as Architect, among which were the Peoples Gas Building, Wrigley Building, Continental and Commercial National Bank Building, Straus Building, the Federal Reserve Bank Buildings, the Field Museum of Natural History, and the Chicago Union Station, in Chicago, Ill., which was the last large work with which he was associated, and the Equitable Building, in New York, N. Y.

Mr. Furman died at the Presbyterian Hospital in Chicago on September 7, 1925, following a brief illness. His wife, Florence O'Mullen Furman, whom he married in London, had died in 1908, leaving no children. He is survived by three sisters and two brothers.

Although Mr. Furman's professional life was one of distinction and outstanding success, his private life was perhaps even a greater achievement. He was a man of strict integrity and of a notably affable and kindly nature. His constant cheerfulness and good humor, and this despite a chronic illness in his later years, won for him a host of intimate and devoted friends.

He was a member of the University Club of Chicago and the Engineers Club of New York.

Mr. Furman was elected a Junior of the American Society of Civil Engineers on July 2, 1890, and a Member on December 7, 1904.

JOACHIM GOTSCHE GIAVER, M. Am. Soc. C. E.*

DIED MAY 29, 1925.

Joachim Gotsche Giaver, the son of Jens Holmboe Giaver and Hanna Birgit Holmboe, was born on August 15, 1856, in Gjovik, a small town owned by his family, near Tromso, Norway. His father, of a prominent Norwegian family, was a large landholder and one of the leading figures in the fishing industry in Northern Norway. Tutored at home, Mr. Giaver entered the Trondhjems Technical College, at Trondhjem, Norway, from which he was graduated in 1881 with the degree of Civil Engineer.

As the engineering field in Norway was limited at that time he came to America in 1882, and found employment as Draftsman for the Northern Pacific Railroad Company at St. Paul, Minn. At the close of 1883, Mr. Giaver left for Pittsburgh, Pa., to become a Draftsman for the Shiffler Bridge Company and from 1885 to 1890 served as Chief Engineer of that Company. During that period he designed several of the bridges over the Allegheny and Monongahela Rivers at Pittsburgh, and by odd coincidence one of his first engagements was the design of the structural framework for the Statue of Liberty in New York Harbor.

Mr. Giaver forged rapidly to the front as one of the leading structural designers of the United States and, in 1891, he went to Chicago, Ill., to become Assistant Chief Engineer of the famous World's Columbian Exposition. Having been one of the first to recognize the importance of wind bracing in the structural framework of buildings, he was in charge of the perfecting of this feature in the structural design of the buildings for the Exposition. He designed the three-hinge arch in the dome of the Liberal Arts Building which at that time was the largest truss of its kind in the world, having a span of 368 ft. 0 in.

Following the Exposition, Mr. Giaver was engaged in the general contracting business from 1893 to 1896 and served as Bridge Designer for the Sanitary District of Chicago from 1896 to 1898. In this latter position he designed the various bridges over the Chicago Drainage Canal.

During the World's Columbian Exposition, Mr. Giaver had become acquainted with and worked with Chicago's famous architect, the late Daniel H. Burnham, and, in 1898, he became Chief Engineer for the firm of D. H. Burnham and Company, which position he held for eighteen years, until 1915. During this time, Mr. Giaver's engineering work was in the practical development of the modern skyscraper from the old spread-footing foundation, cast-iron column, wrought-iron structural framework to the modern caisson foundation and structural steel framework.

As Chief Engineer for the Burnham Company, he had charge of more than four hundred of the largest buildings in the United States, among which were the Flat Iron, Gimbel, Maiden Lane, and Equitable Buildings in New

* Memoir prepared by Amasa C. Bull, Esq., Chicago, Ill.

York, N. Y.; the Field Museum, Continental and Commercial National Bank, Railway Exchange, Peoples Gas, Conway, Field, and other buildings in Chicago, Ill.; the Union Station and Post Office in Washington, D. C.; the Frick, Oliver, Smithfield, and First National Bank in Pittsburgh, Pa.; the May Company in Cleveland, Ohio; and the Wanamaker and Land Title Buildings in Philadelphia, Pa. One of his most interesting designs was that for the dome of the Mount Wilson Observatory in California.

In 1915, Mr. Giaver interested himself in the question of licensing structural engineers in the State of Illinois. He was the leader in securing the passage in 1915 of a bill to this effect by the Illinois Legislature, as the result of which structural engineers are allowed to practice their profession on equal terms with the architects in that State. Prior to this it had been impossible for an engineer to practice in building operations, except as an employee of an architect, as under the former law, building plans could not be lawfully approved unless bearing the signature of a licensed architect.

In 1920, Mr. Giaver was decorated with the order of Knight of St. Olaf, 1st Class, by King Haakon of Norway, in recognition of his prominence as an engineer and his activities on behalf of Norwegians in the United States. This is the highest honor accorded by the Norwegian Government to a noncitizen of that country, Mr. Giaver having received his final papers as a citizen of the United States in 1896.

After the death of Mr. Burnham in 1915, Mr. Giaver established offices in Chicago as a Consulting Engineer, and, in 1916, organized the architectural and engineering firm of Giaver and Dinkelberg. His last work as a member of this firm, finished only a few months before his death, was the engineering design of the 42-story Jewelers Building being erected at Wabash Avenue and Wacker Drive, Chicago, which will be the tallest office building west of New York.

Mr. Giaver was married in New York on September 3, 1883, to Louise C. Schmedling, of Trondhjem, Norway. He is survived by his widow, two daughters, Astrid (Mrs. Ralph Holmboe), Birgit (Mrs. A. C. Bull), and three sons, Erling, Finn J., and Einar W. Giaver.

In private life, Mr. Giaver was an enthusiastic yachtsman. It was his principal hobby and he won many prizes racing his boats on Lake Michigan. He was a Trustee of the Norwegian American Hospital in Chicago; President of the Structural Engineers Association; former Director of the Western Society of Engineers; President of the Norwegian Engineers Association; Past-President of the Chicago Norske Klub; former Vice-Commodore of the Columbia Yacht Club; and a member of the Engineers Club, Svenska Klubben, Chicago Athletic Club, and Chicago Yacht Club.

Mr. Giaver was elected a Member of the American Society of Civil Engineers on September 12, 1916.

WILBUR FRANCIS GOODRICH, M. Am. Soc. C. E.*

DIED FEBRUARY 26, 1925.

Wilbur Francis Goodrich, the son of Charles A. and Eleanor M. Goodrich, was born on August 18, 1853, at Lunenburg, Mass. He was educated at the Cambridge, Mass., Grammar and High Schools and at Comers' Commercial College at Boston, Mass. In 1873, he entered the Massachusetts Agricultural College, but remained only one year, having been compelled to leave because of illness.

On April 27, 1874, he began his engineering studies in the office of Shedd and Sawyer, Civil Engineers of Boston, where he remained for three years. His first work was that of surveying house lots at Chestnut Hill Reservoir, Newton, Mass. In 1877, he was employed on the Newton, Mass., Water-Works.

In 1880, Mr. Goodrich was engaged from June to September by the Nashua and Lowell Railroad Company as Assistant to the late Frederick Brooks, M. Am. Soc. C. E.; in September and October, he was with the late James B. Francis, Past-President, Am. Soc. C. E., on work on the Locks and Canals at Lowell, Mass., and in November and December, he was in the service of the Massachusetts Central Railroad Company as Assistant, in charge of a party, laying out work for construction.

From December, 1880, to March, 1881, Mr. Goodrich was employed by the City of Lawrence, Mass., as Transitman and Levelman on a survey of a section of the Valley of the Spicket River. From April, 1881, to January, 1883, he served the Fitchburg Railroad Company as Assistant in charge of a party, under the late Edmund K. Turner, M. Am. Soc. C. E., Chief Engineer, his principal work being the laying out of work for construction.

From January, 1883, to April, 1884, he was employed by the New York and New England Railroad Company as Assistant Engineer in charge of construction. This was contract work for which Mr. Goodrich prepared all the plans and made all the estimates. From April to December, 1884, he was with Whitman and Breck, Civil Engineers, of Boston.

From April to August, 1885, he served with the late William S. Barbour, M. Am. Soc. C. E., Chief Engineer of the City of Cambridge, Mass., as Inspector on the laying of 3 miles of 30-in., iron, water pipe and also in the removal and rebuilding of a drawbridge. From October to December, 1885, he was with the Massachusetts State Drainage Commission and for the six months following with Mr. E. Bowditch, of Boston, on topographical surveys at Ipswich, Mass.

In 1886 Mr. Goodrich was appointed Resident Engineer on the Toledo, St. Louis, and Kansas City Railroad, in charge of changing 63 miles of road from narrow to standard gauge and the building of a stone bridge foundation, a pier, and two abutments over the Big Wildcat River, two miles west of Kokomo, Ind. Following this engagement he was employed as Resident Engineer on the Mackinaw, Toledo, and Saginaw Railroad, and, subsequently, he was engaged

* Memoir compiled from information on file at the Headquarters of the Society.

for six months as Consulting Engineer on water-works in Vermont and on plans for electric street railways at Steubenville, Ohio, and Newport, R. I., as well as a reservoir for the United States Government on Coasters Harbor Island, Rhode Island.

As a Contractor with Mr. J. F. Barry, of New York, N. Y., Mr. Goodrich constructed three miles of electric railroad at Steubenville, one mile of street-railroad on Southern Boulevard, New York, and two miles at Richmond, Va. He also installed a 34-in. pipe line through ledge rock in Rockville, Conn. He then accepted the position of Resident Engineer with the Kansas City and Toledo Railroad Company, his work consisting of change of line covering 76 miles, from Ramsey, Ill., to St. Louis, Mo., including the construction of bridges, etc. Subsequently, he became Assistant Engineer with the Old Colony Railroad Company at Boston, and, later, was engaged in private engineering work, including the construction of the sewer system for the Metropolitan Park Commission of Massachusetts and change of line of the Revere Beach Railroad at Crescent Beach, Revere, Mass. His work also included change of grade at street crossings at Lowell, Mass., for the Nashua and Lowell Railroad Company.

From 1891 to 1894, Mr. Goodrich served as Assistant Engineer of the Metropolitan Sewerage Commission of Massachusetts. During this period he also constructed a wharf at Deer Island, in Boston Harbor, and for ten months following this engagement he served as Construction Engineer of a reservoir for an additional water supply at Yarmouth, Mass. He also held the position of Consulting Engineer for the Portland Stoneware Company's Plant, at Portland, Me., and was engaged for six months on inspection work at Payson Park Reservoir, at Cambridge, Mass. He also acted as Consulting Engineer for the construction of a water-works system at Edwardsville, Ill., and for the Coffeen Coal and Copper Company, on the construction of its plant at Coffeen, Ill.

In July, 1896, Mr. Goodrich became Assistant Engineer of the Boston Terminal Company in charge of laying out foundations, tracks, etc., for the New South Station, Boston. In 1900, he served for six months with the New York Central and Hudson River Railroad Company at Buffalo, N. Y., and also as Consulting Engineer of coal and iron property at Bedford, Pa.

In 1901, he had charge of construction at the Stanley Electric Plant, at Pittsfield, Mass., and, at the same time, acted as Consulting Engineer for the Austin Street Railroad, at Austin, Tex. He later served as Consulting Engineer for the Westfield Water-Works, Westfield, N. J., and the Piqua, Ohio, Electric Street Railroad Company, and made surveys and estimates for an electric railway from Washington, D. C., to Great Falls and Fairfax Court House, Va.

In 1902, Mr. Goodrich acted as Consulting Engineer for mill works at Adams, Mass., and examined coal property at Riddlesburg, Pa., and Middlesboro, Ky. He was also engaged as Consulting Engineer for mills at Saugus and Lawrence, Mass.; for the electric street railway at North Andover, Mass.; the Revere Boulevard, Revere, Mass.; and made plans and estimates for the Montreal Terminal Water Power Plant at Kinderhook Creek, N. Y.

In the same year he was placed in full charge of the work at the plant of the Gale Creek Coal Company, at Wilkeson, Wash., which comprised opening the mine, installing new machinery, and constructing new buildings. He also made examinations and prepared reports on the Denver, Lakewood, and Golden Railroad. In the State of Washington, he reported on the water power of the Nesqually River, the coal property of the Burnett Coal Company at Carbonado, and coal mines at Franklin, Fairhaven, and Whatcom, as well as coal property at Fairfax and Mulmont. He also made an examination and reported on the Tacoma and Eastern Railroad at Tacoma.

In 1903 and 1904, Mr. Goodrich served as Engineer in charge of pumping out and installing machinery in a coal mine in Gayton, Va., and as Consulting Engineer on work in other cities in New England and the South. He also served as Consulting Engineer and reported on the construction of a plant for the Amalgamate Graphite Company at Johnsburg, N. Y., and, in 1905, made examinations and reports on the Connecticut River below Springfield, Mass., as well as for the Newfoundland, Labrador, and Sandwich Bay Company.

From July, 1905, to July, 1906, he was engaged as Consulting Engineer for the Nevada Northern Railroad Company and from 1906 to 1908 in private work in Boston. In 1909, he was employed as Consulting Engineer to the Boston Finance Commission and, in 1910, was Engineer in charge of pumps and engines in mills at Adams, Mass. He also held the position of Engineer of the Municipal Filtration Company at Boston.

In 1911, he served as President of the T. M. Filter Company of Boston and, until 1915, carried on a private consulting practice in several cities in Massachusetts. In 1916, he was again Consulting Engineer for the Boston Finance Commission; was engaged in machine-shop designing at Fitchburg, Mass.; and served as Engineer of the Shirley Peat Works at Shirley, Mass.

In 1917, and 1918, Mr. Goodrich held the positions of Engineer for the Elm Street Bridge at Manchester, N. H.; Resident Engineer on the Fort Smith and Western Railroad; and Consulting Engineer for the Boston and Maine Railroad Company. During this period he was also Inspector of the building of a wharf, pier, and pier shed at the Army Base at South Boston, Mass., and, in 1919, he became Inspector at the Army Base and also held the position of Construction Engineer for the Eastern Massachusetts Street Railway Company, with work at Chelsea, Randolph, Salem, Peabody, Revere, Weymouth, Lynn, and Lowell, Mass.

In 1921, he was appointed Inspector of a bridge over the Connecticut River at Springfield, Mass., and from 1922 to 1923 was engaged in private work for the Boston Finance Commission and was also Engineer in charge of the relocation of railroad yards and tracks at Springfield, Mass.

From 1924 until his death on February 26, 1925, Mr. Goodrich was engaged in private practice which included the building of a coal trestle, water tanks, and Colonial filling stations for the J. F. Kennedy Company, of Boston.

He is survived by his widow, Mary L. Goodrich, two sons, and two daughters.

Mr. Goodrich was a member of, and Treasurer of, the Railway Appliance Association of Providence, R. I., and an Associate Member of the Alumni of the Massachusetts Agricultural College. He was a member of the First Methodist Episcopal Church and also of Soley Lodge, F. and A. M., of Somerville, Mass.

He was essentially a home man, taking more pleasure with his family than with social clubs and organizations. Having a kindly disposition and a ready smile he made friends easily and retained such friendships throughout his life.

Mr. Goodrich was elected a Member of the American Society of Civil Engineers on May 4, 1887. He was also a member of the Northeastern Section of the Society.

JOHN LYELL HARPER, M. Am. Soc. C. E.*

DIED NOVEMBER 28, 1924.

The importance of hydro-electric power development was just beginning to be realized when Mr. Harper came to Niagara Falls, N. Y., in 1902. With his broad vision and ability and situated as he was at this mightiest source of power, he was destined to take the lead in an industrial achievement which remains unsurpassed anywhere in the world. At his death he was recognized as one of the greatest engineering minds of the age and the famous development in the Gorge below the Falls of Niagara will always stand as a monument to his genius.

John Lyell Harper, the younger of the two sons of Joseph F. and Quintilla K. Harper, was born on a farm in a hilly section of New York State called Harpersfield, on September 21, 1873. Like most farmers' sons, he had to work long, hard hours in the fields as well as climb the mountain every day to attend the country school in the next valley; but the rigors of country life served only to develop his keen mind and foster in him a passionate love of Nature which he retained throughout his life.

He loved books and applied himself diligently to the pursuit of knowledge, very early showing more than ordinary interest in experimenting with running water. There were plenty of mountain streams around his home and it was his special study, with a degree of success beyond his years, to attempt to control the powers of Nature, damming up one stream and diverting the course of another to turn mills and water-wheels of his own invention. Thus, his boyhood was spent and at the age of twenty he had finished the course of study at Stamford Seminary; whence he followed his own particular star to Cornell University, from which he was graduated with the degree of Mechanical Engineer.

From Cornell, Mr. Harper went to Seattle, Wash., as a Draftsman with the Oregon Improvement Company, making designs for the repair and construction of railway equipment. After four months, however, he resigned this position to enter the employ of the Union Electric Company where the field of practical experience included the repair and testing of motors, transformers, and general electrical apparatus.

In June, 1898, he secured the position of Operating and Construction Engineer of the Twin City Rapid Transit Company, of Minneapolis, Minn., and remained with that Company a year. In this position his training was broader and more along the lines in which he was most interested. Among other things he had a great deal of experience in designing and constructing substations, installing underground cables, testing water-wheels, and similar work in connection with the operation of the 10 000-h.p. water-power plant of the Company.

* Memoir prepared by N. R. Gibson, and O. D. Dales, Members, Am. Soc. C. E., and G. R. Shepard, Esq.

At the end of the year Mr. Harper transferred his interests to the firm of I. W. Gray and Company and was responsible for the design of an electric railway and steam power plant for Mankato, Minn.

Steadily, he was increasing his experience and his value, and, in 1899, he took his first important position, as Field Representative for Messrs. Floy and Carpenter, Consulting Engineers, of New York, N. Y., on their project to build a hydro-electric power plant for the St. Croix Power Company of Wisconsin at Appleriver, Wis. He was in entire charge of the construction of this development which was completed in three years.

It was the turning point in his career when in 1901 he came East, to Buffalo, N. Y., to represent certain manufacturing and engineering interests at the Pan-American Exposition, for there he got into touch with the Niagara Falls Hydraulic Power and Manufacturing Company and in 1902 accepted a position with that Company as Assistant to the Engineer, the late Wallace C. Johnson, M. Am. Soc. C. E. It was there that his principal work began, and from that time until his death in 1924, the story of his life is intimately associated with the history of the development of power from the waters of the Niagara River.

This Company in 1881 had begun the construction of a power-house called Station No. 1 for supplying electric power for commercial purposes. In February, 1902, when Mr. Harper came to Niagara Falls, this plant had a capacity of 2 000 h.p., and a new power-house called Station No. 2 had been partly constructed, having at that time a capacity of about 20 000 h.p. In two years he became Chief Engineer and prepared plans for the completion of Station No. 2 and, in 1904, when this was accomplished, it had an installed capacity of 33 000 h.p. Station No. 1 was then abandoned and the construction of Station No. 3 begun, which was ultimately to have a capacity of 130 000 h.p. From that time rapid improvement was made and further plans for the future were under way when, in 1909, the Governments of Canada and the United States set a limit to the quantity of water that could legally be diverted for power purposes. Plans already made were carried out, but incentive to greater achievement was thus temporarily removed.

During the World War emergency, the Niagara Falls Power Company, Hydraulic Power Company, and Cliff Electrical Distributing Company, were merged under the name of The Niagara Falls Power Company, owning all developments on the American side and controlling the Canadian Niagara Power Company on the Canadian side. The combined plants had a total installed capacity of 350 000 h.p., and it was a fitting tribute to Mr. Harper's vision and ability that the developments of the consolidated companies were placed in his hands as Chief Engineer, and that, in 1919, the responsibility of Vice-President was added.

The shortage of power was serious in this period and when the War Department requested plans for the most economical development for utilizing the remaining water available for diversion, it was the Harper plan that was accepted. This provided not only for immediately placing all developed power

at the disposal of the Government agents for distribution to specified customers who were making the materials vital for war work, but also for the rush development of another 100 000 h.p. without sacrifice of permanency of work or efficiency of conversion.

These construction plans were being rushed to completion when the signing of the Armistice made speed less important; however, the whole 100 000 h.p. was put in operation within twenty-two months from the time it was authorized. Shortly afterward, the Government of the United States established the Federal Power Commission and its approval was given to the engineering plans of The Niagara Falls Power Company. A license for fifty years was issued for all the water permitted to be diverted from the American side of the Falls in accordance with the terms of the existing treaty, with the exception of 500 cu. ft. per sec., which was reserved for diversion through the New York State Barge Canal.

As no further water was available, the only source of additional power was the use of some of the water under increased head. Plans accordingly went forward for the construction of Station No. 3-C which was begun in April, 1921, and completed in two years. The water for this Station was brought from the upper river under the city in a tunnel 32 ft. in diameter. Each of the three units in this plant has a capacity of 70 000 h.p.—at present, the largest installation in the world.

In connection with the Niagara development, Mr. Harper was especially interested in the question of the preservation of the scenic beauty of the Cataract in its relation to diversion of water for industrial purposes. For the scientific engineering study of this problem he designed and had built a model of the Niagara Falls and Rapids on a scale large enough to determine with a reasonable degree of accuracy the effect of diversion on the Falls and Rapids and to actually demonstrate the feasibility of the various plans for remedial works which are necessary to prevent the present rapid and irregular recession of the Horseshoe Falls. He also wrote several papers on this subject and thus brought his opinions and the results of his research to the attention of the public.

Mr. Harper found time to interest himself in chemical and metallurgical research, particularly along the lines of the application in these industries of electric service. He was successful in inventing and patenting the Harper electric furnace, for the commercialization of which he organized, shortly before his death, the Harper Electric Furnace Corporation.

He also initiated, in 1924, the organization of the firm of Harper and Taylor, Incorporated, to carry on a consulting engineering practice in conjunction with his Engineering Staff at the Power Company.

In 1898, he was married to Linda E. Wheeler, of Ithaca, N. Y., who, with two sons and three daughters, survives him.

Mr. Harper was a man of high ideals and absolute integrity, a loyal friend, and devoted to his family. A lover of Nature and of the out-of-doors, his chief hobby was the cultivation of flowers and fruits and his gardens were always a delight.

Cut off in the prime of life, in the midst of plans and visions for the future, it was some consolation to those who knew him that he lived to see the completion of his two latest projects. Throughout his work he maintained the highest engineering and moral standards, and his premature death was a loss to the profession.

Mr. Harper was elected a Member of the American Society of Civil Engineers on June 5, 1907.

JOHN FILLMORE HAYFORD, M. Am. Soc. C. E.*

DIED MARCH 10, 1925.

John Fillmore Hayford, the son of Hiram and Mildred Hayford, was born at Rouses Point, N. Y., on May 19, 1868. His early education was secured, while a farm boy, at the small stone schoolhouse not far from the farm.

Mr. Hayford was graduated from Cornell University in 1889, with the degree of Civil Engineer, and immediately entered the service of the United States Coast and Geodetic Survey at Washington, D. C., as a Computer. In 1892, he was made Assistant Astronomer in charge of field parties on the International Boundary Commission, laying out the boundary between the United States and Mexico, on which work he was engaged during 1892 and 1893.

On the completion of the Boundary Survey, he returned to the Coast and Geodetic Survey as Aid, and, later, as Assistant in 1894 and 1895. He then resigned to become Instructor in Civil Engineering at Cornell University, which position he held until 1898, when he again entered the Coast and Geodetic Survey as Expert Computer. In 1900, he was made Chief of the Computing Division, succeeding Mr. Charles A. Schott, and, in addition, was appointed Inspector of Geodetic Work. In this dual capacity he served the Nation until 1909, when he resigned to become Director of the College of Engineering at Northwestern University at Evanston, Ill., a position which he held until his death. He died of a complication principally dropsical in character, after an illness of three months.

While carrying on the regular work of the two departments of the Survey over which he had supervision, Mr. Hayford found time to conduct many original investigations. His theory of isostasy brought him international reputation, for which he was awarded, in 1924, the Victoria Medal of the Royal Geographic Society of Great Britain, an honor accorded to only two other Americans. His work with the transit micrometer and precision level revolutionized longitude determinations and precise level work, and he was a great factor in the adoption of the U. S. Standard Geodetic Datum, which has now become the North American Datum.

During the time that he was developing his theory of isostasy, Mr. Hayford made computations as to the figure of the earth, and his values of the lengths of the earth's semi-major and semi-minor axes, together with the ratio of polar flattening, were adopted in October, 1924, by the International Geodetic and Geophysical Union, as being the values which best fitted the various continents of the earth. He was twice selected to represent the United States as Geodetist at International Geodetic Conferences, once at Budapest, Hungary, and again at London, England.

* Memoir prepared by William H. Burger, Prof. of Civ. Eng., Northwestern Univ., Evanston, Ill.

As an active member of the Philosophical Society and of the Engineers' Club of Washington, he presented many papers. He was a member of the Cosmos Club of that city and took great delight in there meeting friends and visitors to the Capitol City.

At Northwestern University, as in Washington, Professor Hayford found time to do a prodigious amount of work other than that connected with his regular duties as Director of the College of Engineering. Especially notable was his work as Research Associate of the Carnegie Institution, studying the laws of evaporation, etc., underlying changes in lake levels on the Great Lakes, and in investigating factors affecting stream flow.

In 1912, Professor Hayford was selected by the Arbitrator, the late Chief Justice White, to head the Commission of Engineers to survey the disputed boundary between Panama and Costa Rica, and, later, was a member of the Commission of Engineers and Geologists sent to study the slides at the Panama Canal. In 1915, he was appointed by the President as a member of the National Advisory Committee for Aeronautics, and during the World War he was engaged with a group of scientists at the U. S. Bureau of Standards in devising instruments for recording airplane performance.

Professor Hayford was elected a member of the National Academy of Sciences, one of the highest honors granted to scientists in this country. He was also a member of the American Astronomical Society, American Association for the Advancement of Science, National Research Council of the American Geophysical Union, Western Society of Engineers, and the Society for the Promotion of Engineering Education. In 1918, George Washington University conferred on him the degree of Doctor of Science.

Although he was a scientist of the highest attainment, there was probably no field in which he took keener delight than in considering the problems of engineering education. He was honored by being elected President of the Society for the Promotion of Engineering Education for 1918-19.

As a citizen of the community in which he passed the last fifteen years of his life, Professor Hayford was most highly esteemed, and took an active interest in civic problems and affairs. He was a member of the Rotary Club, University Club, Northwestern Chapter of Sigma Xi, and the Unitarian Church of Evanston, and of the Chaos Club of Chicago, Ill.

Professor Hayford was the author of "Geodetic Astronomy", a joint author of "The Adjustment of Observations by the Method of Least Squares," and author of numerous special reports, monograms, and articles dealing with geodetic, geophysical, geological, and educational subjects.

More than a quarter of a century of very intimate association with Professor Hayford, first as a member of the U. S. Coast and Geodetic Survey, and, later, as a member of the Faculty at Northwestern University, revealed the following characteristics to be uppermost in his life: Intense energy of body and mind, strict honesty of thought and purpose, and a hatred of all sham and pretense. He had the great faculty of making and holding friends; he seldom entered into anything without giving to it his fullest energies; and he obtained the keenest enjoyment out of life.

He was married on October 11, 1894, to Lucy Stone, of Charlotte, N. Y., who survives him, with four children, Walter S., Maxwell F., John B., and Phyllis Hayford. The latter is a Junior in the College of Engineering at Northwestern University, and the three sons have engineering degrees from the same institution.

Professor Hayford was elected an Associate Member of the American Society of Civil Engineers on May 6, 1896, and a Member on April 2, 1907.

CURTIS HILL, M. Am. Soc. C. E.*

DIED OCTOBER 18, 1925.

Curtis Hill, the son of William Moberly and Ann (Gossett) Hill, was born near Independence, Mo., on September 4, 1870, on a farm acquired by his grandfather, Adam Hill, who came from Kentucky to Missouri on horseback in 1830. The Hill family is of sturdy pioneer stock and is one of the oldest in the United States, the first of that name having emigrated from England to America in early Colonial times.

Curtis Hill's early education was obtained in the public schools of Jackson County, Missouri, and at Woodland College, at Independence. He was graduated from the University of Missouri in 1896 with the degree of Bachelor of Science in Civil Engineering, and a year later received the degree of Civil Engineer from Cornell University. While at the University of Missouri he was prominent in athletics and played three years on the football team, serving one year as Captain.

Mr. Hill's professional work was connected chiefly with railroads, waterways, highway bridges, highways, and municipal construction. He was engaged as Instrumentman on railroad construction in Mexico in 1892, prior to his graduation from the University of Missouri, and after leaving Cornell University, in 1897, he was employed by the Illinois Central Railroad Company for a few months on track construction. He again engaged in railroad work in 1899, this time with the Chicago and Northwestern Railway Company.

From September, 1897, to August, 1899, Mr. Hill was with the United States Deep Waterways Commission, engaged in making hydrographic and topographic surveys and estimates for a proposed canal outlet for the Great Lakes. During the next two years he was employed by the Central Bridge Company, of St. Louis, Mo., as Designer, Contracting Agent, and Erection Superintendent.

Beginning in October, 1901, Mr. Hill spent almost six years with the Sewer Department of St. Louis, eighteen months as Assistant Engineer and the remainder of the time as Engineer of Sewers. In the latter position he had charge of all field surveys and construction work pertaining to sewers, the cost of the work done under his direction amounting to about $5 000 000.

In July, 1907, Mr. Hill was appointed State Highway Engineer of Missouri by Governor Folk, being the first to hold that office. Two years later, on account of the highly satisfactory character of his work, he was re-appointed by Governor Hadley and remained in office until April, 1913. During his encumbency he did considerable pioneer work in connection with highway construction, laying the foundation for the extensive development later author-

* Memoir prepared by Victor H. Cochrane, M. Am. Soc. C. E.

ized by vote of the people. His valuable services in this office were commemorated by Mr. J. M. Lowe in the dedication of his book, "National Old Trails Road", as follows:

"To Curtis Hill, the first State Highway Engineer of Missouri, whose spirit rose to a full comprehension of the duties and obligations of his high office, and whose intelligence and lofty vision enabled him to grasp with full appreciation the mighty pioneer problems which he alone had to solve, this book is respectfully and affectionately dedicated."

In April, 1913, Mr. Hill became City Engineer of Kansas City, Mo., and during the next five years he had charge of a great variety of municipal construction aggregating about $10 000 000 in cost, and also made plans for proposed sewers, flood protection works, trafficways, and other improvements. For one year during this period he acted as Advisory Engineer to the Board of Park Commissioners of Kansas City.

On June 7, 1918, occurred the tragic event that caused Mr. Hill to be incapacitated for the remainder of his life. He was shot in the head by a disgruntled contractor, a man of violent temper and unsound mentality. Some time previously, this contractor had been awarded the contract for the construction of a small bridge, which he had failed to complete satisfactorily. Later, he submitted a bid for a much larger bridge, and because of the previous trouble and the fact that the bid seemed to be much too low, Mr. Hill recommended that the contract be not awarded to him; however, the contractor persuaded the Board of Public Works that he could build the bridge properly and expeditiously, and he was given the work. He was wholly without experience in bridge construction and had no adequate equipment. After he had worked several months without making any progress, the Board annulled his contract and gave the work to a responsible and experienced firm. The contractor was present at the meeting of the Board when this action was taken, and he immediately shot Mr. Hill.

At first it was thought that Mr. Hill's injury would prove fatal, but after undergoing an operation for the removal of a piece of the bullet from the brain, he seemed considerably improved; however, the wound had caused a partial amnesia, from which he never fully recovered. He was retained by the City as Assistant City Engineer until April, 1925, and during 1923 and 1924 he was able to work occasionally, although for only a few days at a time. In April, 1925, he was pensioned by the City. At this time his health was in such a critical state that death seemed imminent, but he lived until October 18, 1925.

During the entire period of his illness Mr. Hill was uniformly cheerful, and accepted his fate without bitterness and with a degree of fortitude that was the marvel of his friends.

On account of his pleasing personality, his kindliness, his helpfulness, and his fair-mindedness, Mr. Hill was well liked by his associates and respected by every one. He was a man of good intellectual attainments and excellent judgment, and possessed the ability to analyze a given situation or problem and to determine the best course of action under the circumstances. His honesty and integrity were recognized by all who came in contact with him, and his ability and trustworthiness as an engineer and public servant were amply

demonstrated by the fact that although he was a lifelong Democrat, he was retained in office by Republican officials as readily as if he had belonged to that party.

In 1899, Mr. Hill was married to Flora Lewis, of Missoula, Mont., who was the daughter of a pioneer missionary to the Northwest Territories. He is survived by his widow and two children, William Moberly Hills, an engineering student in the University of Missouri, and Elizabeth Hill Gordon.

He was a member of the Presbyterian Church, the Beta Theta Pi Fraternity, the Kansas City Engineers' Club, and was a Thirty-second Degree Scottish Rite Mason.

Mr. Hill was elected an Associate Member of the American Society of Civil Engineers on October 2, 1901, and a Member on January 3, 1907.

HENRY CLARENCE HODGKINS, M. Am. Soc. C. E.*

DIED NOVEMBER 8, 1925.

Henry Clarence Hodgkins was born at Carthage, N. Y., on December 12, 1854, the son of Ezra and Amelia (Fuller) Hodgkins. His mother's ancestry has been traced to Edward Fuller, who came to America in the *Mayflower*. The Hodgkins and Fuller families belong to a group of miners and manufacturers who were attracted to Northern New York by the mineral wealth and splendid water-power facilities of the Black, Grass, and Oswegatchie Rivers. The Towns of Fullerville and Rossie were the sites of foundries and furnaces operated by Fuller Brothers, one of whom, Ashbel, was the maternal grandfather of Henry Clarence Hodgkins.

Mr. Hodgkins was graduated from Union College with the degree of Civil Engineer in 1875. He then began a long and useful career as Engineer in the survey and improvement of the islands of the St. Lawrence River, including the following: Thousand Island Park, Westminster, Round Island, Hillcrest, Grenell Island, and Central Parks. He also did considerable landscape work in parks and cemeteries at Watertown, N. Y., and extensive surveys in a long litigated dispute between the Rossie and Karney Ore Mines.

In 1880, he became Assistant Engineer on the Water Power Pumping Station at Watertown, and in 1881 held the position of Topographer on the New York and Boston Inland Railroad surveys. In 1882, he designed and supervised the construction of three masonry arch bridges across the Grass River in St. Lawrence County, New York, with an aggregate length of 850 ft., and also served as Transitman on the location of the Carthage and Adirondack Railroad.

From 1883 to 1885, Mr. Hodgkins served as City Engineer of Watertown, and in this capacity designed and supervised the construction of the Court Street Bridge and approaches with a clear span of 170 ft. This bridge in 1921 was replaced by a double-deck concrete structure.

In 1884, he entered into partnership with Hinds, Moffett, and Company, which a short time afterward became the firm of Moffett, Hodgkins, and Clarke. As the engineer member of this firm, he had charge of the plans and construction of seventy-five water-works including those at Duluth, Minn., Butte, Mont., and Peoria and Galesburg, Ill. In connection with the firm, he had supervision of the surveys of the Norwood and Massena Railroad, the Kinderhook and Hudson Railroad, and took personal charge of the location and construction of the Gouverneur and Oswegatchie Railroad. The firm also acted as Engineers of the Lake Street Elevated Railroad in Chicago, Ill., installed and operated three gas plants and ten central station electric lighting plants, and installed one of the first central alternating-current plants at Rochester, Minn., in 1887.

* Memoir prepared by William M. Booth, Esq., Syracuse, N. Y.

Mr. Hodgkins served as President of the Montreal Water and Power Company from 1890 to 1893 and until 1900 was President of the Electric Engineering and Supply Company, manufacturers on a large scale of electric lighting supplies. At this time he was also interested in the appraisal, arbitration, negotiation, and sale of the properties of many water companies to towns.

In 1902, he served as Engineer for the Town of Waterloo, Ont., Canada, in the construction of its water-works, and, also, as Engineer for the Village of Carthage, N. Y., in obtaining its water supply by gravity from the Adirondacks, fifteen miles away.

From 1904 to 1907 Mr. Hodgkins was employed in connection with the transmission lines of the Northern Ontario Light and Power Company, Limited, and as Consulting Engineer for the City of Berlin, Ont., Canada, in the installation of electric pumping, filtration, and a concrete water tower. He also served as Consulting Engineer for the City of Brantford, Ont., on the revision of its distribution system and increased water supply, including reservoir and electric pumping; as well as Engineer for the Galion Water Company, for an increased water supply and a pumping plant. From 1907 to 1914, Mr. Hodgkins was engaged in general consulting work.

From 1923 until his death he held the position of Engineer for the City of Cortland, N. Y., studying the remodeling and enlarging of the water distribution system, the new water supply, the question of pumping by electric *versus* steam power, and the designing and constructing of a complete new pumping station. In 1914, he served as Engineer for the proposed suburban water supply at Toronto, Ont., Canada, and as Consulting Engineer for the City of Kitchener, Ont., for its additional water supply, pumping mains, and reservoir. Mr. Hodgkins also served as Engineer for the Village of Manlius, N. Y., from 1918 to 1921, on its additional water supply works, electric pumping station, and conduit.

On June 11, 1889, Mr. Hodgkins was married to Mary Ida Follett, of Newark, Ohio, and in the autumn of that year they removed to Syracuse, N. Y., where they have since resided. Two of their three children are living, Henry Follett Hodgkins and Marian Hodgkins Baxter.

In June, 1925, Mr. Hodgkins joined the surviving members of his Class at Union College in the celebration of its Fiftieth Anniversary. This was a very happy occasion. He was a member of the Technology Club of Syracuse and was elected a member of the American Water Works Association on April 18, 1888.

His contributions to the literature of his profession were made through papers presented at the annual meetings of the Societies of which he was a member. He was an authority on franchises, and this subject was the title of a much discussed paper before the American Water Works Association, in Cincinnati, Ohio, in 1915. The Syracuse Technology Club received his hearty support and co-operation. He attended the meetings with great regularity, contributed papers, and served on its committees. His knowledge of the topography of Central and Northern New York always surprised his associates.

For nearly a quarter of a century Mr. Hodgkins was a member and officer of the First Presbyterian Church of Syracuse, and to these duties he brought the dignity, integrity, and accuracy of the engineer. As a companion he was genial, fond of anecdote, and ready to draw from a broad personal experience and careful reading. His interest in the comprehensive physical development of the City of Syracuse was unusual. His civic pride was of the highest order. In his death, the Engineering Profession has lost a useful member. He will be missed by many friends.

Mr. Hodgkins was elected a Member of the American Society of Civil Engineers on June 6, 1911.

OLAF HOFF, M. Am. Soc. C. E.*

DIED DECEMBER 24, 1924.

Olaf Hoff, the son of Martin C. and Gunhild Hoff, was born in Smaalenene, Norway, on April 2, 1859. He received his elementary education in the Real-gymnasium at Ringerike, Norway, and entered the Polytechnic Institute at Christiania (now Oslo), Norway, from which he was graduated in 1879 with the degree of Civil Engineer and with the highest honors ever granted by the Institute.

In 1879, Mr. Hoff came to the United States, and in the spring of 1880 entered the service of the Keystone Bridge Company as Assistant Foreman in one of the shops of the Company at Pittsburgh, Pa. In a few months he was transferred to the Drafting-Room, where he was gradually advanced, eventually becoming Assistant Chief Engineer.

From 1881 to 1883, he was in the employ of the Mexican Central Railroad, first as Bridge Engineer and, later, as Locating Engineer on the Tampico Division. From 1883 to 1885, Mr. Hoff served as Chief Engineer of the Shiffler Bridge Company, of Pittsburgh.

From 1885 to 1901, he was engaged in consulting and contracting practice in Minneapolis, Minn., acting, at the same time, as Western Representative of the Shiffler Bridge Company. In 1891, he built a steel railroad bridge across the Mississippi River at Minneapolis for the Minneapolis and Western Railway Company, and devised the method of erecting this bridge without falsework. He designed a highway bridge across the Mississippi River at Muscatine, Iowa, 2 000 ft. long, with a 400-ft. cantilever span. He also acted as Consulting Engineer on several bridges crossing the Mississippi River at St. Paul, Minn., and made competitive designs for others, such as the Washington Bridge across the Harlem River, New York, N. Y., and two arch bridges across the Mississippi River, one at Nicolet Avenue and another at Lake Street, Minneapolis.

From 1901 to 1905, Mr. Hoff served as Engineer of Structures for the New York Central and Hudson River Railroad Company, in charge of bridges and buildings, and was identified with the renewal and reconstruction of more than four hundred bridges.

From 1905 to 1908, he was a member of the contracting firm of Butler Brothers-Hoff Company. This Company, as contractors, built the Michigan Central Railway Company's tunnel under the Detroit River between Detroit, Mich., and Windsor, Ont., Canada. The Railroad Company's plans called for a new type of subaqueous tunnel construction, consisting of twin steel tubes to be placed in a dredged trench and encased in concrete under water. Mr. Hoff gave all his exceptional inventive and sound engineering talent to the solution of a suitable design for the steel tubes and practical methods for floating and lowering them in place to correct alignment and

* Memoir prepared by Sverre Dahm, M. Am. Soc. C. E., and J. L. Holst, Chf. Engr., Todd, Robertson, Todd Eng. Corporation, New York, N. Y.

grade, and for an adequate and economical encasement of these tubes with concrete placed in deep, swiftly flowing water.

From 1908, Mr. Hoff was engaged in consulting practice in New York, N. Y. The success of his past engineering performances had brought him an enviable reputation and he was therefore consulted by individuals and corporations regarding large problems of building construction, including subways, tunnels, harbors, and bridges.

The type of subaqueous tunnel used under the Detroit River and the methods employed in its construction had proved to be so satisfactory in every respect that Mr. Hoff secured, in competition with other tunnel types, the contract for the construction of the four-track tunnel carrying the Lexington Avenue Subway under the Harlem River in New York. This contract, awarded the McMullen-Hoff Company of which he was a member, was undertaken in 1912 and satisfactorily completed in 1915.

He acted as Chief Consultant to the Cunard Steamship Company, Limited, in connection with its proposed steamship terminal in the Port of New York and as Consulting Engineer to the New York Central Railroad Company on the design and construction of the A. H. Smith Memorial Bridge across the Hudson River at Castleton, N. Y., and of the Michigan Central Railroad Arch Bridge across the Niagara River, at Niagara Falls, N. Y.

Mr. Hoff's inventive mind concerned itself with many subjects. He invented methods for submarine pile-driving, reinforced concrete piles, grain-bin construction of reinforced concrete, fireproof floor construction, etc. His studious nature kept him fully abreast with the progress of his profession, and he possessed the inventiveness combined with a clear, analytical mind and the sense of fairness required for a successful engineer. These qualities made for him a great many friends and admirers in his profession, to whom he added many more among the laymen through his winning personality, his kind helpfulness, and his attention to other people's needs.

In 1885, Mr. Hoff was married to Josie Johnson Vea, of Stoughton, Wis. He is survived by Mrs. Hoff and five children, two daughters, Mrs. Olga Hoff Fernald and Mrs. Borghild Hoff Lyman, and three sons, Matthew, Olaf, and Trygve Hoff.

He was a member of the American Society for Testing Materials, American Association for the Advancement of Science, Engineers' Club of New York, National Geographic Society, Colony Club of New York, and Commonwealth Club of Montclair, N. J.

Mr. Hoff was elected a Member of the American Society of Civil Engineers on May 6, 1885.

CLIFFORD MILBURN HOLLAND, M. Am. Soc. C. E.*

DIED OCTOBER 27, 1924.

Clifford Milburn Holland was born at Somerset, Mass., on March 13, 1883. He was the only child of Edward John Holland and Lydia Frances Hood. His father's ancestors lived in Maine, where they had moved from Massachusetts soon after the Revolution. On his father's side he was descended from Dr. Francis Le Baron, the "nameless nobleman" of early Plymouth. His mother's family came from about Providence, R. I., and Fall River, Mass., and was descended from Roger Williams and others of the earliest settlers.

He attended public schools in Somerset until 1892, then six years in St. Joseph, Mich., and then one year at the High School in Fall River, after which his family moved to Cambridge, Mass. He was graduated from the Cambridge Latin School in 1902 and entered Harvard University, receiving the degree of Bachelor of Arts in 1905 and the degree of Bachelor of Science in Civil Engineering in 1906. It is noteworthy that he completed the work for both degrees in four years.

Before leaving Harvard, he had successfully passed civil service examinations and had been appointed Assistant Engineer in the Engineering Forces of the Rapid Transit Railroad Commission of New York, N. Y. In June, 1906, he began his engineering career with an assignment to the construction of the Battery-Joralemon Street Tunnel, in which position he continued until its completion in 1908. The work was of an especially difficult and trying character, but he met every task with enthusiasm and liking and performed it very quickly and completely. He had decided to specialize in compressed-air tunneling, but no one could foresee that six years of political delay would elapse before the start of new river tunnels. He was engaged at first in completing the construction records in connection with extra claims, then, for a time, in field charge of a portion of the Fourth Avenue Subway in Brooklyn, N. Y., and, later, the new tunnels coming into prospect, he was assigned to a study of the sections to be recommended. For that use he gathered exhaustive data as to the dimensions, depths, and construction conditions of all similar tunnels that had been built in America and Europe, made a comparative analysis of their stresses and parts, and compiled the results. The work was admirably done and proved most useful, besides giving Mr. Holland a breadth of recorded information on the subject few could equal.

When, in 1914, contracts were let for the Old Slip-Clark Street and Whitehall Street-Montague Street Tunnels, Assistant Engineer Holland was entrusted with direct charge. His age was then thirty-one, but there was no question as to his fitness. His responsibilities were afterward increased when contracts were let for the Willoughby Street, Fourteenth Street, and Sixtieth Street Tunnels, making the contract value of work under his charge about $26 000 000. With five double-tube tunnels, of which four were subaqueous, in progress at once, involving a vast amount of engineering and official detail;

* Memoir prepared by the following Committee: Robert Ridgway, Past-President, Am. Soc. C. E., *Chairman*, and Charles Gilman and Frederick C. Noble, Members, Am. Soc. C. E.

with frequent emergencies requiring him to visit widely separated points and render quick, sure decisions at any time of the day or night, the situation would have dismayed any but a man of great courage, ambition, and exceptional ability. In 1916 he was accorded the long desired title and emoluments of Division Engineer. The entire work was carried along according to the best engineering precedents and without serious mishap. At the end of this connection, in June, 1919, the amount and range of Mr. Holland's subaqueous tunneling experience and his close relation to it, as well as his marked success in such work, placed him uniquely in his chosen specialty.

The New York State and New Jersey Interstate Bridge and Tunnel Commissions having been empowered by their respective State Legislatures to cooperate in the construction of a vehicular tunnel under the Hudson River, and realizing, as the Commissioners express it in their Annual Report, "that it was of vital importance to the project to secure the highest degree of technical guidance to develop and carry out this great engineering project", appointed Mr. Holland as their Chief Engineer, which office he assumed July 1, 1919. The report further says:

"After a most careful deliberation the Commission was unanimous in inviting Mr. Clifford M. Holland of Brooklyn, New York, to accept its appointment as chief engineer. The New Jersey Interstate Bridge and Tunnel Commission participated in this action.

"In securing Mr. Holland's acceptance of this position, the Commission felt that it had been singularly fortunate. At the time of his appointment he was tunnel engineer of the Public Service Commission, First District, State of New York, and was in immediate charge of the construction of all the subway tunnels under the East River. Mr. Holland has probably had a greater and more successful experience in the work of subaqueous tunnel construction than any other member of his profession."

The problem Mr. Holland was given to solve involved a number of features without precise precedent and the expenditure of about $42 000 000. An effective engineering organization had to be built up of men selected for their technical and personal qualifications rather than for political reasons, and it is greatly to the credit of the Commissioners that this right was accorded. Many plans for construction and traffic handling had been proposed and these were carefully studied and investigated. The plan finally recommended by Mr. Holland will provide a pair of cast-iron tubes, shield-driven, each measuring 29 ft. 6 in. in outside diameter and accommodating two lines of traffic in the same direction in each tube. The adoption of this plan, which has been vindicated, cost the Chief Engineer a severe struggle in which he was obliged to defend his recommendation, with all the grit and resources at his command, against the criticisms and rival plans brought forward by other engineers.

To the question of ventilation of the tunnel after completion Mr. Holland gave a great deal of personal attention, carrying out experiments in conjunction with the University of Illinois, Yale University, and the United States Bureau of Mines, and making frequent trips for that purpose, as well as an examination of ventilation conditions in European tunnels for vehicular traffic. These investigations and others relating to design, power requirements, prob-

able traffic and operating income, and other features, are fully described in his Annual Reports, published by the Commissions, and form an unusually fine record.

While Mr. Holland appeared to be generally in vigorous health, it is probable that he suffered acutely at intervals during several years. His sudden, unexpected death occurred on October 27, 1924, at Battle Creek, Mich., where he had gone for rest and treatment.

Mr. Holland was married on November 5, 1908, to Anna Coolidge Davenport, of Watertown, Mass., who survives him, as do four children, Anne, Clarissa, Benita, and Lydia.

At the time of his death Mr. Holland was a member of the Board of Direction, which adopted the following resolution:

"On October twenty-seventh, nineteen hundred and twenty-four, Clifford Milburn Holland, obedient to the call of the Divine Providence, entered the great Beyond. His friends and associates cherish his memory. He was strong, active, and fearless in the right, kind and considerate of all, a man of attainment, of initiative, and of native ability. Young in years, but old in accomplishment, he lived intensively, yet the joy of living was always his.

"Few, indeed, are endowed with the qualities of leadership, with the ability which inspires confidence and with the inborn knowledge of men and things as was he. His future lay great before him. His past was one of inspiration. His work stands as an enduring monument.

"We, his fellow members on the Board of Direction of the American Society of Civil Engineers assembled in meeting at Pittsburgh, Pennsylvania, on this first day of December, nineteen hundred and twenty-four, desire to record our sorrow which is beyond the power of words to express. The Society and the profession have sustained an incalculable and inexpressible loss.

"In mute and reverent silence we stand in the presence of an inscrutable Providence. Yet in a measure we find our consolation in being the better and the richer because in the fullness of his life we knew him, and knowing, did love and honor him.

"Our sympathy goes out to his family and to all he held dear and it is the desire of this Board of Direction, speaking for all the membership of the Society, that this expression be entered upon its minutes, be printed in its *Proceedings* and be, in suitable form, sent to the family of Clifford Milburn Holland."

He was active in the affairs of the Harvard Club of New York and the Harvard Engineering Society. Following is the minute passed by the Board of Managers of the Harvard Club:

"In the death of Clifford Milburn Holland, the Harvard Club of New York has lost a loyal and earnest member. He took a deep interest in the work of the Club, serving faithfully as a member of the Committee on Admissions and as a member of the Board of Managers. He was prominent in the affairs of the Harvard Engineering Society during the past twelve years, in which time he held all of its offices. He was equally interested in the new Harvard Engineering School, a member of its Visiting Committee, and an inspiration to the undergraduate studying engineering.

"He fought squarely and with all the energy at his command for whatever he deemed to be right. A loyal and unselfish friend he was always ready to help those who needed his assistance. Forceful and diplomatic, the benefit of his counsel was sought by all. Acknowledged to be an authority in that

branch of engineering to which he had devoted his working life, his career was cut short at the moment of bringing to fruition the monumental work that bears his name.

"In grateful recognition of his services to Harvard and to his fellow men, we—the Board of Managers of the Harvard Club—spread upon our records this minute to his memory."

At a meeting of the Harvard Engineering Society, held for memorial exercises, action was taken to rename the engineering scholarship stipend established at Harvard by that Society, to be known thereafter as the Clifford M. Holland Memorial Aid in Engineering. A resolution was adopted, from which is excerpted the following:

"In the death of Clifford Milburn Holland of the Class of 1906, The Harvard Engineering Society has lost one of its most active and useful members, loved and respected by all. He served the Harvard Engineering Society of New York as Treasurer in 1914-15, Secretary in 1915-19, and Vice-President in 1919-20, and The Harvard Engineering Society as Second Vice-President, 1920-21, and as President, 1922-23, in all of which positions he left a distinguished record. He gave unstintingly of his time and strength in the discharge of his duties and his support and counsel were ever available in the conduct of the affairs of the Society. He took a very active part in the consolidation of the Association of Harvard Engineers, the Lawrence Scientific School Association, and the Harvard Engineering Society of New York, which resulted in the present strong National Society. He took a great interest in the new Harvard Engineering School and, as Chairman of the Committee on University Relations of the Society, directed the influence of the alumni body in its co-operation with and assistance to the School."

Mr. Holland was also a member of the American Association of Engineers and of the Engineers' Club of New York.

As a tribute to the Chief Engineer who gave so much to make the tunnel a success, and as a lasting monument to his memory, the New York State and the New Jersey Interstate Bridge and Tunnel Commissions, within a short time after his death, officially named the tunnel "The Holland Tunnel". This fitting and magnanimous act is deeply appreciated by Mr. Holland's associates and doubtless will be by engineers generally.

Engineering work with which he was entrusted was always managed and executed according to the best standards, that result being secured in a manner that won him the regard, as well as the respect, of the contractors who executed the work, as witnessed by the following tribute:

"The Executive Council of the General Contractors' Association desires to place on record, as a minute of this meeting, its expression of sorrow over the death of Clifford M. Holland, Chief Engineer of the Hudson Vehicular Tunnel.

"Mr. Holland possessed with his extraordinary ability as an engineer those qualities of tact, courtesy and fairness that won the respect and affection of all those with whom he came in contact, socially or professionally.

"In his death the community has lost a public servant of inestimable value; the engineering profession, a brilliant leader; his intimates and associates, a beloved friend.

"As contractors, many of whom were privileged to come in contact with him, we honor ourselves in paying this tribute to Clifford M. Holland, who combined unswerving loyalty to his professional duty, with that spirit of honesty that conceded even-handed justice in all his dealings."

Resolutions of sorrow and appreciation were adopted by the New York State and New Jersey Interstate Bridge and Tunnel Commissions, and by the Board of Transportation of New York City which had succeeded to the control of the rapid transit work with which Mr. Holland was formerly connected.

It was characteristic of him that, even when his professional burdens were the heaviest, he found time to serve on committees of the Society and to share generously in its counsels. His earnest sympathies and activities were always to be enlisted in any movement he felt to be for the real benefit of engineers and the profession.

The loss of Clifford Holland was felt inconsolably by his many sincere friends, and to a peculiarly notable degree even by those whose acquaintanceship was slight. His rare personal qualities, so manifestly genuine, attracted friendship at once. In any gathering, his presence would be a buoyant, lively influence, or his absence would be noted and regretted. In every way he was human, sociable, likable. His place in many hearts will hardly be filled.

The following verse is a tribute *in memoriam* by Mrs. Marguerite Janvrin Adams, the wife of one of Mr. Holland's classmates:

"He is not dead who leaves on earth enshrined
His image in a work of faith and skill;
He has not died, when we can listen still
To words of praise that everywhere we find
On comrades' lips. Each day will subtly bind
Us closer to him, whose untiring will
Struggled thus valiantly and nobly 'til
The task completed lay,—to aid mankind.
He who has made on earth one work complete
To live beyond this little span of days
That we call life—at parting of the ways
Has left a monument before our feet
At which we bow in reverence. Thus we stand
So near in homage we can clasp his hand."

Mr. Holland was elected an Associate Member of the American Society of Civil Engineers on October 29, 1912, a Member on April 18, 1917, and served as a Director from 1922 until his death.

MINARD LAFEVER HOLMAN, M. Am. Soc. C. E.*

DIED JANUARY 4, 1925.

Minard Lafever Holman, the son of John Henry and Mary Ann (Richards) Holman, was born in Mexico, Oxford County, Me., on June 15, 1852.

He attended Washington University in St. Louis, Mo., and was graduated from that institution in 1874 with the degree of Bachelor of Arts. The honorary degree of Master of Arts was conferred on him by his Alma Mater in 1905.

Mr. Holman served as Assistant Engineer in the Office of the Superintendent of Architecture of the United States Treasury Department for two years after his graduation; and then one year with the firm of Flad and Pfeifer, Engineers, at St. Louis. In 1877, he was appointed Assistant Engineer to the late Thomas J. Whitman, M. Am. Soc. C. E., Water Commissioner at St. Louis. He retained this position for ten years and was then appointed Water Commissioner by Mayor D. R. Francis, serving in this capacity for three terms of four years each. At that time, the Water Commissioner not only had full charge of the design, construction, and operation of the water-works but was also a member of the Board of Public Improvements, which was charged with the design and construction of all public works for the City of St. Louis.

As Water Commissioner, Mr. Holman displayed rare ability in designing and constructing the extension of the water-works at the Chain of Rocks and the extension of the distribution system, involving an expenditure of about $10 000 000. This extension included a new intake located in the channel of the Mississippi River at the Chain of Rocks, about seven miles above the former intake at Bissell's Point; a tunnel under the river from the intake to the pumping station; a new low-service pumping plant having a capacity of about 100 000 000 gal. per day; six settling basins with a combined capacity of 180 000 000 gal.; and a brick and concrete conduit from the Chain of Rocks to Bissell's Point.

Mr. Holman's untiring efforts to reach the correct solution of the various problems encountered in this work, his honesty of purpose, his ready recognition of the meritorious work of his assistants, and his freedom from political influence in the organization of his Department, inspired those who served under him. As a member of the Board of Public Improvements, he upheld the traditions which enabled this Board to transact the public business with honesty and fairness. His broad knowledge of engineering helped to guide the Board in the proper solution of each new engineering problem. As Chairman of the Committee on City Lighting, he had charge of the conduit construction for the electric wires, and the preparation of the specifications and letting of contracts for the lighting of streets, alleys, and public buildings.

Mr. Holman kept well informed regarding engineering developments, especially those tending to improve the water-works. He installed high-duty

* Memoir prepared by Edward Flad, Baxter L. Brown and James C. Travilla, Members, Am. Soc. C. E.

triple-expansion pumping engines and down-draft boilers in the pumping plants, thereby materially reducing the cost of operation. Under his direction, electric cranes were installed in the engine houses and electric drives in the machine shop.

After the expiration of his third term as Water Commissioner, Mr. Holman accepted the position of Superintendent of the Missouri Edison Electric Company, which he held for five years. In 1904, he organized the firm of Holman and Laird, Consulting Hydraulic and Mechanical Engineers, and continued in active practice until ill health forced his retirement. He died at his home in St. Louis, on January 4, 1925, after a prolonged illness.

Mr. Holman was recognized as an authority in the field of water-works engineering, and was frequently consulted by various cities in connection with water-works problems. He served on the Board of Appraisers of Denver, Colo., which determined the value of the water system of that city and fixed the schedule of water rates.

He was actively interested in the American Society of Mechanical Engineers, having served as Vice-President in 1894-96 and in 1903-05, and as President in 1908-09. He was also an Honorary Member of the American Water Works Association and of the Engineers' Club of St. Louis, having served as President of the latter in 1888 and 1910.

On September 7, 1879, Mr. Holman was married to Margaret H. Holland, of St. Louis. His widow and three sons, Charles H., Minard H., and George R., survive him, one daughter, Mary Holman, having died in 1918.

The City of St. Louis is indebted to Mr. Holman for twenty-two years of faithful and unselfish service. He lived a noble and useful life; a seeker after truth, patient and untiring in his investigations, with a keen analytical mind, combined with unusual engineering ability, his acts inspired public confidence and general recognition of his honesty, ability, and fidelity.

Mr. Holman was elected a Member of the American Society of Civil Engineers on April 2, 1884, and served as Vice-President of the Society in 1905 and 1906.

CLARENCE LORING HUSSEY, M. Am. Soc. C. E.*

DIED DECEMBER 5, 1925.

Clarence Loring Hussey was born in Milford, Mass., on November 16, 1884. He was the son of the late Albertus and Effie A. (Holmes) Hussey, both of whom were born in Milford, where Mrs. Hussey lived until a few years ago.

Mr. Hussey was graduated from the Massachusetts Institute of Technology in June, 1908. He immediately entered the employ of the Providence Engineering Works as Foreman in charge of automobile experiments and testing, and remained with that firm until March, 1909, when he became a member of the Engineering Staff of F. P. Sheldon and Sons, of Providence, R. I., Mill Construction Engineers. From April, 1910, to July, 1912, Mr. Hussey was employed by the Rhode Island Electric Car Company on designs and experimental work relative to street railway power plants. While with this company he designed and supervised the construction of extensive car barn facilities and several bridges.

From July, 1912, until his death Mr. Hussey served as Bridge Engineer for the Rhode Island State Board of Public Roads and as such supervised the design and the construction of all bridges on the State Highway System. In addition, he conducted the investigation for and designed the proposed $3 000 000 Washington Bridge over the Seekonk River, which is to connect the City of Providence with the Town of East Providence. Previous to his death he was directing the examination and preliminary design for a proposed toll bridge across Mount Hope Bay to connect the Island of Rhode Island, on which is located the City of Newport, with the mainland at Bristol. The construction of this bridge is being promoted in order to provide a direct route between the Cities of Providence and Newport.

Among the many original ideas which Mr. Hussey introduced in the construction of concrete arch bridges in Rhode Island was the design which allowed approximately a 50% reduction in the volume of abutments and arch rings for a given width of road. This design called for the carrying of a sidewalk and railing on brackets anchored to the arch ring. On the back of these brackets lay inclined spandrel walls which materially reduced the dead load due to the spandrel fill. This form of construction made necessary light sidewalk railings in the design of which Mr. Hussey again exhibited striking originality.

He was particular in the selection of mineral aggregates to insure high strength concrete. His special mixtures for contraction joints permitted a larger range of use of these troublesome features of construction, and whenever it became necessary to combine concrete with other materials his designs were unique and effective.

By nature Mr. Hussey was of a quiet, studious disposition. This manifested itself in his investigations of concrete mixtures as applied to the State

* Memoir prepared by G. H. Henderson, M. Am. Soc. C. E.

bridge work and to the construction of his own home which was of concrete. He originated most of the standards now in vogue in his Department; these included an elaborate file of records, photographs, and cost data. In fact, the whole conduct of the State bridge work became highly systematized under his direction and this in large measure accounted for its success.

He was also a keen student of structural design. His ideas, although marked by striking originality, had the saving virtue of reasonableness. In numerous instances he put them into practice to the great economy of the State bridge work. In his conduct of his Department, he was noted for his rigid, almost inflexible, principles applied alike to his colleagues, to contractors, and to himself.

In spite of a reserved outward manner, within he was most friendly and companionable. This became very evident to those who knew him in social or professional organization work. For several years he was Secretary of the Technology Club of Rhode Island (graduates of the Massachusetts Institute of Technology). He was also active in the Providence Engineering Society. His attitude in these services was always one of helpfulness and his efforts were characterized by an innate thoroughness and conscientiousness. Few demands were made on his help without a willing response and no duties did he undertake without their full accomplishment.

As a mark of respect to the memory of its late Bridge Engineer, the Rhode Island State Board of Public Roads, at its meeting on December 9, 1925, adopted unanimously the following resolution:

"*Whereas,* it hath pleased Almighty God in his divine wisdom to call from his earthly labors Clarence L. Hussey, our friend and co-worker; therefore be it

"*Resolved* that the State Board of Public Roads record its sense of severe loss in the decease of a highly efficient and conscientious member of its staff. Throughout his thirteen years of association with the State Board of Public Roads he performed faithfully and well every task to him assigned. He rendered a public service which may justly be pointed to with pride and held up as an inspiration to others called into public service; and be it further

"*Resolved* that this Board does hereby express to the family of the late Clarence L. Hussey its most sincere sympathy in their bereavement, which loss is shared by the members of this Board in a very personal sense; and be it further

"*Resolved* that this resolution be spread upon the minutes of this meeting and that the Clerk be and he hereby is directed to transmit a copy hereof to the family of our late respected associate and Chief Bridge Engineer."

For several years previous to his death Mr. Hussey, who was unmarried, resided with his parents in Providence. Besides his mother he is survived by a sister, Mrs. John R. Frazier, of Providence.

He was a member of the Masonic fraternity, in addition to local technical societies, and served on various bridge structure committees with the American Association of State Highway Officials and the National Research Council.

Mr. Hussey was elected a Member of the American Society of Civil Engineers on April 7, 1924.

THOMAS NOTTINGHAM JACOB, M. Am. Soc. C. E.*

DIED MAY 25, 1925.

Thomas Nottingham Jacob, the son of W. W. and Helen Williams Jacob, was born at Washington, D. C., on February 6, 1866. His maternal grandfather, Col. John Stutt Williams, of Virginia, served with distinction in the War of 1812.

Mr. Jacob's early engineering experience was gained by service in minor capacities in the Engineering Departments of the Chicago, Milwaukee and St. Paul Railway Company, the Illinois Central Railway Company, and the Union Pacific Railroad Company, from 1886 to 1891. He was then appointed Assistant Engineer on the Kanawha and Michigan Railroad and was engaged on location and construction work for four years, principally in West Virginia.

In April, 1895, he became Assistant Engineer with the United States Engineer Corps, and was assigned to the Rock Island (Illinois) District, where he remained until November, 1897. His work while with the Government was in connection with surveys and plans for the flood control of the Mississippi River.

Mr. Jacobs left the Government service to return to railroad work with the Wabash Railway Company and, later, with the Illinois Central Railway Company, the Chicago, Milwaukee and St. Paul Railway Company, and the St. Louis Valley Railway Company (now the Illinois Division of the Missouri Pacific Railroad).

In 1903, he formed a partnership with Frank Hutchinson, M. Am. Soc. C. E., for the general practice of Civil Engineering, with offices at East St. Louis, Ill., and, in 1904, he conducted the field investigations relative to flood protection and control at Kansas City, Mo. This partnership continued until the early part of 1909, when Mr. Jacob was appointed Chief Engineer of the East Side Levee and Sanitary District, which was organized for the purpose of protecting about 150 sq. miles of industrial territory in St. Clair and Madison Counties, Illinois. As Chief Engineer of this District, he worked out plans of flood prevention and drainage, in conjunction with the late John A. Ockerson, Past-President Am. Soc. C. E., as Consulting Engineer, involving an expenditure of about $7 000 000. Mr. Jacob served in this capacity until January, 1914, when he again entered general engineering practice, first, in East St. Louis, and, later, in St. Louis, Mo., making a specialty of drainage and levee work, in which he was quite successful. His practice covered important work in Indiana, Illinois, and Missouri, and, at the time of his death, he was Chief Engineer of the Peru, Ind., Flood Control District.

* Memoir prepared by Baxter L. Brown, M. Am. Soc. C. E.

Mr. Jacob was a man of high moral character and commanded the respect of all with whom he came in contact. On November 29, 1893, he was married to Margaret T. Leonard, of Hugheston, W. Va., who survives him.

He was a member of the Engineers' Club of St. Louis, the St. Louis Railway Club, and the St. Louis Institute of Consulting Engineers.

Mr. Jacob was elected a Member of the American Society of Civil Engineers on May 4, 1909.

WILLIAM SIMPSON KELLER, M. Am. Soc. C. E.*

DIED SEPTEMBER 9, 1925.

William Simpson Keller was born, on February 20, 1874, at Tuscumbia, Ala., and was a son of Arthur Henley and Sally (Simpson) Keller. His father who was a native of Tuscumbia, was Captain and Paymaster in Roddy's Command, Confederate Army, was promoted to the rank of Major just as the war closed, and was a prominent lawyer and editor. He was a grandson of David and Mary (Moore) Keller, of Tuscumbia, the latter a direct descendant of Governor Spottswood, first Colonial Governor of Virginia, and a second cousin to Gen. Robert E. Lee.

Mr. Keller received his early schooling at Tuscumbia, attended the State Normal School at Florence, Ala., and was graduated with the degree of Bachelor in Civil Engineering from the University of Alabama in 1893.

He was County Surveyor of Colbert County, Alabama, during 1897 and 1898; Assistant Engineer of Shiloh National Park from 1900 to 1905; Chief Engineer of the Good Roads Commission, Madison County, Tennessee, from 1905 to 1910; with the United States Office of Public Roads from 1908 to 1909; Engineer in charge of road construction in Dallas County, Alabama, in 1910 and 1911. In 1911, Mr. Keller was appointed State Highway Engineer of Alabama, which important post he held until his death.

The love, respect, and esteem in which Mr. Keller was held could not be better stated than in the following editorial that appeared in the *Montgomery Advertiser,* Montgomery, Ala., on September 10, 1925:

"SIMPSON KELLER

"The death of William Simpson Keller, in the prime of his life, is a distinct loss to the people of Alabama, and to the State government which is engaged in administering the benefits to the people which they have claimed. Both the people and the State government are poorer by the death of this high-minded and efficient public servant who had demonstrated his capacity for a highly specialized public service.

"His friends, those who knew him well and intimately, find inexplicable the decree of Providence which removed from his place in the activities of mankind this efficient and faithful public servant who through many years of apprenticeship and experience had demonstrated that he possessed in a rare degree the ability and energy which his high professional position required. He was essentially a product of Alabama. He was born among the people of Alabama, lived among them all his life, was educated among them and among them did his work of life. The death of this man of ability and character recalls the life of his father, who was so well known and admired by the members of a past generation. Captain A. H. Keller was a member of the Civil War generation and he faithfully served the Confederacy as a soldier till the collapse of the Confederacy, which involved the people of the South in financial and material ruin. For many years afterwards Captain Keller was the brilliant editor of a paper in Tuscumbia, which exerted no little influence in the affairs of the State. There in clean-minded, high-thinking, his children grew up about him. It is a tribute to a fine example of an older generation merely

* Memoir prepared by R. P. Boyd, M. Am. Soc. C. E.

to say that he was the father of that famous genius, Helen Keller, who courageously overcame the handicaps of Nature, and of Simpson Keller, whose expert professional skill inaugurated the era of good roads in Alabama.

"The younger Keller prepared for his professional career at the University of Alabama and in him was mingled the love and pride in his chosen profession and a love for and an appreciation of his native State. Alabama was preparing to enter upon an era of good road building, but the sentiment had not found adequate expression. The first stage of the campaign to give Alabama good roads was the bonding of several counties to finance the great undertaking in those counties. It was natural that Dallas, a leader of this movement of progress, should call in for direction a native of Alabama who had previously demonstrated his energy and ability, and so Simpson Keller was called in as County Engineer to undertake this great work. Much depended upon the integrity and professional skill of these early county engineers. The taxpayers had taxed themselves to pay for a great public work the nature of which they had not known, as no work of this kind had been done by previous generations, and they scrutinized closely this heavy expense and the results that it brought. Dallas County entered the work in a whole-hearted way, but somewhat timidly and nervously. But under the direction of Mr. Keller, this work of road building was an unqualified success and when the taxpayers of Dallas viewed and used the good roads they were eminently satisfied that they had authorized the bond issue. In time the creation of good roads became an activity of the State and the able Engineer who had been so successful in Dallas County, was called to superintend the greater work of building good roads for the State. He made his job one of the most important in the State, and although the law relating to the State Highway Commission was inadequate, this law was never altered without some of the men of influence considering its possible effect on Mr. Keller's office.

"As to how a road should be built and where it should be located, there are many differences of opinion among men. Through the many years he was in office, Mr. Keller was successful in composing these difficulties, not merely because he was diplomatic and polite, but because he was just and impartial and guided by the highest principles of integrity. Many of our States have had highway scandals over the misuse of the large sums of money involved in their construction, but there has been none in Alabama, where the funds were administered by an honest, high-minded gentleman, who strove always to administer the trust that was imposed in him for the good of the people. The work for good roads in Alabama is far-flung and comprehensive. Much of it has already been accomplished and in these splendid highways will be found the monument of Simpson Keller, who was the right man in the right place. It is the beginning of an era and a man who was conspicuous in ushering in the era will not be forgotten by a grateful people when they travel the smooth and beautiful highways which they owe in a large degree to his skill.

"Mr. Keller, in his dependability, his faithfulness to his duty, and his grasp of the problems of his office was an inspiration to his associates, both his superiors and his subordinates.

"He was a man of striking personality, warm, genial and cordial, and considerate of the rights of all. He leaves a most pleasant memory to all who knew him and tender and pleasant memories to those who were admitted to his friendship. A faithful public servant, a patriotic citizen, a loyal friend, and a helpful neighbor who loved his fellow men passed when he died. He went in the prime of life and when he had every reason to expect many years of useful activity. He died literally 'with his harness upon his back.'"

Mr. Keller was an Elder in the Presbyterian Church, a Rotarian, a Fellowcraft Mason, but was taken ill before receiving his master's degree. He served as Director and Past-President of the American Association of State Highway Officials, and was a Director of the American Road Builders Association.

In 1902, he was married to Aline Moore, of Columbia, Tenn., who died in February, 1911. In 1913, he was married to Annie Searcy, of Tuscaloosa, Ala., who survives him. Other relatives are two sisters, Mrs. L. Warren Tyson, of Montgomery, Ala., and Miss Helen Keller, of New York, N. Y.; one brother, Phillips B. Keller, of Mineral Wells, Tex., and an aunt, Mrs. L. K. Lasseter, of Selma, Ala.

Mr. Keller was elected a Member of the American Society of Civil Engineers on July 2, 1913.

WALTER GILL KIRKPATRICK, M. Am. Soc. C. E.*

DIED MAY 8, 1925.

Walter Gill Kirkpatrick was born in Canton, Miss., on September 6, 1859. His early education was acquired in the public schools of his native town. He was also a student of the University of Mississippi for one session, 1877-78.

After filling a subordinate position in 1881 with a surveying party of the Denver, South Park, and Pacific Railroad Company, Mr. Kirkpatrick entered Vanderbilt University where he received four degrees, Bachelor of Engineering, in 1886, Civil Engineer, in 1887, Bachelor of Science and Master of Science, in 1889, and was for two years Fellow and Assistant in Engineering.

He spent several years in municipal, bridge, and railroad engineering in Tennessee, partly as Assistant Engineer and partly in responsible charge of work, and was then, successively, United States Assistant Engineer in charge of a party surveying the Cumberland River for a system of locks and dams, locating Lock A; Secretary of the Engineering Association of the South; Acting Professor of Civil Engineering, for a short time, in Union College, Schenectady, N. Y.; and Engineer in charge of the Tennessee Centennial Exposition, for a period of six months.

For several years, Mr. Kirkpatrick's work was largely in Mississippi, where he was engaged as a Designing and Constructing Engineer for electric light plants, water-works, and sewerage systems in Canton, Holly Springs, West Point, Crystal Springs, and other of the more important towns of the State. In 1898, he was made the first Municipal Engineer of the City of Jackson, Miss.

In 1899, Mr. Kirkpatrick constructed a Melan arch bridge in Jackson, the first of its kind to be built south of the Mason and Dixon Line and the sixth of its kind in the world. It was only 6 in. thick at the crown, and was built of reinforced concrete. The old surface wore away and a new one has replaced it, yet the body of the structure, enwrapped in the strength given it by its designer, stands to-day and is giving continuous service.

A few years later, he constructed the first concrete sidewalks to be laid in Mississippi. With opposition on all sides, he built these walks confidently and unhesitatingly. He also constructed the first radial brick chimney in Mississippi. It was built in ten days by four men, and is still giving continuous service. He also drew up the first plumbing sanitary ordinances in Mississippi —ordinances which have been adopted by nearly every town of any size in the State and by many towns in other Southern States.

The facts thus briefly enumerated, and others which might be mentioned, abundantly justify the claim that Mr. Kirkpatrick did genuinely pioneer work in his profession and that it was work of the highest grade.

From Jackson, he went to Birmingham, Ala., as Municipal Engineer of that city, after which he was with The Alabama Power Company and then

* Memoir prepared by Alfred Hume, Chancellor, Univ. of Mississippi, University, Miss.

became City Engineer of Monroe, La. Later, still, he was engaged in private practice as a Consulting Engineer in Atlanta, Ga. He served as Designing and Consulting Engineer for more than a score of towns and cities in nearly all the Southern States, building water-works, drainage systems, electric light plants, etc. He also served as Consulting Engineer for a number of the largest Southern cities. For two years prior to his death, he had been Professor of Municipal Engineering at the University of Mississippi.

The following is quoted from resolutions adopted after Professor Kirkpatrick's death by the Faculty of the University of Mississippi:

"As a student at Vanderbilt University, he was conspicuous for his fine scholarship and fine manhood. A student of deep and earnest purpose, he was an inspiration to the younger men. He made it a principle to master each subject from day to day; he hesitated at no task; he found no problem too difficult. His splendid success in no way spoiled the lovableness of his young manhood. The faculty early showed its high esteem by appointing him to a responsible teaching fellowship and by the bestowal of various other honors.

"His later life was of a piece with his college years. Always and everywhere he was a Christian gentleman.

"As a practicing engineer he had the highest regard for professional thoroughness and professional ethics. He worked with a patience and accuracy worthy of all emulation. In Nashville, Tenn.; in Jackson, Miss.; in Monroe, La.; in Birmingham, Ala.; and in many other Southern cities, he held positions of the highest responsibility and held them with honor to his profession. He loved his work.

"As a University professor he was a deep student, an enthusiastic teacher, and a warm friend. Even as a practical engineer he was a valued teacher, for he was always an inspiration to the young engineers under him.

"We mourn his loss,
A beautiful life has ceased to be,
A gentle star has been blotted from the galaxy."

The writer was intimately acquainted with Professor Kirkpatrick from the time of their college days at Vanderbilt University. In a recent report to the Board of Trustees of the University of Mississippi, referring to the Faculty, he said:

"The University has suffered a heavy loss in the death of Professor Walter Gill Kirkpatrick of the Chair of Municipal Engineering. He died on the 8th of May, when the Government Steamboat, *Norman,* sank in the Mississippi River, about sixteen miles south of Memphis. The Engineers of the Mid-South had been holding a two days' session in the City of Memphis, and had been down the river on the fatal day, inspecting Government work. Members of the American Society of Civil Engineers were in conference on the boat at the time of the disaster.

"Although Professor Kirkpatrick had been connected with the University only two years, he had made a profound impression on his students. While his loss seems simply irreparable, yet the moral and spiritual effect of his tragic death is one of the finest things I have ever witnessed. The affection and esteem in which he was held has created a spirit and atmosphere of

incalculable value. I have never known a more admirable man, one whose life was whiter or more straight. He was the very soul of honor. Not a single blemish marked his record. I think that no mere man ever had a more nearly flawless character or led a more blameless life."

The same disaster that caused the death of Professor Kirkpatrick resulted in the drowning of his wife, *née* Willie Jones, of Canton, Miss. They had no children.

Professor Kirkpatrick was elected an Associate Member of the American Society of Civil Engineers on April 6, 1892, and a Member on October 5, 1898.

CHARLES WILLIAM KNIGHT, M. Am. Soc. C. E.*

DIED MAY 20, 1923

Charles William Knight, the son of Joseph H. and Julia E. (Butts) Knight, was born at Stanwix, near Rome, N. Y., on October 26, 1847. He was graduated from the Rome Academy, having had among his teachers the Hon. Elihu Root and Professor Oren Root. He also attended the Eastman Business College.

Mr. Knight's father was a land surveyor and carpenter and under his instruction the son learned the elements of surveying and gained a thorough knowledge of the carpentry trade, which stood him in good stead in his later engineering work. He familiarized himself with the cabinet maker's trade also, in which he was able to do highly creditable work. His next earliest experience in civil engineering was under the late George W. Chase, City Engineer and Surveyor of Rome, N. Y. While with Mr. Chase, he determined to make civil engineering his life work and applied himself to such studies as would fit him for that profession. He was associated with the late Peter Hogan, a Civil Engineer of Albany, N. Y., on several projects, among which were the water-works systems of Grand Rapids and Muskegon, Mich., and the original water-works system of Gloversville, N. Y.

After the completion of these works, Mr. Knight, as Contractor, built considerable parts of the sewerage system of Gloversville, and, later, became associated with the late Adam Miller, of Saratoga Springs, N. Y., and built under contract many systems of water-works. In 1881-82 he served as Engineer for R. D. Wood and Company, of Philadelphia, Pa., Contractors, on 6 miles of 48-in. pipe line from the Kensico Dam of the Bronx River supply. The partnership with Mr. Miller continued until about 1885, after which Mr. Knight discontinued contracting to devote his time to the practice of his chosen profession, making a specialty of Hydraulic and Sanitary Engineering.

A partnership was formed with Charles C. Hopkins, M. Am. Soc. C. E., in December, 1887, which continued until January 1, 1890, when J. W. Ledoux and J. W. Kittrell, Members, Am. Soc. C. E., were added to the partnership, forming The Stanwix Engineering Company, of Rome, N. Y. Mr. Ledoux retired in the fall of 1890, and Mr. Kittrell in 1896, the firm then becoming Knight and Hopkins. This latter association continued until 1910. In 1912, with his son, Arthur P. Knight, Mr. Knight organized the engineering firm of C. W. Knight and Son, which continued until the death of the elder Mr. Knight.

During his long career, Mr. Knight served as Chief Engineer of many complete systems of water-works, among which were those of Sayre and Athens, Scottdale, Uniontown, Muncy, Marietta, Tunkhannock, Connellsville, Greenville, and Uniontown, in Pennsylvania; Cambridge, Cazenovia, Frankfort, Ilion, Jordan, Ossining, Skaneateles, Wellsville, and Cleveland, in New York; and Newcomerstown, in Ohio. He was also Chief Engineer of the storage and distribution reservoirs of the Altoona, Pa., Water-Works; of the Westmoreland

* Memoir prepared by Charles C. Hopkins, M. Am. Soc. C. E.

Water Company's System supplying Greensburg and other Pennsylvania boroughs; of the Bear Rock Run and the Bell's Gap Run Reservoirs for the Pennsylvania Railroad Company; of the new water supply for DuBois, Pa.; and of improvements to the supplies of many other municipalities. In his work he was called upon to appraise the value of many existing water-works systems and to act as expert in many legal cases involving the diversion of water.

Those who were acquainted with Mr. Knight knew him to be a man of innate honesty and fairness and of a most genial nature, modest and unassuming. He never allowed his temper to get the better of him, nor did he show umbrage at provocation. His early experience as a contractor taught him fair dealing in his later work, and in all his engineering engagements his well formulated opinions carried great weight. Temperamentally, he was an optimist, always seeing the good and the bright side of life and its affairs, and a lover of the beautiful in human character and in Nature. He took a great interest in all matters pertaining to his native town and city.

Mr. Knight was a devout and consistent member of the Presbyterian Church, and was also a member of the Rome (N. Y.) Club.

He was twice married, his first wife having been Altay Elizabeth Potter, of Cleveland, N. Y., whom he married on October 18, 1875. Of the four children born of that marriage, one son, Arthur P. Knight, survives him. Mrs. Knight died on December 18, 1884. His second wife was Charlotte L. Lyndon, of Eaton, N. Y., whom he married on October 16, 1907, and who, with two children, Dorothy L. and Edgar Franklin, survives him.

Mr. Knight was elected a Member of the American Society of Civil Engineers on July 9, 1906.

CHARLES WALTER LAWRENCE, M. Am. Soc. C. E.*

DIED APRIL 1, 1925.

Charles Walter Lawrence, the son of C. F. and Mary A. Lawrence, of Claremont, Calif., was born at Plain Grove, Lawrence County, Pa., on June 24, 1872.

He received his engineering education at Pennsylvania State College, from which he was graduated in 1897, with the degree of Bachelor of Science in Civil Engineering. He returned to his Alma Mater in 1904 to receive the degree of Civil Engineer.

In September, 1897, Mr. Lawrence was appointed Instructor in Civil Engineering at Pennsylvania State College, where he remained until June, 1899, when he accepted a position as Draftsman with the Pennsylvania Steel Company, at Steelton, Pa.

In October, 1901, he entered the employ of the Brown-Ketchum Iron Works, at Indianapolis, Ind., as Structural Engineer on the design of steel building and bridge work. In September, 1904, he returned to Pennsylvania State College as Assistant Professor of Structural Engineering, which position he retained until September, 1906, when he became Professor of Civil Engineering at the James Milliken University, Decatur, Ill., which Department he established and directed until June, 1909. His summer vacations from 1906 to 1909 were spent in practical work as Engineer with the Brown-Ketchum Iron Works, on steel design, as Designing Engineer with the Westlake Construction Company, St. Louis, Mo., and as Engineer with the American Bridge Company, Lassig Plant, on design and checking of details.

For fourteen years prior to his death, Professor Lawrence served as Professor of Civil Engineering and as Dean of that Department at the University of Southern California, Los Angeles, Calif. It was largely through his efforts that the Department was developed into one of the leading engineering colleges in the United States.

In Professor Lawrence's early demise, the Engineering Profession loses an able and clear-headed thinker, and the community and the educational institution which he served, an honest, public-spirited man, and an able teacher.

To those of his many friends who came in contact with him, the outstanding features of his character were his whole-souled and unselfish devotion to his profession, his loyalty and friendship for those with whom he was associated, simplicity of character, and forgetfulness of self.

Professor Lawrence was a Charter Member and Vice-President of the Los Angeles Chapter of the American Association of Engineers, later becoming a

* Memoir prepared by Henry Z. Osborne, M. Am. Soc. C. E.

member of its Board of Directors; a member of the Society for the Promotion of Engineering Education; and a member of Chi Epsilon, the National Honorary Civil Engineering Fraternity.

He is survived by his widow and two sons, Harold Glover and Charles Oliver Lawrence.

Professor Lawrence was elected an Associate Member of the American Society of Civil Engineers on January 8, 1908, and a Member on January 20, 1922.

JAMES ALBERT McDONOUGH, M. Am. Soc. C. E.*

DIED AUGUST 8, 1925.

James Albert McDonough was born at Knoxville, Tenn., on December 17, 1869, the son of Dr. James S. and Mary Lenorr McDonough.

He received his education in the schools of his native city, completing the course in Civil Engineering at the University of Tennessee and taking post-graduate work there in 1894 and 1895.

In June, 1895, Mr. McDonough entered the service of the Ohio River, Knoxville, and Tidewater Railway Company and between this date and 1897 was employed by that company and others on topographic surveying and drafting work. From 1897 to 1901, he was engaged as Inspector and Draftsman at Port Royal, S. C., on the design and construction of buildings, dry docks, and other naval yard works, and from 1901 to 1904, was employed at the Navy Yard at Boston, Mass., and the United States Bureau of Yards and Docks, Washington, D. C., as a Designer on similar work.

In November, 1904, he entered the United States Engineer Department at Wheeling, W. Va., as a Junior Engineer engaged on the design of locks, dams, etc., for the canalization of the Ohio River, and from this time was employed on this work in various capacities. He was promoted to be Assistant Engineer in 1914, and in 1915 was transferred from Wheeling to the office of the Division Engineer at Cincinnati, Ohio, where, at the time of his death, he was acting as Head of the Designing Department and Assistant to the Division Engineer.

Mr. McDonough was married in 1916 to Martha Longley, of St. Clairsville, Ohio, who with his mother and three sisters survives him.

He was deeply interested in his profession and devoted much of his time to its study and to participation in its activities. While well versed along broad engineering and scientific lines, Mr. McDonough possessed special knowledge of the inland waterways of America and Europe and was regarded as an authority on that subject. Always a firm believer in the ultimate success of the Ohio River improvement, on which he spent so many years of his life's work, his inability to see its approaching completion is particularly regrettable.

Mr. McDonough was elected an Associate Member of the American Society of Civil Engineers on April 3, 1907, and a Member on May 3, 1910. He had also served as President of the Cincinnati Section of the Society and was an active member of the Engineers Club of Cincinnati.

* Memoir prepared by C. W. Kutz, M. Am. Soc. C. E.

JOHN HENRY MADDEN, M. Am. Soc. C. E.*

DIED JANUARY 22, 1925.

Within twenty-seven years after he had received his degree as Civil Engineer at Columbia University, New York, N. Y., John Henry Madden became Chief Engineer of the Transit Commission, after an active career in the supervision of construction of the New York underground railroads which made him an expert and well qualified him for such a responsible position. Few engineers can equal such a record of achievement in a similar period of time. His untimely death cut short a career which promised a brilliant future.

Born in New York, N. Y., on October 18, 1875, John Henry Madden received his preliminary education in the public schools and then entered Columbia University, from which he was graduated in 1897 with the degree of Civil Engineer. His first work after his graduation was with William Barclay Parsons, Hon. M. Am. Soc. C. E., who designed and directed the construction of New York's first subway. Young Madden worked as a Surveyor and Draftsman for the new underground railroad and became so interested in the work that he made it virtually his life's pursuit.

For only a few years did he interrupt his work on underground railroad construction. He devoted two years to service with the United States Geological Survey as Field Assistant on topography and another year to engineering design and construction under Charles W. Leavitt, M. Am. Soc. C. E., to whom he was Assistant Engineer. In 1901, he returned to his first love and became Assistant Engineer on the construction of a section of the first subway in Broadway between 60th Street and 82d Street, under the Board of Rapid Transit Railroad Commissioners of New York. When he had been on this work for six years, a change in the law replaced the Board of Rapid Transit Railroad Commissioners with the Public Service Commission for the First District. In 1907 he was transferred to the staff of the new Commission with the title of Assistant Engineer and remained in its employ and on the same kind of work for eleven years.

In those eleven years Mr. Madden showed the stuff of which he was made. He handled the most difficult and dangerous kind of subway construction, always with credit to himself and to the great satisfaction of his superior officers, among whom were Alfred Craven and Daniel L. Turner, Members, Am. Soc. C. E., and Robert Ridgway, Past-President, Am. Soc. C. E., each in turn the Chief Engineer of the Commissions conducting subway construction. Included in this period of Mr. Madden's activity were supervision of extensions of stations in the first subway between 157th Street and Dyckman Street, Manhattan—a delicate piece of work because it had to be done during the daily operation of the subway trains; the construction of four sections of the new subways—Dual System—in Lexington Avenue between 53d and 104th Streets, Manhattan; the construction of two more sections in Park Place, Beekman and William Streets, Manhattan; and four more sections in Flatbush Avenue, Brooklyn, between Atlantic Avenue and Malbone Street. All

* Memoir prepared by Le Roy T. Harkness, Transit Commr., New York, N. Y., and Frederick L. Cranford, M. Am. Soc. C. E.

this was difficult underground construction which taxed the skill of the most experienced engineers. His work on the William Street Subway is historic in its success in underpinning lofty buildings and avoiding damage to abutting property.

In 1917, as a reward for his faithful and efficient services, Mr. Madden was appointed by the Public Service Commission to be Engineer of Rapid Transit Operations, in charge of expenditures and distribution of revenues under the operating contracts of the subways of the Dual System. The World War brought the United States into armed conflict in 1917, and the Government called many engineers into its service. Mr. Madden was one of them, receiving and accepting in the summer of 1918 an appointment from the War Department as Assistant Director of Construction of Nitrate Plants. The Director was Frederick L. Cranford, M. Am. Soc. C. E., and in association with him, Mr. Madden was in charge of the construction of the three Government nitrate plants at Muscle Shoals, Ala., and Toledo and Cincinnati, Ohio.

At the conclusion of the war Mr. Madden became a member of Mr. Cranford's Company—Frederick L. Cranford, Inc.—where he remained until 1921. In that year the Transit Commission was created by law, and empowered to make a valuation of all the street railroad properties in New York City. The Commission chose Mr. Madden for this work and appointed him its Valuation Engineer. He organized the work and made a complete valuation of the subways, elevated roads, and street surface lines, submitting to the Commission a monumental report, which is one of the greatest of its kind and is recognized as a model throughout the United States. In 1924, the Transit Commission appointed him its Chief Engineer, a position which he held at the time of his death.

Mr. Madden was highly talented and in addition was gifted with a personality which attracted warm friendships. Great ability in an engineer combines many attributes—technical knowledge, practical experience, common sense, courage, vision, fairness, scientific honesty, executive ability—all of which John Madden had, together with a positive and forceful directness which, although outspoken, never offended. Where he was known he was always respected and loved, and the sense of loss when his death occurred was marked by unusual and spontaneous expressions of regret containing warm tributes to his character and ability.

Mr. Madden was elected a Junior of the American Society of Civil Engineers on October 7, 1902, an Associate Member on May 4, 1904, and a Member on June 16, 1919.

VIRGIL GEORGE MARANI, M. Am. Soc. C. E.*

DIED NOVEMBER 2, 1925.

Virgil George Marani was born on July 4, 1868, at Regio, in the Province of Emilia, Italy. He was left an orphan when very young and, with his two brothers, was removed to Edinburgh, Scotland, where he received a common school education and was taught to forget his native tongue. At the age of eleven, young Marani ran away from school, but was brought back and by way of discipline and punishment was sent to a naval schoolship known as H.M.S. *Conway,* located at Liverpool, England. He served on this ship for two years and then was given an honorable discharge because he was considered to be of insufficient physical strength to complete the naval course. Determined to build up his physical strength and to see the world, the thirteen-year old boy shipped on a full rigged sailing ship of the British Merchant Marine which, at that time, was one of the largest in the world, and began a career as a sailor which lasted until he was twenty-one years of age. In that time, he had served on sailing vessels and steamships, had circumnavigated the globe twice, and had sailed many times around Cape Horn and the Cape of Good Hope.

On coming of age, in 1889, Mr. Marani inherited his share of his mother's estate and had the good judgment and the ambition to use this money for his education through high school and university. Within four years he had completed both high school and university work, having been graduated from the University of Toronto in 1893, with the diploma of Civil Engineer. In June, 1924, the degree of Civil Engineer was conferred on him by his Alma Mater.

During his vacations, from 1889 to 1893, Mr. Marani held the position of Chief Inspector of Sewerage Works at Brantford, Ont., Canada, for Willis Chipman, M. Am. Soc. C. E., Sanitary Engineer of Toronto, Ont., Canada, and immediately following his graduation he was engaged as Transitman on survey work for Mr. W. J. White, at Buffalo, N. Y., and, also, as Chief of Field Party and General Inspector for Mr. Edward F. Ball.

Within a year after his graduation from the University of Toronto, however, Mr. Marani went to Cleveland, Ohio, where he was employed in the City Engineer's Office, successively, as Assistant City Draftsman, Chief Draftsman, and Inspector and Engineer of Sanitation. In 1895, he became Assistant Engineer with the Cleveland Gas Light and Coke Company, and in 1900 was promoted to be Engineer of Construction, holding this position for six years. In this capacity he detailed and planned all buildings, machinery, foundations, etc., for a plant covering more than eleven acres.

From 1907 to 1909, he was Engineer Superintendent of the Cuyahoga County Court House, at Cleveland, Ohio, a monumental structure costing $5 000 000. Following the completion of this building in 1910, he was appointed Building Commissioner of the City of Cleveland, which office he

* Memoir compiled from information furnished by H. H. Macdonald, Secretary, The Gypsum Industries, Chicago, Ill.

held for one year. During this time he revised the City Building Code, established a fee system, etc.

In 1912, Mr. Marani engaged in private practice and designed and superintended the construction of buildings of all types. He also served as Consulting Engineer for the National Fireproofing Company, of Pittsburgh, Pa., and until 1918 as Consulting Engineer for the United States Gypsum Company, leaving this Company to serve during the World War as Representative of the War Service Committee on Gypsum. From 1918 until his sudden death at his home in Evanston, Ill., Mr. Marani was engaged as Chief Engineer of The Gypsum Industries.

Mr. Marani was among the foremost authorities on gypsum in the United States. He was a prolific writer on this subject as well as on construction materials, building codes, fire-protective requirements, etc. Endowed with a genial and friendly personality, he was regarded with affection and admiration by all with whom he came in contact.

Mr. Marani was a member of the American Society for Testing Materials, the American Association of Engineers, Western Society of Engineers, Cleveland Engineering Society, and the National Fire Protection Association. He was also a member of the Masonic Fraternity, and of the Lake Shore Athletic Club and the Old Colony Club.

Mr. Marani was elected a Member of the American Society of Civil Engineers on February 4, 1914.

CHARLES STEWART MAURICE, M. Am. Soc. C. E.*

DIED FEBRUARY 20, 1924.

Charles Stewart Maurice was born at Perth Amboy, N. J., on June 29, 1840, the son of Charles Frazier and Cornelia Joline Maurice. On his father's side, the family was of Welsh and Scotch-Irish descent, and on his mother's, a combination of Huguenot French and Holland Dutch, the latter having been among the earliest settlers of New Amsterdam.

In 1842, Charles Frazier Maurice, at the earnest solicitation of a number of friends, opened a small private school at Napanock, N. Y. Several years later, the growing school needing enlargement, was moved to Sing Sing (now Ossining), N. Y., and was merged with the old Mount Pleasant Military Academy, which became one of the best known private schools of its time. It was here that the son received his early education. In 1858, he entered Williams College at Williamstown, Mass., as a Sophomore, and was graduated in 1861, the Salutatorian of his Class, and a member of the honorary society, Phi Beta Kappa.

In order to serve his country in the Civil War which by this time had come to be considered as more than a "90-day affair," Mr. Maurice decided to enter the Navy. In order to render effective service, however, he desired to prepare himself for a Commission on the Engineer Staff, and began the study of Marine Engineering, entering Rensselaer Polytechnic Institute, Troy, N. Y., during the fall of 1861, where he covered the subjects allotted to the Sophomore and Junior years in one year. On November 17, 1862, he was commissioned Third Assistant Engineer (Midshipman), U. S. Navy, and reported for duty at the Washington Yard, where he was assigned to the *Ossipee,* which later joined the North Atlantic Squadron, doing duty on the blockade of the Southern States on the Atlantic seaboard.

Never having had robust health, the restricted ration available in those days brought on severe and prolonged attacks of indigestion, and in the summer of 1863, Mr. Maurice was ordered home on sick leave. He never completely recovered from the effects of this illness, and was subject to indigestion, more or less severe, for the remainder of his life. On rejoining the Navy in the autumn of that year, he was ordered to the Portsmouth Navy Yard, and assigned to the fitting out of the *Agawam,* one of the "90-day" gunboats, built "double ended" for service on the narrow, crooked rivers of the South. Before her entire completion the *Agawam* was ordered to sea in chase of a Confederate privateer known to be off the New England coast, and was very nearly lost in a gale off Cape Sable, Nova Scotia. After her refitting, she joined the North Atlantic Squadron in the spring of 1864, Mr. Maurice going with her as Second Assistant Engineer, having been promoted to that rank on March 23, 1864.

The spring and early summer of 1864 was spent by Mr. Maurice on the James River, where a small fleet of ironclads and gunboats was keeping open

* Memoir prepared by George H. Maurice, M. Am. Soc. C. E.

a line of communication with General Grant, and was under frequent fire from enemy batteries and sharpshooters along the banks, notably at Dutch Gap and Malvern Hill. He was then transferred to the steam frigate, *Colorado*, of the West Gulf Squadron, doing blockade duty while Admiral Farragut was fighting in Mobile Bay, the *Colorado* not taking part in the fight, as she drew too much water to cross the bar. It is interesting to note that the late Admiral George Dewey was a Lieutenant on the *Colorado* at this time. Mr. Maurice was later transferred to the flagship, *Malvern*, of the North Atlantic Squadron, but had returned to the *Colorado* when she took part in the second attack on, and the capture of, Fort Fisher, on January 15, 1865. He remained in the Navy until December 21, 1865, on which date he resigned and was honorably discharged after declining the appointment as Assistant Professor of Mathematics at the United States Naval Academy at Annapolis, Md.

The problems of rapid transit in New York, N. Y., were even then demanding solution; the railway termini—both the Hudson River Railroad on West 30th Street, and the Harlem and the New Haven Railroads on Park Avenue, between 26th and 27th Streets, were far removed from the business center on Lower Broadway. Several lines of river steamers designed to run a "commuter's service" were planned to operate on both the East River and the Hudson River, and Mr. Maurice was employed as Engineer by the Lower Hudson Steamboat Company. He designed the engines for the two boats of that Company, the *Sleepy Hollow* and the *Sunnyside*, built during the spring of 1866. He then trained the engine-room crews of these boats, which proved to be the fastest boats on the river with the exception of the famous *Mary Powell*, a much larger boat. They ran from the Battery, New York, to Sing Sing (now Ossining) and Peekskill, N. Y., but needless to say rapid transit around New York by water was not a success, and the Company went into bankruptcy. It was probably during the latter part of the winter of 1865-66 that Mr. Maurice found time to work for about two months in a foundry and machine shop at Peekskill, thus acquiring shop experience.

During the fall of 1866, he became interested, with his boyhood friend, Eugene Underhill, in the tanning business, and they spent the winter of 1866-67 at Liberty, N. Y., and also at Great Bend, Pa., investigating and observing the operations of the large tanneries in those sections. In the spring of 1867, they built their tannery from the plans of, and under the supervision of, Mr. Maurice, at Athens, Pa., this section of Bradford County then being in the center of large forests of original growth of hemlock, the bark of which was necessary for their operations. In the autumn of 1869, he disposed of his interest to his partner, and returned to the family home at Briarcliff, N. Y.

During the next few years the little village of Athens, situated on the banks of the North Branch of the Susquehanna and the Chemung Rivers, instead of being at the junction of the Pennsylvania and New York State systems of canals (now abandoned in that section), was in the close vicinity of the junction of four railroads. This rapid transition from water to rail transportation had been brought about by the work of the late Col. C. F. Welles,

a man of vision, sprung from the best pioneer stock in the valley of the North Branch. This change appealed so strongly to the business sagacity of the late Mr. N. C. Harris, a leading merchant and banker of this section, that he introduced Mr. Maurice to the late Charles Kellogg, M. Am. Soc. C. E., who had a patent on combination wooden and iron bridges and having already started works at Athens for their fabrication, was desirous of extending them. Mr. Maurice secured a contract from the old Oswego Midland Railroad covering timber bridges in which more than 1 000 000 ft. of timber was used, and afterward, in 1871, the partnership of Kellogg and Maurice was formed. An office was maintained in New York, of which Mr. Maurice was in charge until 1874, when he moved to Athens with his family, and there he continued to reside until his death.

The firm of Kellogg and Maurice was one of the pioneers in the building of iron bridges, and the second to build those of steel. Its first bridge of any note was one over the Tombigbee River in Southern Alabama, with a draw-span which was erected without falseworks, an unprecedented feat at that time, and one which was the subject of a paper* presented to the Society by Mr. Maurice on December 17, 1873. Among other early works of this firm may be mentioned a section of the Third Avenue Elevated Railroad in New York, noteworthy for the methods of erection, bridges in Nova Scotia and Brazil, one over the Snake River, in Idaho, and one over the Platte River at Plattsmouth, Nebr. Later, came the Thames River Bridge, at New London, Conn., with the longest swing-span of its day, 500 ft., double-tracked, but a pigmy beside present-day structures.

The partnership continued until 1884, when a merger was formed with other firms in the same business, and the Union Bridge Company was organized. The firm was composed of Charles Macdonald, Past-President, Am. Soc. C. E., formerly of the Delaware Bridge Company; the late Thomas C. Clark, Past-President, Am. Soc. C. E., formerly of Clark, Reeves and Company; the late Edmund Hayes, M. Am. Soc. C. E., and George S. Field, M. Am. Soc. C. E., of the Central Bridge Company; the late Charles Kellogg, M. Am. Soc. C. E., and Mr. Maurice. Shops were maintained at Buffalo, N. Y., as well as at Athens, Pa., and the Company became internationally famous for the number and importance of the bridges it built in all parts of the world, and for the excellence and integrity of its work.

Pin-connected bridges were the standard in those days. With the introduction of steel, special methods and plant became necessary and all these requirements were met by the partners with either original designs or improvements on tools already in use. As an instance, for the famous Hawkesbury River Bridge, in New South Wales, the Bessemer steel for the eye-bars came from England and was manufactured into bars at Athens; before they were accepted, however, these bars had to be annealed in special furnaces built for the purpose; and full-sized tests were made in the 600-ton hydraulic testing machine also built at Athens for this purpose. The sinking of the

* "An Account of the Erection of a Draw-Bridge without False Works", *Transactions*, Am. Soc. C. E., Vol. XI (1873), p. 330.

caissons for the piers of this bridge in the rapid tidal flow of the river was probably the most hazardous construction work undertaken by the Company; the spans were floated into position on pontoons.

Other noteworthy bridges built by the Company were the Poughkeepsie Bridge over the Hudson River, the Cantilever Bridge over the Niagara River, the Cairo Bridge over the Ohio River, the Memphis Bridge over the Mississippi River, and many other bridges over the Mississippi, Ohio, and Missouri Rivers.

In 1895, Mr. Maurice was obliged to retire from business on account of ill-health, and spent the summer of 1896 in Europe. He continued to reside in Athens, taking daily drives over the hills of which he was so fond, and spending the winters at Jekyl Island, Georgia.

On April 28, 1869, at St. George's Church, New York, he was united in marriage to Charlotte Marshall, daughter of John G., and Marian Marshall Holbrooke, both of whom were descended from the oldest Pilgrim and Puritan stock of New England. Of this union nine children were born: Archibald S., Marian B., and Margaret S., residing at Athens, Pa.; George H., of Eagle Springs, N. C.; Charles F., of Glen Ridge, N. J.; Cornelia (Mrs. Robert Wilkinson), of Poughkeepsie, N. Y.; Albert T., of Rye, N. Y.; Emily M. (Mrs. C. W. Dall), of Cedarhurst, N. Y.; and Charlotte, who died in infancy. Mrs. Maurice, who had endeared herself to the community by her many kind deeds and acts of charity, and was beloved by all who knew her, died in 1909. Besides the sons and daughters, there survives a brother, Benjamin Maurice, of Mamaroneck, N. Y., and eleven grandchildren.

Of a retiring and quiet disposition, never voluntarily speaking of himself, Mr. Maurice's outstanding characteristics were absolute accuracy of mind and justice to all by thought and deed. He was a lover of Nature, and sought his pleasure and recreations in the woods and fields, as botanist, trout fisherman, wing shot, or as rider or driver, as the seasons and chance offered. During his early manhood, the flights of wild ducks and geese were especially alluring, and many a shooting trip was planned in connection with the building of bridges over Western rivers. In middle life, fly-fishing claimed a larger share in his recreation, and his usual summer vacations were spent somewhere in the wilds of Canada, accompanied by one or two of his sons, where his delight and pride was to land a 4-lb. trout with a 4-oz. rod from swift water. He rode horseback until he was over seventy years of age. To the time of his final illness he kept up his daily drives with fine horses, driven by himself until failing strength compelled him to relinquish the reins, and afterward by automobile.

At the time of his death, he was a member of the Loyal Legion, the Phi Beta Kappa Society, President of the Spaulding Memorial Library, of Athens, member of the American Forestry Association, the Jekyl Island Club, and the University and Union Clubs of New York City.

Mr. Maurice was elected a Member of the American Society of Civil Engineers on May 15, 1872.

JOSEPH MAYER, M. Am. Soc. C. E.*

DIED DECEMBER 13, 1924.

Joseph Mayer was born at Schriens, Vorarlberg, Austria, on February 11, 1855. His father, Anton Mayer, a native of Bludeur, Austria, was the owner of a flour mill and bakery and also of a hotel. His mother was Marie Bickel, also of Bludeur. Joseph Mayer was graduated from the Polytechnicum of Vienna, Austria, in 1880, with the degree of Professor of Mathematics and Descriptive Geometry for Realschulen.

After coming to the United States, Mr. Mayer was employed in the Chicago Office of the Delaware Bridge Company, serving for two years as Draftsman and for two years as an Assistant Engineer. Following a trip to Europe he was with the Union Bridge Company from September, 1885, to September, 1896, as Assistant Engineer in the New York Office from 1885 to 1890; in the Buffalo Office from 1890 to 1895; and as Chief Engineer in the New York Office in 1895 and 1896.

During this time he made designs, calculations, and estimates for innumerable bids, mainly for superstructures, and superintended detail plans for successful bids, among which were those for the following four large cantilever bridges: The Kentucky and Indiana Bridge across the Ohio River at New Albany, Ind. (Delaware Bridge Company); the Poughkeepsie Bridge across the Hudson River; the Kanawha River Bridge in West Virginia; and the Kentucky River Bridge.

From 1896 to 1908, Mr. Mayer practiced as a Consulting Engineer in New York, N. Y. Until 1901, he worked on a proposed railway suspension bridge across the Hudson River at 59th Street, making designs, plans, and estimates therefor for the Union Bridge Company. The late Alfred Noble, Past-President, Am. Soc. C. E., had agreed to be its Chief Engineer if the design met with his approval and if the project were successfully financed, but being a member of the Isthmian Canal Commission, he was unable then to give the study of the design his personal attention. Subsequently, he spent approximately two weeks in going over this work, personally re-checking all Mr. Mayer's assumptions and formulas and many of the stresses. He approved entirely of Mr. Mayer's design and plans, and so reported to the proposed financiers. The project failed to materialize, however, not because of difficulty in financing, but because of inability to secure the necessary legislation. The bill passed the State Legislature, but was vetoed by Governor Odell for the stated reason that it was a Special Bill disguised in the form of a General Bill.

After the failure of the Hudson River Bridge project, in May, 1901, Mr. Mayer was engaged as Consulting Engineer for the Union Bridge Company, making plans and estimates for a proposed suspension bridge for Sydney Harbor, Sydney, Australia, both as to substructure and superstructure. This design won a prize. Later, under a second competition, Mr. Mayer (as Consulting Engineer for the Pennsylvania Steel Company) made another design

* Memoir prepared by Edwin Duryea, M. Am. Soc. C. E.

and estimate of cost for a suspension bridge for Sydney Harbor, but neither of these bridges has been built.

Shortly thereafter (beginning in August, 1901), Mr. Mayer made a considerable study of the Brooklyn Bridge, New York, jointly with Edwin Duryea, M. Am. Soc. C. E. Following the alarming discovery by a man traveling across the bridge that seven short suspenders near the middle of the north main cable had failed, the District Attorney for New York County, the late Eugene Philbin, appointed Mr. Duryea to make an examination of the bridge and report on its safety and on the responsibility for its neglect. All traffic was stopped for a day or two while temporary repairs were being made. After a hasty inspection of the structure had been made, the District Attorney consented to the appointment of Mr. Mayer as an Associate Consulting Engineer. In the ensuing detailed and protracted study of all parts of the bridge, Mr. Duryea made the field examination and Mr. Mayer the stress analyses. The joint report was placed by the District Attorney before the Grand Jury, which ordered more careful and more frequent inspections of all parts of the bridge. This report was censured severely by the Bridge Department of New York City and its friends, and the Consulting Engineers spent much time for several months in refuting the attacks in various technical periodicals, many of which had published the report in full.

Subsequently, Mr. Mayer was Consulting Engineer on the construction of the power plant of the Ontario Power Company at Niagara Falls. He designed all the bridges and viaducts for the Buffalo and Susquehanna Railway Company and was engaged in other miscellaneous engineering work.

Leaving his consulting work in 1908, Mr. Mayer was Principal Assistant Engineer of the Quebec Bridge until its completion in November, 1917. He then retired from active practice and moved to Pasadena, Calif., where he made his home, occupying his time in the study of economics and social science in which he was much interested, until his sudden death.

Mr. Mayer was married in October, 1900, to Catherine Proescher, of New York, who, with their son and only child, Joseph Edward Mayer, a Teaching Fellow in Chemistry in the University of California, Berkeley, Calif., and a brother in Austria, survives him.

Charles Macdonald, Past-President, Am. Soc. C. E., and for many years President of the Union Bridge Company, writes regarding Mr. Mayer as follows:

"I can say of his [Mr. Mayer's] standing as a designer of bridges that it was of the highest order of merit. I cannot call to mind the many plans he worked out for us, but I remember one particular design for which he deserves all the credit, namely, a suspension bridge to cross the Hudson River at 59th Street, New York. It was accepted by the New York and New Jersey Commissioners, but the project failed to secure the necessary capital.

"The liquidation of the Union Bridge Company in its later years made it necessary to dispense with Mr. Mayer's services, but I shall always remember with pride and gratitude his never failing attention to duty while I had the pleasure of being associated with him."

Ralph Modjeski, M. Am. Soc. C. E., one of the Engineers and Commissioners who had charge of the reconstruction of the Quebec Bridge, writes about Mr. Mayer's work there, as follows:

"He was employed as Principal Assistant Engineer in the Montreal office of the Board of Engineers and was particularly in charge of all calculations and designs. He was connected with that work from October, 1908, until its completion. His great usefulness came from the fact that he was a most unusual mathematician as well as an excellent designer."

Mr. Mayer was a frequent contributor to the *Transactions* of the Society, having been the author of six papers and having contributed many discussions which dealt not only with the subject of bridges, but also with other subjects, such as "Canals Between the Lakes and New York", "The Just Value of Monopolies and the Regulation of the Prices of Their Products", catenary trolley construction, centrifugal pumps and fans, principles of valuation, etc. He was nothing less than a genius in the practical application of higher mathematics to bridge design, particularly to the design of suspension bridges.

Mr. Mayer was elected a Member of the American Society of Civil Engineers on October 3, 1894.

MANSFIELD MERRIMAN, M. Am. Soc. C. E.*

DIED JUNE 7, 1925.

Mansfield Merriman, the son of Mansfield and Lucy Merriman, was born at Southington, Conn., on March 27, 1848. His father was a descendant of Captain Nathaniel Merriman, who came from England to Boston, Mass., in 1632, settled in New Haven, Conn., about 1640 and was, in 1670, one of the founders of Wallingford, Conn. His mother was a descendant of John Hall, who came from England to Boston in 1633, settled in New Haven in 1639, and who also was one of the founders of Wallingford.

Mansfield Merriman received his early education at the South Center District School and Lewis Academy, both situated at Southington. In 1866, he left school and went to work on his father's farm. He was employed later in a factory and printing office, taught a country school, studied geometry, surveying, and mathematics in his spare time, and on April 5, 1867, was appointed a County Surveyor. Playfair's Euclid was his first technical book, but he early formed the habit of regularly buying books. During 1866 on a total income of $172 he acquired thirty books at a cost of $27.50 These books included such titles as "Elements of Philosophy," "Letters on Astronomy," "First Lessons in Greek," "Latin Prose Composition," "Lady of the Lake," Blair's "Rhetoric," and Flint's "Surveying." While engineering and mathematics claimed most of his effort, yet his leisure time was devoted in a surprising degree to literature, to history, and to poetry. Along these lines as well as in botany, geology, physics, chemistry, and genealogical research, he found pleasure and recreation.

In spite of his father's stern opposition, but with the sympathetic aid of his mother, he went to New Haven and passed the entrance examinations at Sheffield Scientific School in 1868. He received second prize for excellence in studies during his Freshman year and a prize for excellence in botany in his Senior year, was President of his Class in his Junior and Senior years, and was elected a member of Book and Snake.

After graduating with the degree of Bachelor of Philosophy, in 1871, Mr. Merriman studied as a Graduate Student and received a second degree, Civil Engineer, in 1872. He became an Assistant in the United States Engineer Corps, in which position he remained for a year. Later, he spent six months studying in Germany, at Hanover, Dresden, and Berlin. Returning to New Haven, he was engaged on bridge construction for several months and became Assistant in Civil Engineering at Yale University in 1874, which position he held until 1877. During these years he resumed his studies at the Yale Graduate School, receiving the degree of Doctor of Philosophy, in 1876. In 1877 and 1878 he was Instructor in Civil Engineering and Astronomy at Yale.

In the fall of 1878, Mansfield Merriman went to Lehigh University, Bethlehem, Pa., as Professor of Civil Engineering. Engineering education was

* Memoir prepared by the following Committee: Horace Andrews, *Chairman*, Walter R. Okeson and A. B. Hill, Members, Am. Soc. C. E.

then in its infancy, with few textbooks and with little known as to the proper technique of teaching. With his advent at Lehigh began Professor Merriman's great contribution to engineering education, first, in the form of teaching methods that rendered a complicated subject so simple that boys in his lecture-room were astonished to find his conclusions already formulated in their minds before he stated them; and, second, by the creation of a series of textbooks quite unequalled at the time of their publication, and many of which, after thirty or forty years, are still in daily use in colleges. This latter fact was made possible by the careful and constant revision given to these textbooks, many of which ran through numerous editions.

Perhaps no other man contributed so much to the success of Lehigh University as an engineering school, or had so great an influence in the establishment of her ideals and practices. His own rapidly advancing reputation as a teacher and engineer did much to attract favorable attention to this young school, and the high standards set in his Department induced similar standards in all the other Engineering Departments.

At the Annual Convention of the Society in the City of Mexico, in 1907, Professor Merriman was present, and his reception must have proved very gratifying to him, as it was most enthusiastic, especially at the assemblages in the Mineria, where many of his former pupils had again the privilege of meeting him. Many of the engineering works shown to the members present at that Convention were carried out by the Spanish speaking students who had formerly been under Professor Merriman at Lehigh University.

Lorenzo Perez Castro, M. Am. Soc. C. E., in *The Revista Mexicana de Ingenieria y Arquitectura* for August 15, 1925, wrote:

"During half a century, Merriman, as a great educational force, unceasingly expounded the principles of directness and simplicity in teaching and instruction. * * * Through natural inclination he loved study from the years of his youth. * * * By his own efforts he became an engineer, a mathematician and a man of science. * * * He had recourse to all the fountains within his reach in the effort to satisfy the divine desire. As steps in the ladder he acquired Latin and Greek as well as French and German, all of which he could read fluently. * * * The remembrance of Merriman and his pure constructive work, so beneficial to his fellow men, will be permanent and lasting. It will live in his pupils and students as in all those who, through generations to come, are to profit by his instruction and writings; and when, in the course of time, his books of applied studies become antiquated through the natural evolution of human knowledge, the master will remain embodied in his subjective life, or life of remembrance, with that worthy legion of men who live for humanity."

What Mansfield Merriman did for Lehigh University in a large way, he did for many other engineering schools indirectly through his textbooks, and the whole Engineering Profession owes a great debt to him.

In 1903, while still at Lehigh, he was a member of a Special Commission appointed by Mayor Low, of New York, N. Y., to report on plans for the Manhattan Bridge across the East River. Professor Merriman was also for four years, 1881-85, Acting Assistant in the United States Coast and Geodetic Survey, in charge of summer triangulation work in Pennsylvania.

In 1906, the University of Pennsylvania conferred on Professor Merriman the degree of Doctor of Science, and, in 1913, the degree of Doctor of Laws was conferred on him by Lehigh University.

In 1907, he resigned his position as head of the Civil Engineering Department at Lehigh University and engaged in consulting practice in New York, specializing in hydraulic problems and bridge design and construction.

Professor Merriman's work as an author and editor began in 1876, his thesis for the degree of Ph.D. at Yale, "Elements of Least Squares", having been published in 1877. He served as Editor-in-Chief of the "American Civil Engineers' Pocket Book," beginning in 1908 (first issued in 1911; Fourth Edition, 1920); Associate Editor of Johnson's (now Appleton's) Universal Encyclopedia, 1892-98, having written and edited the articles on Civil Engineering; Joint Editor with Mr. R. S. Woodward of "Mathematical Monographs" (twenty-one volumes), published from 1896 to 1921; author of "The Theory and Calculation of Continuous Bridges" (1876); "Elements of the Methods of Least Squares" (London, 1877); "The Figure of the Earth" (1881); "Method of Least Squares" (1884; Eighth Edition, 1911), translated into Spanish; "Mechanics of Materials" (1885; Eleventh Edition, 1914); "Treatise on Hydraulics" (1889; Tenth Edition, 1916); "Strength of Materials" (1897; Sixth Edition, 1912); "Elements of Sanitary Engineering" (1898; Fourth Edition, 1918), translated into Japanese; "Precise Surveying and Geodesy" (1899; Second Edition, 1912); "Elements of Mechanics" (1905); "Elements of Hydraulics" (1912); "Mathematical Tables" (1915); "Recreations in Mathematics" (1917), published under the pseudonym of "H. E. Licks"; joint author with John P. Brooks, Assoc. M. Am. Soc. C. E., of "Handbook for Surveyors" (1895; Fourth Edition, 1912); and with Henry S. Jacoby, M. Am. Soc. C. E., of "A Textbook on Roofs and Bridges", in four volumes (1888-98; Fourth Edition, 1917). He also contributed on many occasions to the papers and discussions of the Society and to various technical magazines. *Engineering News-Record,* in its number for April 17, 1924, celebrating the completion of fifty years in its engineering work, contained (page 649), a specially prepared paper from Professor Merriman. The total number of his books printed to 1925 was 340 000.

As a member of various scientific and mathematical organizations, Professor Merriman contributed to their proceedings and also prepared numerous articles for the engineering and technical press. He was one of the founders of the Society for the Promotion of Engineering Education and its President in 1896; one of the original organizers, in 1898, of the American Section of the International Association for Testing Materials, holding the office of Chairman of the organization until 1900; he was, therefore, one of the charter members of the American Society for Testing Materials at the time of its organization in 1902, and was elected President in 1915. He was a Fellow of the American Association for the Advancement of Science and Vice-President of the Engineering Section in 1894; member of the American Philosophical Society; American Institute of Mining and Metallurgical Engineers; American Mathematical Society; New York Academy of Sciences; Mathematical Asso-

ciation of America; Yale Engineering Association; Wallingford Historical Society; Engineers' Club, New York, N. Y.; re-elected President of the Class of 1871, Sheffield Scientific School, in 1921; member of H. Stanley Goodwin Lodge, F. and A. M., Bethlehem, Pa., and former District Deputy Grand Master.

Professor Merriman's own evaluation of the science of teaching and of his philosophy of life was expressed in an address delivered in 1911 at Southington, Conn., before the Alumni Association of Lewis Academy, when he said:

"Benjamin Franklin published about 1780 an essay on the 'Usefulness of the Mathematics'. This is one of those simple and wonderful articles which that great man prepared for the express purpose of influencing the young men of America, and it explains how mathematics lies at the foundation of surveying, engineering, and astronomy. In it occurs a reference to the 117th proposition of the 13th book of Euclid's Geometry, and Plato is quoted as saying that a man who could not understand this proposition ought not to be ranked among rational creatures. This essay first came into my hands in 1864, and its perusal greatly impressed me, especially the reference to Euclid, and accordingly I sent to New Haven by my aunt, who went there twice a year to buy supplies for her millinery trade, to purchase a copy of Playfair's Euclid, which was then used as a textbook at Yale College.*

"During an experience of more than thirty years, I have had good opportunities for estimating the influence which teachers actually exert. Time only allows me here to say that such influence seems to be slight outside of the class exercises. Teachers who go out upon the bleachers and swing their hats usually lose the respect of students in the class room. Teachers who select students as favorites under the idea of influencing them, put themselves in a most awkward position, which injures all parties concerned. The influence of teachers upon pupils seems to lie almost entirely in training them to proper habits of order and obedience, and in securing from them satisfactory attention to the lessons assigned. Special interest in particular lines of study, high ambitions, and resolves toward forming better habits of life appear to come to a boy not from teachers but from parents, friends, fellow students, and books. On the whole then, it seems to me wise for a teacher to confine himself zealously to the work of instruction, being always strictly impartial in attempting to influence his pupils, if he desires to attain the highest degree of success.

"A good definition of success lies in its contrast with another word. Proceed means to go ahead, but succeed means to go ahead and to get there. With all young men and young women who have formed a purpose, there exists an ambition to succeed. To this end hard work is necessary, and also the results of this work must be a little better than those of the average men and women who are engaged in the same kind of labor. But even these cannot bring success unless the worker rejoices in his work and sees that it brings each year better and better results. True success is not the attainment of money or fame, but rather the joy and satisfaction of the work itself and the consciousness that its results are regarded as valuable by those competent to judge.

"And the message that I would fain try to bring is this: Have joy in your labor, and then your work shall be well done; perhaps also some of the results of that work shall exert inspiring influences in directions of which you yourself do not dream."

* This incident played a direct part in formulating Professor Merriman's determination to go out into that great world which lay beyond the horizon of his ancestral home.

Professor Merriman was married on June 5, 1875, to Wanda Kubale, of Posen, Germany. He is survived by five children, Thaddeus, Lucile, Alice Pauline, Richard Mansfield, and Norman Nathaniel, issue of this marriage; two of the sons, Thaddeus and Richard Mansfield, are members of the Society. Mrs. Merriman died on March 10, 1889, and Professor Merriman was married on May 24, 1891, to Anna Rosina Godshalk, of Bethlehem, Pa., who died on January 8, 1907. He was married for the third time on June 6, 1910, in New York City, to Bazena Treat Downes. There were no children by the second or third marriage.

Professor Merriman was elected a Junior of the American Society of Civil Engineers on May 12, 1875, and a Member on September 3, 1884.

CHARLES HENRY MILLER, M. Am. Soc. C. E.*

DIED MAY 8, 1925.

Charles Henry Miller was born at Strasburg, Lancaster County, Pa., on November 30, 1866, the son of Henry B. and Elizabeth (Bartholomew) Miller, who were also natives of Lancaster County. He received his education in the public schools of Strasburg, and was graduated from the High School in 1884 and from Lehigh University, with the degree of Civil Engineer, in 1888. Immediately following his graduation, Mr. Miller became identified with the improvement of the Mississippi River under the direction of the United States Corps of Engineers. While in this employ he conducted surveys, dredge work, bank revetment, etc., and held the titles of Instrumentman, Draftsman, Assistant Engineer, Chief of Survey Party, and, finally, Superintendent of Construction, his employment having extended over a period of thirteen years.

In 1901, Mr. Miller was made Superintendent of Construction of the McClintic-Marshall Construction Company at Pittsburgh, Pa., and had charge of the building of the Pittsburgh plant of that Company. He maintained this connection for four years. In 1905 he was made Engineer of River Protection for the Missouri, Pacific, and Iron Mountain Railway System, but resigned this position in 1911, to organize and become President of the Miller Engineering Company, Little Rock, Ark. This Company was engaged in both engineering and construction work, and Mr. Miller had personal charge of the Engineering Branch. During the six-year period ending in 1917, he served as Chief Engineer of the Cairo Levee District, the St. Johns Levee and Drainage District, and the Indian Bayou Drainage Districts Nos. 1 and 2; he was a member of the Board of Consulting Engineers for several railroad companies on river bank protection and drainage work; and Consulting Engineer for the United States Government on the "sunk land" cases in Eastern Arkansas. His Company acted as Contractors for municipal improvements in Batesville and Little Rock, Ark.; built five miles of river-bank protection work for the Caddo Levee Board on Red River, Louisiana; Dam No. 2 in the Ouachita River, Louisiana; and extensive dike and bank protection work on the Mississippi River, the last two having been constructed for the U. S. Corps of Engineers.

In the midst of these activities as an Engineer and Contractor, Mr. Miller put aside all thought of personal interest on the entrance of the United States into the World War, and enlisted in June, 1917, receiving a commission as Major of Engineers. He acted as Constructing Quartermaster in charge of the building of Camp Cody at Deming, N. Mex. In December, 1917, he was appointed Commanding Officer of the 2d Battalion of the 23d Engineers (Highway Regiment). Major Miller arrived in France in April, 1918, and was placed in charge of railway, highway, camp, motor-park, and hospital construction, dealing with as many as 15 000 troops, including service battalions, prisoners, and Chinese laborers.

* Memoir prepared by Alfred M. Lund. M. Am. Soc. C. E.

In February and March, 1919, he commanded the 2d Battalion of the 307th Engineers of the 82d Division. In April, 1919, he returned to the United States, and received an honorable discharge on April 5, 1919.

On his return to civil life, Major Miller re-organized the Miller Engineering Company as the Miller-Butterworth Company, Engineers and Contractors. This firm immediately launched into the active road-building program of Arkansas and built thirty-three miles of "Warrenite" pavements in Arkansas County. Major Miller still continued to devote his attention to the engineering part of the Company's work. He was appointed by the United States Supreme Court as a Commissioner to decide on twelve miles of the boundary between Arkansas and Mississippi, and he also served on a commission to establish a portion of the boundary between Oklahoma and Texas. He acted as Consultant or as Arbiter in many suits on highway work about which he was recognized as an authority. At the time of his death he was serving as representative of the State of Arkansas on a Board appointed to equalize the taxes of Conway County.

Besides being President of the Miller-Butterworth Company, Major Miller was Vice-President of the Southern Sand Company, President and General Manager of the Allen Gravel Company, and Vice-President of the Southern Material and Construction Company.

Major Miller was also active in scientific and civic affairs. He was a member of the American Association of Engineers, the American Railway Engineering Association, and the Little Rock Engineers' Club, and a Director of the Federated Engineering Council, and the Little Rock Chamber of Commerce.

In 1900, he was married to Edna Ward, of Luna Landing, Ark., by whom he is survived. He is also survived by two daughters, Mrs. Edgar A. O'Hair wife of Capt. E. A. O'Hair, F. A., U. S. Army, Fort Sill, Okla., and Mrs Stacy C. Howell, wife of Dr. S. C. Howell, Little Rock, Ark.

Major Miller was very popular with all his associates and acquaintances and highly respected by his fellow engineers. He was generous with his means and his time and always active in any undertaking that concerned the welfare of individuals or of the community in which he lived.

He lost his life on May 8, 1925, when the U. S. Steamer *Norman* sank in the Mississippi River, carrying to their death twenty-three of the passengers and crew. The passengers were engineers and their families in attendance at the Mid-South Convention of Engineers, at that time meeting at Memphis, Tenn.

Major Miller was elected a Member of the American Society of Civil Engineers on May 2, 1899.

FRANK MILLER, M. Am. Soc. C. E.*

DIED MAY 29, 1923.

Frank Miller the fourth son of Matthew and Sara Anne (Thompson) Miller, of Manchester and Sale, Cheshire, England, was born in Manchester, England, on June 23, 1862. After a preparatory education in private schools in Sale and Southport, he went to Germany and continued his education, attending schools in Lahnestein, Düsseldorf, and Dresden, where he was a student at the Polytechnicum. During the summer vacations he traveled with a private tutor and studied art in many cities of Europe.

On his return to England, his father wanted him to enter the British Army, or to join him in his business of cotton manufacturing, as he had large interests in Lancashire, but the boy preferred to follow his own inclination in the choice of a profession and, finally, decided to enter Owen's College, Victoria University, England, to continue his study of engineering. He was for some time a lecturer at Owen's College.

For one year Mr. Miller served as Machinist and Draftsman at Appleby Brothers' Bridge and Crane Works, near London. From 1883 to 1885, he was Assistant in the office of Sir John Fowler and the late Sir Benjamin Baker, Hon. M. Am. Soc. C. E., Consulting Engineers, London, making plans for bridges, masonry construction, railroads, and details for the Forth Bridge in Scotland. From 1885 to 1888, he held the position of Assistant Engineer of the Lancashire and Yorkshire Railway Company, in charge of design and construction for four-tracking 10 miles of a difficult section of the road, including bridges, station buildings, retaining walls, etc. He also made marine surveys for deepening and improving the channel and harbor at Fleetwood, England.

In 1888, Mr. Miller went to Montreal, Que., Canada, to gain wider experience and to find a larger field in engineering work, and until 1889, he was connected with the Grand Trunk Railway Company of Canada, making surveys for railroad extensions. From 1889 to 1891, he served as Draftsman, Designer, and Estimator for Riter and Conley Steel Works, Pittsburgh, Pa., and from 1891 to 1892, he was engaged in designing new structures for the Brooklyn Elevated Railroad under the late O. F. Nichols, M. Am. Soc. C. E., Chief Engineer. From 1892 to 1895, he was with Cooper, Hewitt and Company, at Trenton, N. J., at the plant of the New Jersey Steel and Iron Company, in charge of draftsmen, designing bridges, buildings, and structural steel work of all kinds, and making estimates.

From 1895 to 1903, Mr. Miller was in private practice as Consulting and Constructing Engineer and as a member of the Structural Engineering Com-

* Memoir prepared by John B. Humphreys, Esq., Paterson, N. J.

pany, of New York, N. Y. During this time a large number of difficult engineering works were designed and constructed successfully, including the plant of the Central Lard Company at Jersey City, N. J., a large building filled with heavy oil tanks on every floor. This building, the cost of which was about $250 000, was constructed on a swamp. The Passaic Iron Foundry was also built under the supervision of this Company, as well as the steel work of numerous office, loft, and mill buildings and bridges, including their foundations. The Long Beach, N. Y., Draw-Bridge and various pile protection works were also designed and their construction superintended by the Company. In 1902, Mr. Miller designed, estimated, and superintended the construction of the floating derrick of 120 tons capacity for the United States Navy Yard at Portsmouth, N. H.

From 1903 to June, 1909, he was Chief Engineer of the Snare and Triest Company, Contracting Engineers, during which period he designed and superintended the construction of the coffer-dams for the building of the foundations for, and also superintended the erection of the steel work of, the highway draw-span of the Flushing Bridge, Flushing, N. Y., built at a cost approximating $280 000. Mr. Miller designed and estimated the cost of large fireproof warehouses, and railroad locomotive and repair shops, built for the United Railways, at Havana, Cuba, at a cost of $500 000. He also designed and estimated the cost of three concrete and steel ocean piers, built for the United Railways of Havana and the Cuban Central Railway, at Havana and Cienfuegos, Cuba, as well as numerous bridges (for railroads), and coal-handling plants. He planned the method of building the Manhattan Subway Terminal of the Williamsburgh Bridge, New York, N. Y., the contract price of which was about $1 100 000; he also designed and superintended the shoring and underpinning of the adjoining buildings, as well as the shoring of the street railway tracks and temporary roadways.

Mr. Miller designed the plant and method of erecting the steel work of the approaches of the Queensborough Bridge at 59th Street, New York, and Long Island City, N. Y., over the East River. He designed the coffer-dams, pile and concrete construction of the tunnel connecting the Delaware, Lackawanna and Western Railway Station at Hoboken, N. J., with the Hudson and Manhattan Tunnel, and arranged the method of construction. He also designed the coffer-dams, foundations, and steel work for the Perth Amboy Bridge across Raritan Bay and superintended the construction. He designed, estimated and superintended the construction of sixteen large floating derricks for The Merritt and Chapman Derrick and Wrecking Company and The M. P. Smith and Sons Company, both of New York. These derricks had a lifting capacity of from 25 to 150 tons, and were built at a total cost of about $500 000. This work, executed for The Snare and Triest Company, represents some of the large contracts, but, in addition, Mr. Miller had charge of all engineering matters affecting designs and erection, and of a large part of the estimates.

He subsequently entered into partnership under the firm name of Long and Miller, Consulting and Contracting Engineers, New York. While a member of that firm, he was interested in the development of Larchmont Gardens, reconstruction work at Fort Slocum, and the widening of a part of Fifth Avenue, New York, and was also engaged on many other pieces of engineering and construction work in and around that city. The firm of Long and Miller dissolved partnership in 1915, and Mr. Miller continued the practice of his profession alone, as a Consulting Engineer with an office in New York.

At the outbreak of the World War, he offered his services to both the United States and Great Britain, but was not accepted on account of his health. He had hoped that his experiences as an engineer would be of service to the Allied Forces.

For many years Mr. Miller served as Consulting Engineer for Messrs. Merritt and Chapman, and was associated with that Company on several of its large contracts, notably the laying of the Narrows Siphon. It was Mr. Miller who raised the American liner *St. Paul* after she had turned over at her pier at the foot of West Twenty-second Street, New York, and had lain fast in the mud for some time.

In April, 1920, he visited the West Indies, in order to make plans and specifications for harbor works at East Harbour in the Turks and Caicos Islands group.

In June, 1920, he became seriously ill, but, after being in a critical condition, he finally recovered sufficiently to resume his business. From time to time, he suffered greatly, but never allowed his health to deter him, to curb his ambition, or to handicap him in the execution of any piece of work he had in hand.

At different times, Mr. Miller did work for and in connection with the Keystone Cement and Fireproofing Company. He was also interested in the development of Belwood Park, a part of the Hewitt Estate, near Newark, N. J.

The last work that Mr. Miller undertook and executed was the design for the great dome on the new Roman Catholic College, Marywood, at Scranton, Pa., which is considered a very beautiful piece of work, the second or third largest dome in the United States, and, as one of his business associates said, a "lasting tribute to his wonderful talent for design, and to his memory". He had the gratification, in the last few weeks of his life, of knowing that it had been successfully erected.

His profession was to him an art, and his genius comprised a diversified talent for design, but he also inherited from his Scotch ancestry his strongly practical characteristics.

In the autumn of 1922, Mr. Miller suffered a severe recurrence of his previous illness, and notwithstanding a very brave effort on his part to overcome his malady, he never regained his normal strength, although striving to the last to continue active work. He died on May 29, 1923, after two weeks of acute illness.

In 1889, Mr. Miller was married to Ada Elizabeth Sawyer, the only daughter of Thomas Spencer Sawyer, of Deeplish, Rochdale, England, who, with one daughter, Dorothy Ethel, survives him.

In social life Mr. Miller was popular and beloved by many. He had a high sense of humor, not boisterously exhibited, but when greatly amused, a sort of concealed laughter permeated his entire body. His life was a kindly and a useful one.

He was a member of the Canadian Club, and the Engineers Club of New York. In religion, he was a member of the Protestant Episcopal Church, and usually attended a daily service at one of the city churches. He was an ardent lover of the best in music, this taste having been fostered and cultivated during his long residence in Germany.

Mr. Miller was elected a Member of the American Society of Civil Engineers on October 5, 1904.

CHARLES MILLER MORSE, M. Am. Soc. C. E.*

DIED JUNE 18, 1921.

Charles Miller Morse was born in Buffalo, N. Y., on January 11, 1854. He was the son of David R. Morse, a financier and merchant in that city, who for several years was President of the Erie County Savings Bank.

In 1870, Mr. Morse entered Yale University, intending to take the Classical Course, with a view to a literary career, but he developed a taste for applied science and studied Mechanical Engineering for two years. He supplemented his study at Sheffield Scientific School by practical shop training in the puddling mill of the Union Iron Works at Buffalo.

After leaving Yale, he was employed, in 1873, on a survey for the Buffalo and Jamestown Railroad, and from 1873 to 1874, was Transitman with the U. S. Engineer Corps on work along Lakes Erie and Ontario. In 1876, he went to Dunkirk, N. Y., where he learned the trade of machinist at the Brooks Locomotive Works, and in 1877 and 1878, he served in that capacity in the shops of the New York, Lake Erie, and Western Railroad Company at Buffalo, and also in the shops of the Lake Shore and Michigan Southern Railway Company at Cleveland, Ohio.

Mr. Morse was afterward engaged as Draftsman and Assistant to the Superintendent of Motive Power with the Erie Railroad Company. In the latter position he had charge of the reconstruction of the locomotives of the Company from broad gauge to standard gauge, the work having been done at the Locomotive Shops of The Dickson Manufacturing Company at Scranton, Pa. From 1878 to 1881, he designed and superintended the construction of railroad shop equipments for the New York, Lake Erie, and Western Railroad Company at Buffalo and at Hornellsville, N. Y. From 1881 to 1882, he was Superintendent of the Crown Point Iron Company, at Crown Point, N. Y., and, in 1882, entered private practice in New York, N. Y. From 1883 to 1888, he also acted as New York representative for several manufacturers of machinery.

In 1888, he returned to Buffalo where he was engaged in private practice as a Mechanical Engineer and became head of the Buffalo Engineering Company. From 1890 to 1894, he acted as representative of Otis Brothers and Company, of New York, and, subsequently, as representative of the Babcock and Wilcox Boiler Company.

Mr. Morse was City Engineer of Buffalo for seven years. On December 26, 1901, he was appointed Deputy Engineer Commissioner in charge of the Bureau of Engineering of the Department of Public Works, serving until December 31, 1908, and receiving much commendation for his honest and efficient work. During his administration, the overflowed lands in South Buffalo were reclaimed, and an extensive report on the subject written by him in 1903, was published† by the Buffalo Society of Natural Science in 1908.

* Memoir prepared by Charles Warren Hunt, Secretary Emeritus, Am. Soc. C. E.

† *Bulletin*, Buffalo Soc. of Natural Science, Vol. VIII (1908), No. 2.

On August 6, 1907, the United States Government issued to him a license as Chief Engineer, and he was attached to the Naval Militia Steamer *Hawk* in the District of Buffalo.

In December, 1890, Mr. Morse was married to Kathleen Edgar, of Easton, Pa. Owing to the ill health of his wife, he bought a small fruit farm in Mount Dora, Fla., where he spent several winters, meanwhile retaining his business connections in Buffalo and New York. Mrs. Morse died on May 11, 1916. In 1917, he disposed of his home in Buffalo and moved to Florida permanently. At this time he gave up engineering practice and engaged in farming.

On April 3, 1918, Mr. Morse was married to Mary A. Donohue, of Boston, Mass., who survives him.

He died at Mount Dora on June 18, 1921, and was buried at Forest Lawn Cemetery at Buffalo.

He was a member of the American Society of Mechanical Engineers, of the Sons of the American Revolution, the Army and Navy Club of America, Cosmos Club of Washington, D. C., Engineers Club of New York, Buffalo Club, and Columbia Yacht Club, and his genial personality and social characteristics endeared him to all with whom he came in contact.

Mr. Morse was elected a Member of the American Society of Civil Engineers on January 2, 1895.

PAUL HOWES NORCROSS, M. Am. Soc. C. E.*

DIED MAY 8, 1925.

Paul Howes Norcross was born in Atlanta, Ga., on January 19, 1880, the eldest son of Dr. Virgil C. and Fanny Howes Norcross, and a grandson of Jonathan Norcross, the first Mayor of Atlanta and one of its pioneer citizens.

After his preparatory education in the schools of Atlanta, Mr. Norcross entered the Georgia School of Technology and was graduated, in 1902, with the degree of Textile Engineer. Immediately afterward, he spent about six months in one of the large Southern cotton mills, but did not find this branch of engineering especially attractive to him. Accordingly, he obtained a position with the Carolina Bridge Company, of Burlington, N. C., first in the Drafting and Designing Department, but because of his sales ability, which was even then apparent, he was soon transferred to the Contract Department and, later, made Special Sales Representative in charge of territory covering eleven of the Southern States.

The Carolina Bridge Company was later merged into the Virginia Bridge and Iron Company and Mr. Norcross continued with this organization, having been most successful in the promotion and sale of a large number of highway and railway bridges throughout the South. In 1905, he accepted a position with the Westinghouse, Church, Kerr and Company, in connection with the structural design of the Pennsylvania Station in New York, N. Y. After the completion of this work, he became a member of the Staff of Herbert C. Keith, M. Am. Soc. C. E., Consulting Structural Engineer, on special bridge design for the New York Central Railroad, in the electrified zone between Harmon, N. Y., and the Grand Central Station, New York.

In 1906, Mr. Norcross formed a partnership with Gabriel R. Solomon, M. Am. Soc. C. E., under the firm name of Solomon-Norcross Company, with principal offices in Atlanta. The firm engaged in general consulting practice throughout the South, covering all classes of municipal and hydraulic work. In 1910, a branch office was opened in Watervliet, N. Y., and Francis J. Keis, M. Am. Soc. C. E., was taken into the partnership, under the firm name of Solomon, Norcross and Keis, on Northern work. Mr. Solomon retired from the organization in 1918, on being commissioned an officer in the Army, and the firm operated under the name of Norcross and Keis until January 1, 1923, when Mr. Keis retired. Mr. Norcross continued the Atlanta Office, as a Consulting Engineer, until the time of his death.

Mr. Norcross' engineering activities, during the last few years of his life, were largely concentrated on water supply and filtration projects, his firm having served more than fifty municipalities on this particular type of work. At the time of his death, he was Consulting Engineer to the City of Atlanta, where the $3 500 000 pumping and filtration plant was nearing completion, and was in charge of the design and supervision of the new $1 300 000 water supply for Spartanburg, S. C.

* Memoir prepared by George W. Fuller and Gabriel R. Solomon, Members, Am. Soc. C. E., and Frederick H. McDonald, Assoc. M. Am. Soc. C. E.

Among the many projects designed and supervised by Mr. Norcross and his partners might be mentioned: Water supplies at Prattville and Talladega, Ala.; DeFuniak Springs, Milton, Haines City, and Sebring, Fla.; Cartersville, Rome, Jefferson, and Madison, Ga.; Amory, Miss.; Watervliet, N. Y.; Aiken, S. C.; and Cleveland and Morristown, Tenn.; also, special work for the Island of Bermuda; sewage disposal plants at Lexington, Ky., and a number of other cities; water power reports for the Broad River Power Company, Alabama Electric Company, and Selma Electric Company; and flood-control works at Watervliet, N. Y.

At the outbreak of the World War, Mr. Norcross was appointed as Supervising Engineer at Camp Jackson, Columbia, S. C., and, on the completion of this work, served in a similar capacity at Camp Humphreys, Accotink, Va. He was later made Acquisition Agent for Camp Benning, Georgia, and purchased approximately 30 000 acres of land for the Government. He was then called to Washington, D. C., and became a member of the Civilian Staff of the Water Supply Branch of the Construction Division of the Army, in charge of Dabney H. Maury, M. Am. Soc. C. E., then Lieutenant-Colonel, and while on this work, was given many assignments in connection with the water supplies of the camps, cantonments, and Regular Army posts. After the Armistice, Mr. Norcross returned to Atlanta and, with Mr. Keis, continued his consulting practice.

Among his last professional engagements was that as a member of a group of twenty-eight engineers constituting a Board of Review to pass on numerous aspects of the problems of the Sanitary District of Chicago, Ill. He served as Secretary of the Board and as a member of its Committees on Water Supply and on Water Power. The unanimity and promptness with which the Board reported its findings and conclusions on this many-sided proposition of unusual local, interstate, National, and international significance was due in no small measure to the organizing ability, tactfulness, and energy of Mr. Norcross.

Mr. Norcross' activities outside his engineering office were numerous and varied. He had unusual social talents, was thoroughly at home in any company, and was an exceptionally interesting and ready speaker. His keen wit caused him to be sought on all occasions as a presiding officer, and his appropriate remarks greatly enlivened every meeting at which he was present. No one could place a body of men more quickly at their ease, nor overcome a formal reserve more easily, than he.

For many years he was active in the Atlanta Rotary Club and served the Club as President. In 1924, he had the distinction, unique for an engineer, of being made President of the Atlanta Chamber of Commerce, having served that organization as Director, and as Chairman of a number of important committees. He was also President of the Alumni Association of the Georgia School of Technology.

Mr. Norcross lost his life, with twenty-two others, when the steamer *H. E. Norman*, carrying delegates of the First Annual Convention of the Association of Engineers of the Mid-South, sank in the Mississippi River south of Memphis, Tenn., near Kohoma Landing. His attendance at the Convention was in performance of his duty as a Director of the Society in aiding the con-

sideration of the formation of a Local Section. His last speech was on the ill-fated *Norman,* in the course of a river inspection trip forming part of the Convention program, during which he urged that the Engineering Profession should organize so as to be of as much aid as practicable to young engineers.

He was a Scottish Rite Mason, a Shriner, and an Elder in the First Presbyterian Church of Atlanta.

Mr. Norcross was married, in November, 1907, to Mattie L. Holt, of Graham, N. C., who died in October, 1920, leaving a daughter, Catherine Holt Norcross, who survives her parents.

His many friends among the engineers of the United States were particularly gratified at the appreciation of his worth as a citizen shown at Atlanta on May 31, 1925, by a Community Memorial Service, when leading public officials, representatives of important associations, and of his church, characterized him as:

"A Dutiful Son—A Devoted Husband
A Loving Father—A Loyal Friend
A Public-Spirited Citizen
A True Christian".

Mr. Norcross was elected an Associate Member of the American Society of Civil Engineers on July 9, 1906 and a Member on May 7, 1913. At the time of his death he was serving as a Director of the Society to which office he had been elected on January 21, 1925.

CHARLES EZRA PERKINS, M. Am. Soc. C. E.*

DIED JULY 17, 1925.

Charles Ezra Perkins, the son of Simon and Grace Ingersoll (Tod) Perkins, was born at Akron, Ohio, on May 7, 1850. His grandfather, Simon Perkins, went to Ohio from Connecticut in 1800 and settled at Warren, Trumbull County, as the Representative of the Western Reserve Land Company. His maternal grandfather was Judge Tod, father of Governor David Tod, a well-known name among Ohio jurists fifty years ago.

Mr. Perkins was educated at the public schools of Akron and at the Western Reserve Academy, at Hudson, Ohio. He also attended Rensselaer Polytechnic Institute, at Troy, N. Y., from 1868 to 1870, where he took a special course in Civil and Mining Engineering. In 1871, he studied at the School of Mines, Columbia University, New York, N. Y.

On leaving the School of Mines, Mr. Perkins was appointed Assistant City Engineer of Akron and served in that capacity until he was appointed City Engineer in the summer of 1871, to which position he was afterward elected, serving as such until 1877. His work in this connection comprised all kinds of municipal engineering, particularly grading and paving. He was also engaged in the settlement of street improvement claims against the city in process of adjudication. During his term of office preliminary surveys were made for the establishment of sewerage and water systems for the city.

From 1878 to 1883, he was engaged in private practice, including ditch work, bridges, and road improvement, but the greater part of this time was spent in the agricultural implement business.

In addition to his private practice Mr. Perkins served as Surveyor and Engineer of Summit County, Ohio, from 1883 to 1892, in charge of all County engineering work, highway bridges, ditches, highway improvements, and coal mine surveys.

In 1892, he was appointed to the official position of Chief Engineer of Public Works of Ohio, an office created by statute in 1878. As Executive Officer of this great system of waterways, consisting of about 600 miles of canals, he served the State faithfully for sixteen years, during which time the canal properties under his control proved to be of inestimable value to the people, and a distinct and important asset to the State.

After his retirement from his official position in 1908, Mr. Perkins engaged in private practice as a Civil, Hydraulic and Mining Engineer, with an office in Akron. He was a Republican in politics and a party leader in Ohio.

He was married, in 1880, to May Adams, daughter of Mr. Frank Adams, a prominent manufacturer of Akron, who survives him.

Mr. Perkins was elected a Member of the American Society of Civil Engineers on June 6, 1906. He was also a member of the International Association of Navigation.

*Memoir prepared from information on file at the Headquarters of the Society.

CHARLES OSCAR POOLE, M. Am. Soc. C. E.*

DIED APRIL 2, 1925.

Charles Oscar Poole, the son of Reuben and Mary Agnes (Gorace) Poole, was born at Saulsbury, Mass., on June 17, 1859. His father was a Mechanical Engineer and came to the United States from Yorkshire, England.

When Mr. Poole was ten years of age, the family moved to San Francisco, Calif. He attended the public schools there and later took special studies in Mechanical Engineering, which profession he intended to follow.

From 1880 to 1884, he served as Machinist and Blacksmith for the Oregon Improvement Company in the State of Washington, leaving to work for four years with the Newcastle Coal Mine near Seattle, as Steam Engineer. In 1888, he returned to the Oregon Improvement Company as Master Mechanic of the Seattle Division, which position he filled for three years.

In 1891, Mr. Poole returned to San Francisco as First Operator and, later, as Foreman of the Dynamo Room of the California Electric Light Company of San Francisco. In 1894, he was made General Foreman of Shop and Maintenance for the Company, which position he held until, after a consolidation of interests in 1897, he was made General Superintendent of the Electrical Department of what was then known as The Edison Light and Power Company of San Francisco. During the next three years, he was in charge of the management of the entire electric light and power business of San Francisco, except the street railways.

In 1900, he resigned from this position to become General Superintendent and Assistant Manager of the Standard Electric Company of California. In this capacity, Mr. Poole had entire charge of the Construction and Operating Departments and under his direction the early hydro-electric development at Electra was undertaken and the first high-tension transmission line was constructed into San Francisco. During this time, Mr. Poole was interested, also, in the United Gas and Electrical Company which held the electric and gas supply franchise in San José, Calif., and much of the business of this Company was under his supervision as Manager and Supervising Engineer.

In 1902, he accepted a position as Sales Engineer for the Stanley Electric Company of Pittsfield, Mass., and had his headquarters with the Hendrie and Bolthoff Manufacturing and Supply Company, at Denver, Colo. Through this connection, he became acquainted with a Denver group of capitalists who, in 1904, began to construct a hydro-electric power development on Bishop Creek, California, with a power transmission line to Tonopah, Nev. From 1904 to 1905, Mr. Poole was Designing Engineer, with offices in Denver, for the Company, then known as the Nevada Power Mining and Milling Company, and, from 1905 to 1907, he served as Assistant General Manager with offices in Goldfield, Nev.

* Memoir prepared by E. J. Waugh and F. O. Dolson, Members, Am. Soc. C. E.

In 1907, The Nevada California Power Company was organized and from August, 1907, until October, 1923, Mr. Poole was its Chief Engineer. Several allied companies were afterward formed, of which he was also Chief Engineer, notably The Southern Sierras Power Company, The Sierras Construction Company, the Hydro-Electric Company, the Pacific Power Company, and many others.

In 1910, Mr. Poole formed a partnership with Mr. R. G. Manifold, the firm being known as Manifold and Poole, Consulting Engineers. They were the joint authors of "Straight Line Engineering Diagrams". The firm designed the steel tower transmission line of The Southern Sierras Power Company, a pioneer in length and voltage. It is 237 miles long and operates at 87 000 volts from Bishop Creek, in Inyo County, to San Bernardino, Calif.

As Chief Engineer in charge of design, construction, and, for many years, of operation, Mr. Poole was, in a great measure, responsible for the growth and development of the systems of The Nevada California Power Company, The Southern Sierras Power Company and Affiliated Companies, and for the development of the territory which these Companies serve.

In October, 1923, he resigned as Chief Engineer, moved to Los Angeles, Calif., and resumed general practice as Consulting Engineer with Mr. Manifold, as Manifold and Poole. He continued as Consulting Engineer for The Nevada California Power Company group until his death.

Mr. Poole was married in 1913 to Mrs. Cora Weston, of Los Angeles, who survives him. A son, Walter, in the United States Marine Corps, at Mare Island, Calif., and a daughter, Mrs. Erma Lorenson, of Oakland, Calif., children by a former marriage, are also living.

His work covered a period when great strides were made in the electrical industry, and he did as much as any one man in California to extend and simplify the electric and especially the hydro-electric industry of the State. He was foremost in the development of outdoor sub-stations, and long, high-voltage transmission.

Mr. Poole had a fine mind, a faculty of keen observation, and an exceptional memory. He was a clear and forceful conversationalist and speaker, with a ready fund of anecdote and quick wit. He was a truly strong, constructive personality. There were two outstanding characteristics that set him apart from ordinary men. One was a driving energy of mind and body that would not be satisfied with anything partly known or partly done. He typified the dynamos with which he worked and understood. The other characteristic was loyalty and steadfastness. Once having started on a course, he did not waver and he was ever a loyal friend. He will be greatly missed in the Engineering Profession both for his work and for his good fellowship and social qualities.

At its meeting of August 12, 1925, the following resolution was adopted by the Los Angeles Section of the Society of which Mr. Poole was a member:

"Charles Oscar Poole, M. Am. Soc. C. E., a man from our midst, died on April 2, 1925. We, his friends, can but offer to his memory the highest possible tribute for a life, highly successful as the world terms success, but more,

invaluable for its contribution to the advancement of his chosen profession, and for its personal inspiration, which we who knew him well so greatly appreciate and will so greatly miss.

"Since a young man Charles Oscar Poole was closely identified with electrical and hydro-electrical development. His work covered a period when great strides were made in this field, and he did as much as any one man in California to extend and simplify the electrical, especially the hydro-electrical, industry of the State. He was a leader in the development of outdoor sub-stations, and of transmission over long distances. To his efforts can be credited the first high-tension transmission line into the City of San Francisco, where he had for some years control of the entire electric light and power business of that City, excepting only the street railways. The steel tower transmission line of the Southern Sierras Power Company, a pioneer of length and voltage, is a monument to his efforts.

"Courage, untiring energy, vision and love of pioneering work, and loyalty to high ideals were his, and it is these traits of character, as well as his accomplishments, which lead us, his fellows in endeavor, to tender our respect to a man whose memory can only lead to greater progress, such progress as was so strongly the motive of his life."

Mr. Poole was a Fellow of the American Institute of Electrical Engineers and was elected a Member of the American Society of Civil Engineers on October 21, 1924.

AMBROSE VINCENT POWELL, M. Am. Soc. C. E.*

DIED DECEMBER 5, 1924.

Ambrose Vincent Powell, the only child of Col. George W. and Mary (Dunbar) Powell, was born at Laurens, N. Y., on May 4, 1847. He attended the Cooperstown, N. Y., Seminary and, later, studied at Rensselaer Polytechnic Institute at Troy, N. Y., from which he was graduated in 1868 with the degree of Civil Engineer.

In 1869 and 1870, Mr. Powell was engaged in general engineering work, and, in 1871, became Assistant Engineer on the Oil Creek and Alleghany River Railroad. From 1872 to 1875, he held the position of Engineer of the Michigan and Ohio Railroad and in 1876 and 1877, was engaged in general engineering practice at Battle Creek, Mich.

In 1878, he became Engineer for the Receiver of the Chicago and Northwestern Grand Trunk Railroad Company and, in 1879, was Principal Assistant Engineer of the Chicago and Grand Trunk Railroad. In 1880 and 1881, he was Principal Assistant Engineer of the Chicago and Western Indiana Railroad and in 1882 and 1883, Engineer of the South Chicago Dock Company.

In 1884 and 1885, he was Chief Engineer and Superintendent of the Calumet and Chicago Canal and Dock Company, and from 1886 to 1888, he served as Engineer and Commissioner of Public Works of Hyde Park, then a suburb of Chicago, Ill.

From 1889 until his death, Mr. Powell was engaged in private practice as a Consulting Civil Engineer in Chicago, making a specialty of dock and harbor work. He built the lake front harbor improvements at Ashtabula, Ohio, as well as harbor improvements on the Calumet River for the South Chicago Dock Company and for the Calumet and Chicago Canal and Dock Company. He constructed a yard and dry dock for the Chicago Shipbuilding Company, a dry dock for the Superior Shipbuilding Company, and coal-handling plants for E. L. Hedstrom and Company, George Lill Coal Company, O. S. Richardson and Company, and others, at Chicago and elsewhere. He designed and constructed dry docks for several large shipbuilding companies on the Great Lakes, at Buffalo, N. Y., Toledo, Ohio, and at other lake cities. He was the first to use a concrete portal for a dry dock.

Mr. Powell was a successful engineer. His keen observation and logical thinking resulted in sound engineering judgment. His citizenship was always thoughtful and constructive; for many years he was an active member and officer of the Hyde Park Improvement Association, a voluntary organization which was concerned with matters relating to the welfare of that section of Chicago.

* Memoir compiled from information on file at the Headquarters of the Society.

He was a member of the Western Society of Engineers for forty-three years having served as Treasurer in 1887. In 1898, Mr. Powell became Vice-President, and, in 1900, was elected President. He was a member of the Calumet Country Club, the Chicago Engineers Club, and the Union League Club of Chicago. He is survived by his widow, Mrs. Hannah Belle Clark Powell.

Mr. Powell was elected a Member of the American Society of Civil Engineers on February 6, 1901.

WILLIAM LeROY REYNOLDS, M. Am. Soc. C. E.*

DIED APRIL 16, 1925.

William LeRoy Reynolds, the son of Charles N. and Minnie C. Reynolds, was born at Dundas, Ohio, on April 26, 1886. He began his elementary schooling in McArthur, Ohio. In 1895, his parents moved West, settling in Colorado, first in La Junta, then in Monument, and, finally, in 1900, locating permanently in Denver, in which city Mr. Reynolds finished his public school education preparatory to entering college. He was graduated from the University of Colorado, at Boulder, in 1909, with the degree of Bachelor of Science in Civil Engineering.

Soon after his graduation he spent several months at Palisades, Colo., where he was engaged in both office and field work for the Orchard Construction Company. He next accepted the position of Office Engineer for the Antlers Orchard Development Company, at Silt, Colo., an irrigation system for 4 000 acres. From March until December, 1910, he served as Construction Engineer for the Glenwood Light and Power Company, and was in charge of the construction of nine miles of steel pole transmission lines, substations, power-house, and water-works improvements at and near Glenwood Springs, Colo. This work cost $40 000. From December until June, 1911, he made various estimates, surveys, and designs for the Antlers Orchard Development Company, the Glenwood Light and Power Company, the Colorado Orchard Development Company, and the United States Forest Service.

From June, 1911, to July, 1912, Mr. Reynolds was Division Engineer on the construction of Willcox Canal System covering 10 000 acres near Rifle, Colo. From August, 1912, to June, 1913, he was employed by the Board of Public Works, at Denver, as Assistant Engineer, in charge of the Cherry Creek reconstruction work, bridges, walls, sewers, etc., the aggregate cost of which was about $300 000.

In July, 1913, he was appointed Construction Engineer on the replacement of outlet works, at Big Horn Reservoir, near Sheridan, Wyo., the cost of which was estimated at $40 000. After its completion, in December, 1913, he was engaged in private work in Glenwood Springs and Denver, until April, 1914, when he became Assistant Engineer for the Public Utilities Commission of the City and County of Denver, on construction and water-rate cases. He completed this work in August, 1915, and immediately afterward accepted the position of Assistant Engineer for the Van Sant-Houghton Company, and was engaged in estimating the cost of a new water plant for the City of Denver.

In July, 1916, and for the next two years, Mr. Reynolds served in the capacity of Field Engineer for the American Smelting and Refining Company, at Leadville, Denver, Pueblo, and Durango, Colo. During this time he was in charge of the design and erection of smelter structures worth about $350 000.

In March, 1918, he had the honor of being appointed by the Government to a position of great responsibility for the period of the World War. He was

* Memoir prepared by M. C. Hinderlider, M. Am. Soc. C. E.

sent to Nitro, W. Va., where he was made Supervising Engineer, in the Office of the Director of the U. S. Explosives Plant C. Mr. Reynolds was in direct charge of most of the construction and, later, was given the management of the operation of the water system (capacity 60 000 000 gal. per day, the cost of which was about $2 000 000) and also of the sewer and gas systems.

His work at Nitro was valued very highly by the Government which showed its appreciation by appointing him Chairman of the Plant Salvage Board, at the signing of the Armistice. The confining work, long hours, and stern responsibilities during the war, however, had left their imprint upon him. His health began to fail and before the Salvage Board had finished its task of disposing of the plant, Mr. Reynolds was obliged to resign and return to Colorado. He established himself on a small fruit farm near Silt, in 1920, and for the greater part of the next four years devoted most of his energies toward regaining his health. During this period he could engage only in advisory work, and although he was elected President of the Farmers Irrigation Company, his activities were limited.

In April, 1924, he felt that his health had been sufficiently restored to enable him to accept an appointment from the State of Colorado, that of Hydraulic and Railway Engineer, with headquarters in Denver. He held this position for almost a year, when he suffered a physical relapse and, after a short illness, died at his home in Denver on April 16, 1925.

Mr. Reynolds was a member of the Capitol Heights Presbyterian Church, of Denver, and of the Glenwood Springs Lodge No. 65, Royal Arch Masons No. 22.

He was married to Luellen Comer, of Glenwood Springs, Colo., on May 5, 1912. Besides his widow and a daughter, his parents and a sister survive him.

Mr. Reynolds was elected an Associate Member of the American Society of Civil Engineers on February 4, 1914, and a Member on April 14, 1919.

LINDLEY MARSHALL RICE, M. Am. Soc. C. E.*

DIED AUGUST 21, 1925.

Lindley Marshall Rice, the son of James Walker and Bell (Wilson) Rice, was born at Lawrenceburg, Ky., on September 1, 1868. His forebears were of hardy pioneering Scotch-Irish stock and were among the first to cross the Appalachian Mountains to settle in Kentucky. His parents were slave holders at the time of the Civil War.

Little is known of Mr. Rice's boyhood, but his technical education was obtained at the Georgetown College, Georgetown, Ky., where he took a scientific course.

On leaving college in 1888, he went to the Northwest and began the practice of engineering in the State of Washington. His first work consisted of assisting in the construction of a slaughter-house for the firm of Rice and Gardner. When this work was completed, Mr. Rice found employment in the office of Mr. A. Gardner, then City Engineer of Seattle, Wash., as Chainman and Rodman, and he was also engaged in general municipal engineering work. In the spring of 1889, he served with the Fairhaven and Southern Railway Company of Washington as Rodman and was afterward promoted to the positions of Leveler and Transitman. He remained with this Company until the fall of 1890.

At this time the Fairhaven and Southern Railway Company was merged with the Great Northern Railway Company, and Mr. Rice was engaged as Assistant Engineer in charge of construction on the Seattle-Montana Branch, under the late William Parsons Watson, M. Am. Soc. C. E. Although he was only 22 years of age, he carried out the work efficiently.

On the completion of this project, Mr. Rice was transferred to the main line of the railroad, in the Cascade Mountains, where he served as Assistant Engineer, reporting to John F. Stevens, Hon. M. Am. Soc. C. E. This work was finished in the early part of 1893, and he then engaged in private practice for two years.

In 1895, Mr. Rice was employed on the Kalso and Slocan Railroad in British Columbia as Assistant Engineer, but early in 1898 entered the service of the Canadian Pacific Railway Company as Locating Engineer and Division Engineer on Construction. He remained on this work until June, 1900, when he resigned to enter private practice in Seattle. He devoted the following year to the location and construction of logging railroads and subsequently, until 1907, built nearly all the railroads of this type that were constructed in the State of Washington.

In 1905, he organized the Klickitat Irrigation and Power Company and served the Company at various times as Chief Engineer, General Manager, and Director. In 1907, he organized the L. M. Rice and Company, an engineering and contracting corporation, and was at various times its President, Chief Engineer, and General Manager. This Company carried out various

* Memoir prepared from information furnished by L. M. Rice, Jr., and from data on file at the Headquarters of the Society.

contracts, including the completion of about 100 miles of the Kettle Valley Railroad between Midway and Penticton, British Columbia. It had as its principal object the irrigation of arid lands, and as Mr. Rice had studied this subject thoroughly he was recognized as an authority in matters relating to irrigation.

He was connected with many of the large engineering projects of the West and was the first to conceive the idea of irrigating the Horse Heaven Plateau, a vast stretch of level, fertile land located in Southeastern Washington which on account of scarcity of water in summer had not been settled. The Horse Heaven Irrigation District was organized to take over the water rights on the Klickitat and Big Muddy Rivers for use in irrigating the Plateau and Mr. Rice became Chief Engineer of the District.

From 1915 to 1918, his great interest in reclamation worked to his appointment as Chairman of the Executive Committee of the Western States Reclamation Conference, and he was also active in the work of the Washington Irrigation Institute.

During his tenure of office with the Western States Reclamation Conference, Mr. Rice was in constant contact with many of the large Western projects. At this time he also took an active interest in the Wenatchee Heights Irrigation District and the Yelm Irrigation District, both of which were in the State of Washington. In 1918, he served as Chief Engineer of the Quincy Irrigation District.

In recent years, he had spent a great part of the winter months in Eastern cities in an untiring effort to secure financial support for the Horse Heaven Irrigation Project. This work weakened his vitality, and it was shortly after his return to Seattle from one of these trips that his sudden death from apoplexy occurred.

Mr. Rice was married at Edmonds, Wash., on September 9, 1891, to Adelaide E. Leonhardt who, with two daughters, Ophelia and Miriam E., and three sons, Lindley M., Jr., Carleton L., and James W., survives him.

Mr. Rice was elected a Member of the American Society of Civil Engineers on May 31, 1916. He was also a member of the Rainier Club of Seattle and the American Geographical Society.

GEORGE THOMAS ROBERTS, M. Am. Soc. C. E.*

DIED SEPTEMBER 2, 1924.

George Thomas Roberts, the son of George and Jennie (Whiteman) Roberts, was born in Buffalo, N. Y., on September 23, 1871. He attended the public schools and the Central High School of that city until 1891.

At the age of 20 years, Mr. Roberts began his engineering work as a Draftsman with the Lehigh Valley Railroad Company at Buffalo. In 1894, he became a Draftsman in the office of the City Engineer, and, later, was appointed Assistant City Engineer.

In 1901, he formed a partnership with F. V. E. Bardol, M. Am. Soc. C. E., who was at that time City Engineer of Buffalo. The organization was called the Eastern Concrete Steel Company, Building and Engineering Contractors. Mr. Roberts continued in that business until his death.

Among the buildings erected by this Company are the New York State Normal School, City Hospital Buildings, Majestic Theatre, Elmwood Theatre, St. Margaret's Church, Canisius College, all at Buffalo; also, several of the Eastman Kodak Company Buildings, at Rochester, N. Y., the Drill Hall at Cornell University, Ithaca, N. Y., and the Public Library at Westfield, N. Y.

He was a member of the Buffalo Consistory, Ismalia Temple, of Buffalo; Washington Lodge No. 240, F. and A. M.; the Buffalo Club, the Athletic Club, the Park Club, and the Automobile Club; and, also, of the Buffalo Builders' Exchange.

Mr. Roberts was elected an Associate Member of the American Society of Civil Engineers on September 3, 1902, and a Member on March 3, 1908.

* Memoir prepared by Emile Low, M. Am. Soc. C. E.

WILLIAM ROTCH, M. Am. Soc. C. E.*

DIED AUGUST 14, 1925.

William Rotch was born at New Bedford, Mass., on July 22, 1844, the eldest son of William J. and Emily (Morgan) Rotch. On both sides of his family, he came from distinguished ancestry. His great-great-great-grandfather, Joseph Rotch, already a successful shipowner, came to New Bedford from Nantucket, Mass., in 1765. Joseph Rotch and his sons, William and Francis, found New Bedford a farming town doing a little whaling off the coast, and by their energy they established the industry that made the town the great whaling center of the world. Francis Rotch built and owned the *Dartmouth*, the best known of the three ships of the Boston "Tea Party". William Rotch (1738 to 1828) owned the ship, *Bedford*, which first displayed the American flag in foreign waters in 1783. After the Revolution, he established the whale fishery in France, but returned to the United States following the French Revolution. With the decline of the whaling industry, the Rotchs turned their energies to cotton manufacturing. At various times Mr. Rotch's father, William J. Rotch, was President and Director of most of the older New Bedford cotton mills. On his mother's side, Mr. Rotch was a grandson of Charles W. Morgan, one of the great whaling merchants of New Bedford, whose whaling vessel, the *Charles W. Morgan*, has been preserved as a memorial to the whaling industry.

William Rotch was educated at the Friends Academy of New Bedford, and was graduated from Harvard University in 1865, with the degree of Bachelor of Arts. He then entered the Ecole Centrale des Arts et Manufactures, in Paris, France, from which he was graduated in 1869, ninth in a class of 225, with the degree of "Ingenieur Civil".

Mr. Rotch began his professional career in 1871 as Assistant Engineer of the Fall River, Mass., Water-Works, then in course of construction, and served as Chief Engineer from 1874 to 1880, when the works were completed. From 1880 to 1882, he was Consulting Engineer and Purchasing Agent of the Mexican Central Railway Company, the Sonora Railway Company, the Atlantic and Pacific Railroad Company and the California Southern Railroad Company, the lines of the last two now forming the western portion of the main line of the Santa Fé System. From 1884 to 1891, he was Consulting Engineer of the Cleveland, Canton, and Southern Railroad Company, the Lakeside and Marblehead Railroad Company, the New Bedford and Fall River Railroad Company, and other railroad companies in Ohio and Massachusetts.

In 1881, Governor Long of Massachusetts appointed Mr. Rotch as Engineer and Member of the Commission which finally established the boundary line between Massachusetts and Rhode Island that had been in dispute for more than 250 years. He served on this Commission until 1883.

In 1894 and 1895 he was a member of the Re-Organization Committee of the Atchison, Topeka, and Santa Fé Railway, and from 1895 to 1900, he served as

* Memoir prepared by Albert B. Drake, M. Am. Soc. C. E.

a Director of that road. He was also a Director of the Mexican Central Railway Company from 1880 to 1900, and had charge of the first train which ran from Boston to the City of Mexico, in April, 1884. From 1886 to 1894, Mr. Rotch was President of the Tremont Electric Lighting Company and the Consolidated Electric Manufacturing Company, and a Director of its successor, the Walker Company, which Company installed the complete electric plant in the Waldorf-Astoria Hotel in New York, N. Y., then the finest electric lighting plant in America.

Mr. Rotch was an official in many Massachusetts corporations. From 1913 to 1922, he was President of the Federal Wharf and Storage Company; from 1918 to 1922, Vice-President of the State Wharf and Storage Company; and from 1918 to 1922, President of the Fibre Manufacturing Company. He was also President of the Railroad Wharf and Storage Company, the Denbigh Mining Corporation, the Terrible Dunderberg Mining and Powder Company; Vice-President of the Bonanza Development Company; Treasurer of the Broadway Storage Company; Trustee and Treasurer of the Nonquitt Real Estate Trust; Managing Director of the Rotch Travelling Scholarship for Architects; and a Director of the Infants Hospital and the Adams Nervine Hospital. In 1870, he was elected the first President of the Union for Good Works in New Bedford.

Mr. Rotch was President of the Alliance Francaise of Boston and Cambridge, Mass.; Governor of the Massachusetts Society of Colonial Wars; an Honorary Member of the Boston Society of Architects; a member of the Association des Anciens Eleves de l'Ecole Centrale of Paris, the Bostonian Society, the Somerset and Harvard Clubs of Boston, and the Wamsutta Club of New Bedford. He was also a member of the Arlington Street (Unitarian) Church, of Boston.

He was married in 1873 to Mary Rotch Eliot, who survives him, together with three children, Edith Eliot, Charles Morgan, and Clara, the wife of Dr. Channing Frothingham.

Mr. Rotch had both his office and residence in Boston for many years. In spite of his eighty-one years, he had been in excellent health and had attended the Harvard-Yale Baseball Game in June, 1925, at which he was the oldest graduate present. Taken ill at his summer home at Nonquitt, Mass., he was taken to the hospital at New Bedford on June 25, where following an operation his condition was thought to be improving until he suffered a heart attack which caused his death. Possessed of a wonderfully genial personality, Mr. Rotch leaves a host of friends.

Mr. Rotch was connected with the American Society of Civil Engineers for fifty-two years, having been elected a Member on March 5, 1873.

HENRY NORLANDE RUTTAN, M. Am. Soc. C. E.*

DIED OCTOBER 31, 1925.

Henry Norlande Ruttan was born on May 21, 1848, at Cobourg, Ont., Canada, where he received his early education. His parents were Henry Jones and Margaret (Pringle) Ruttan. His grandfather was the Hon. Henry Ruttan, formerly Speaker of the Legislative Assembly of Ontario.

Without the advantages of a college education or a technical training, Mr. Ruttan started while quite young in what became his life work and profession. Beginning in 1867 on the Engineers' Staff of the Grand Trunk Railway Company, he had a varied experience for sixteen years in railway work, as follows: 1869, on Engineers' Staff, Intercolonial Railway Company; from 1870 to 1874, on construction, Intercolonial Railway, and, later, in charge of a Division on Baie de Chaleur, including much heavy bridge work; in 1874, on preliminary surveys, Canadian Pacific Railway, north of Lake Superior; from 1875 to 1877, in charge of a party locating the line of the Canadian Pacific Railway from the summit of the Rocky Mountains, eastward; from 1877 to 1880, Engineer for the Contractor on the construction of the Canadian Pacific Railway between Lake of the Woods, Ontario, and Winnipeg, Man.; and from 1880 to 1885, designed and built bridges over the Red River at Emerson, Man., and over the Assiniboine at Winnipeg. As Engineer and Contractor Mr. Ruttan built the first forty miles of the Manitoba North Western Railway, and as Contractor, the first fifty miles of the Manitoba South Western Railway.

On June 29, 1885, Mr. Ruttan was appointed City Engineer of Winnipeg, and held this position for twenty-nine years, resigning in May, 1914. Among the outstanding features of his work as City Engineer was the design and construction of the Artesian Well System in 1899, when the City purchased the plant of the Winnipeg Water-Works Company which obtained its supply from the Assiniboine River. In 1898, he remodeled the asphalt plant which the City had purchased from contractors, which plant has supplied all the requirements of the City since that time for paving purposes.

In 1905, Mr. Ruttan was instrumental in the installation of a Fire Service Water-Works System with a separate distribution system. This plant is capable of pumping 18 000 000 gal. per 24 hours at 300-lb. pressure. He also designed and constructed the sewerage system of Winnipeg, a difficult task when the flatness of the territory is considered. In 1906, he made the original survey for the hydro-electric system of the City of Winnipeg and, later, acted as Consulting Engineer.

His success as an Engineer is a good example of what can be accomplished by hard work combined with a good mind. Practically all his spare time was given to reading and self-education.

In addition to his engineering achievements, he had an enviable military record, as follows: He enlisted in the Cobourg Rifle Company of the 40th Regiment, Canadian Militia, in 1863, and served with that unit for seven

* Memoir prepared by J. G. Sullivan, M. Am. Soc. C. E., and William P. Brereton, City Engr., Winnipeg, Man., Canada.

years. On November 9, 1883, he was appointed Captain in the 90th Regiment (Winnipeg Rifles), and was promoted to the rank of Major on February 14, 1887. Subsequently, on December 25, 1895, he was appointed Lieutenant-Colonel in command of the unit, which command he held until December 27, 1900.

From 1900 to 1910, Colonel Ruttan was a Reserve Officer, but in April, 1910, he was appointed Lieutenant-Colonel to command the 100th Regiment (Winnipeg Grenadiers), in which appointment he remained until October, 1912, when he was selected to command the 20th Infantry Brigade, with which he served until September 5, 1918. He was appointed Temporary Brigadier General on July 8, 1916, and assumed command of Military District No. 10 (in addition to his duties as Commander of the 20th Infantry Brigade), during the World War period. General Ruttan was one of the first officers in Military District No. 10 to pass the Militia Staff Course.

His war service record is, as follows: Fenian Raid, 1866, for which he received the General Service Medal with one clasp (90th Winnipeg Battalion); North West Rebellion, 1885, actions at Fish Creek (April 24), and Batoche (May 9 to 12), and operations against Chief Big Bear's Band (June-July), for which he received a medal with clasp. He was made a Companion of the Order of St. Michael and St. George for services in connection with the World War (1914-18).

General Ruttan's military training developed a manner that was somewhat awe-inspiring to the young clerk, but his sense of justice and kindness of heart was such that he was admired and respected by all who knew him. He never attempted to shift any responsibility; on the contrary, he often assumed full personal obligation for the mistakes of his subordinates.

As is the case with all public servants he had adversaries and many men were elected to the City Council at Winnipeg and even as Mayor as an opponent to General Ruttan only to become his supporter in a short time.

In many cases the good judgment he displayed in disputed questions became apparent only after a long period of time, such as his decision to use municipal forces only in the construction of improvements during the boom days of 1905 to 1913, which saved the City of Winnipeg from a condition of over-development reached by many other towns in the Prairie Provinces at that time. If 50% of the public officials had the same character and determination to do what was right as General Ruttan, the public operation of utilities, especially those with a low operating ratio, would not be such a bugbear to the ordinary taxpayer.

General Ruttan served as President of the Winnipeg Branch of the Navy League for fifteen years and was granted the Special Service Decoration. He was a Past-President of the Canadian Society of Civil Engineers (now the Engineering Institute of Canada) and a member of the Royal Society.

General Ruttan is survived by his widow, Mrs. Andrian Ruttan, *nee* Barberie, and the following children: Maj. H. A. Ruttan, of Port Arthur, Ont.; Lieut.-Col. C. M. Ruttan, Capt. F. N. Ruttan, and Capt. J. D. Ruttan, all of Winnipeg; and Mrs. H. L. Wethey, of Neepawa, Man., Canada.

General Ruttan was elected a Member of the American Society of Civil Engineers on January 4, 1893.

AMOS SCHAEFFER, M. Am. Soc. C. E.*

DIED OCTOBER 3, 1924.

Amos Schaeffer, the son of Augustus and Amanda (Leibensberger) Schaeffer, was born on a farm at Fleetwood, Berks County, Pa., on February 17, 1867. He was of German ancestry, and of the people who populated a large part of the State of Pennsylvania and made it the flourishing and prosperous section that it is to-day.

His early education was obtained in the public schools, after which he was graduated from the Kutztown, Pa., Normal School. Following a few years of teaching, he entered Franklin and Marshall College at Lancaster, Pa., from which he was graduated in 1889 with the degree of Bachelor of Arts and finished with a year at Sheffield Scientific School, Yale University, from which he obtained the degree of Bachelor of Philosophy in 1890.

Following his graduation, Mr. Schaeffer was employed by the Lehigh Valley Railroad Company on surveys and field work. In April, 1892, he entered the service of Rodgers and Clement, Contractors for the Niagara Falls Power Tunnel, in charge of portal masonry and stone-cutting for the tunnel, which is about 1½ miles long, and is the tail-race for the water that enters the turbines after dropping perpendicularly about 150 ft. at the forebay at Niagara River above the Falls. The tunnel was built under the City of Niagara Falls for the first utilization of the power of the Falls by electricity (1895), and is still in use.

During parts of 1893 and 1894, Mr. Schaeffer was engaged with the United States War Department at Jonesport, Me., in charge of the removal of ledge rock under water in the ship channel and for a short time with the Lehigh Valley Railroad Company on a contour survey for railroad location in Maryland.

In May, 1894, he returned to Niagara Falls, entering the City Engineer's Office as Assistant Engineer, in charge of the design and construction of sewers. He completed the construction of a tunnel trunk sewer in rock; made plans for and superintended the construction of brick and asphalt pavements; designed and constructed the skewbacks and abutments for a 150-ft. span skew steel arch bridge; and located and established street lines and grades. The City of Niagara Falls had grown rapidly in size and population after the introduction of cheap electric power and many new industries had settled there, necessitating additional residential facilities, and during the latter part of his stay, Mr. Schaeffer engaged in private practice on property sub-division and general engineering in connection with the paper and pulp mills which had located there.

In November, 1897, he entered the employ of the City of New York, which, with one short exception, was destined to be his last change. His first work was in the Topographical Bureau, Department of Sewers, Borough of the Bronx. In 1900, on the inception of the work of the Rapid Transit Railroad,

* Memoir prepared by William J. Boucher, M. Am. Soc. C. E.

he transferred to the Rapid Transit Commission where he made a specialty of the sewer problems. The construction of this railroad, built as it is, almost entirely below the streets of the City, caused a most elaborate re-design of the sewer system, necessitating many re-arrangements, new construction, and reconstruction of the trunk sewers and lateral systems. On the resignation of Mr. Calvin W. Hendrick in 1905, Mr. Schaeffer was appointed Engineer of Sewers. The careful investigation, study, design, and construction done under his supervision is amply attested by the results after practically twenty-five years' growth of the great city at a rate never anticipated.

In 1909, Mr. Schaeffer resigned from the Rapid Transit Commission and Sewer Division to become Chief Engineer of Gore-Meenan Company, Sub-Contractors for a section of the Catskill Aqueduct on the east side of the Hudson River, near Peekskill, N. Y. Although he worked hard and gave his best thought and efforts to the success of the work, financial difficulties caused a suspension. This, however, was through no fault of Mr. Schaeffer.

In 1910, Mr. Schaeffer was appointed Consulting Engineer, Borough of the Bronx, New York, a new position, reporting to the President of the Borough. Some years later, he was appointed to a similar position—Consulting Engineer, Borough of Manhattan—which he held until his death, serving in the two Boroughs under five different Presidents and three Mayors. While in this position, Mr. Schaeffer's work was of a most varied character and comprised largely, improvements planned for the future betterment of the fast growing Boroughs to accommodate the increasing traffic and population. Vision, forethought, and sound planning were essential, and with his experience and training, he was well equipped to cope with the many problems which were constantly arising. His intimate knowledge of the laws and regulations of municipalities enabled him to frame his recommendations so that they secured speedy adoption. One of the Borough Presidents has expressed the opinion that he was one of the ablest engineers in the City of New York.

Mr. Schaeffer was of a most pleasing and cordial personality; once he had been gained as a friend, he remained such. His contacts were with all classes, and his tact and diplomacy as well as his thorough knowledge of the facts regarding his work and projects enabled him to present the matter in hand in a pleasing and convincing manner.

He was an ardent church worker, having been affiliated with the Fordham Manor Reformed Church, Bronx, New York, of which he was a member and Elder, and a Member of the Classis. In 1924, he was elected one of three Trustees of the Board of Direction of the Reformed Church of America. Shortly after his death, the Consistory of that Church adopted a resolution, which was spread on its minute book and published in the "Monthly Leaflet", part of which reads, as follows:

"Mr. Schaeffer's character was above reproach. His virtues were the virtues of the stoical philosophy as expounded by Gilbert Murray. 'God, the eternal dramatist', says Professor Murray, 'has cast you for some part in his drama, and hands you the rôle. It may turn out that you are cast for a triumphant king; it may be for a slave who dies of torture. What does that matter to the good actor? He can play either part; his only business is to accept the rôle

given him and perform it well. * * * Do you ever find that history praises a man because he was healthy, or long-lived, or because he enjoyed himself a great deal? History never thinks of such things. The thing that lives is a man's goodness, his great deeds, his virtues, or his heroism. * * * The only good for man is to be good. And when Zeno says "good," he means good in the ultimate Day-of-Judgment sense.'

"Mr. Schaeffer accepted his rôle in life in this spirit. He was not concerned about his ease or his pleasure—only his duty. That is why he held his position, unprotected by Civil Service, through all the mutations of political strife. In the City Government he was a Gibraltar that could not be moved by corruption, flattery, or threat. To him the only question concerning any measure was, 'Is it right, and in the public interest?' In the Consistory, these same traits were always in evidence. His goodness was not expressed by words, but by deeds. He had vision and courage, and boldly faced the future even when the outlook was darkest; much of the progress of the church in recent years we owe to him. He served on many important committees, and always with fidelity and distinction. Everything that came under his scrutiny received thorough and conscientious consideration.

"As a friend and neighbor Mr. Schaeffer was kind and true, ready to help in time of need. He was a charming host and had—what is rare with men as serious as he was—a delightful sense of humor. He was a real man, without sham of any kind. 'The reality of things,' says L. P. Jacks, 'is inversely proportional to the noisiness of the self-announcement.' Mr. Schaeffer was as modest as he was efficient. He never sought the spotlight, but was content to play his rôle even when others took the applause.

"The Consistory as a body hereby expresses its regret at the loss of one of its most useful members. As individuals, the members have lost a genuine friend and lovable companion. They offer their profound sympathy to the widow and orphans left by the deceased, and incorporate this expression of their respect and loss into the official record of the church."

Mr. Schaeffer's health began to fail during the summer of 1924; a long vacation seemed to restore him somewhat, but he died of typhoid fever on October 3, 1924. He was married to Florence Harriot Messmore who, with a son and a daughter, survives him.

Mr. Schaeffer was elected an Associate Member of the American Society of Civil Engineers on February 3, 1904, and a Member on February 6, 1906. He was also a Past-President of the Municipal Engineers of the City of New York.

GRANVILLE WHEATON SHAW, M. Am. Soc. C. E.*

DIED JANUARY 6, 1925.

Granville Wheaton Shaw, the son of Theodore Granville and Matilda (Ward) Shaw, was born in Chillicothe, Ohio, on April 27, 1849. He moved to Louisville, Ky., with his parents in 1851, where he resided for the remainder of his life. His education was obtained in the public schools of Louisville with the exception of five years spent in private schools before he reached his fifteenth year.

In January, 1868, Mr. Shaw entered the service of the Louisville, Cincinnati and Lexington Railroad Company, then building a line between La Grange, Ky., and Cincinnati, Ohio, under the direction of the Chief Engineer, the late I. M. St. John, M. Am. Soc. C. E., and was engaged as Rodman on location surveys and as Assistant Engineer on the construction of shops, roundhouses, etc.

In May, 1869, he went with General St. John to the Louisville, New Albany and St. Louis Railroad (now a part of the Southern Railway System) as Leveler on preliminary surveys of the line from New Albany, Ind., to Mt. Carmel, Ill. In 1870, he was employed as Assistant Engineer on the construction of a bridge across Licking River, at South Covington, Ky., and in building a railroad from that point through Newport, Ky., to connect with the Ohio River Bridge. He was also employed as Draftsman on a Government survey of the Upper Cumberland River under the late S. T. Abert, M. Am. Soc. C. E., U. S. Engineer. In 1872, he was appointed Assistant Engineer on the Louisville, Cincinnati and Lexington Railroad under General St. John and was engaged in the reconstruction of bridges and surveys for railroad extensions.

From 1873 to 1875, Mr. Shaw served as Assistant City Engineer of Louisville, under the late Thomas P. Shanks, M. Am. Soc. C. E., in charge of sewer construction and the extension of a short-line railroad along the river front to East Louisville, and had supervision of all city bridges. He subsequently went to Vincennes, Ind., in the employ of Cunningham and Mettesser, manufacturers of glucose, and for one season commanded the steamer *Vigo,* a Wabash River packet running in the interests of the firm. He also designed a drainage system for the property of the Company and rebuilt its plant.

In 1878, Mr. Shaw returned to Louisville and was employed as Assistant Engineer on the preliminary survey of the Falls of Ohio River with Mr Thomas H. McMichael and, in 1879, was in charge of a survey and cross-sections of the Falls of the Ohio River under Gen. G. Weitzel, Corps of Engineers, U. S. A., completing the field work by the end of the year.

Early in 1880, he accepted the position of correspondent for the *Louisville Commercial* at Frankfort, Ky., during the session of the Kentucky Legislature.

* Memoir compiled from information on file at the Headquarters of the Society.

When the latter adjourned, he was appointed City Editor of the *Commercial* and remained with that newspaper until the fall of 1882, when he established a Bureau for the Testing of Hydraulic Cement at Louisville. From 1883 to 1885, he was engaged in various surveys and works in connection with the Louisville and Portland Canal and the Falls of the Ohio River under the late Col. William E. Merrill, Corps of Engineers, U. S. A., M. Am. Soc. C. E.

In March, 1886, Mr. Shaw accepted the position of U. S. Assistant Engineer in charge of improving the Falls of the Ohio River, at Louisville, and the enlargement of the Louisville and Portland Canal, under Maj. Amos Stickney, Corps of Engineers, U. S. A. He also constructed the new river wall, began the work of enlarging the harbor in front of the city, and was engaged in excavating a channel through rock. He remained in this position until December 31, 1894.

In December, 1895, he accepted the position of Chief Clerk in the U. S. Engineer's Office at Columbus, Ohio, under the late Brig.-Gen. H. M. Chittenden, U. S. A., M. Am. Soc. C. E. (at that time, Lieutenant, Corps of Engineers, U. S. A.), and was engaged in survey work for a canal from Lake Erie to the Ohio River. This work was finished in February, 1896.

Mr. Shaw then went to Milwaukee, Wis., to test cement for the Government and, later, to Missouri to inspect timber. In January, 1897, he was re-appointed by Capt. J. G. Warren, Corps of Engineers, U. S. A. (now Colonel, U. S. A. (*Retired*)), M. Am. Soc. C. E., to a position in the U. S. Engineer Office at Louisville, and again placed in charge of the improvements on the Ohio River. He remained on this work until his retirement in 1912, on account of failing health.

On January 14, 1873, Mr. Shaw was married to Adeline Orpha Wolford, the daughter of Henry Wolford, for many years City Treasurer of Louisville. Mrs. Shaw died on January 1, 1926. A son, George Wolford Shaw, survives him.

Mr. Shaw's standards of conduct were high, especially when pecuniary transactions were involved. To whatever work he was assigned he gave close attention, and did his duty to the satisfaction of those above him. He was a member for several years of the Engineers and Architects Club at Louisville, helping it financially and taking part occasionally in the discussions of technical papers.

After entering the service of the U. S. Engineer Department, Mr. Shaw became interested in the local politics of Louisville, for which his previous employment under the City Engineer and as a reporter for a newspaper had prepared him. This intimacy, however, was not carried so far as to be detrimental to his work under the Engineer Department.

His social life found an outlet in his fondness for vocal music, especially when rendered by male voices. These musical activities were begun as a young man in church choirs, and were continued in wider circles until he was well beyond fifty years of age. Beginning with a quartet of singers and with a fifth man as leader and pianist, he watched a small organization grow to

become a noted institution in the musical life of Louisville. This assemblage of young men had various names—the Arion Club, the Apollo Club, the Louisville Male Chorus—and of all of them he was President for a time. He took charge of arrangements for public performances and many other matters not connected with actual training for concerts, serenades, etc.

Throughout his life, Mr. Shaw was a devoted member of the Protestant Episcopal Church.

Mr. Shaw was elected a Member of the American Society of Civil Engineers on October 5, 1887.

JOSEPH THOMPSON STUART, M. Am. Soc. C. E.*

DIED FEBRUARY 13, 1925.

Joseph Thompson Stuart was born at Port Royal, Pa., on May 28, 1858, and received his early education at the public schools in Allegheny, Pa.

On August 4, 1881, he entered the employ of the Pennsylvania Railroad Company (Pittsburgh Division), as Chainman, but, in October, was transferred to the Construction Department.

In 1886, Mr. Stuart was promoted to be Assistant Engineer of Construction, in charge of change of line and the construction of a four-track arch bridge at Brinton, Pa., on the Pittsburgh Division. In 1887, the construction of the 33d Street Bridge and the extension of the train-shed at Pittsburgh, Pa., was effected under his direction.

From 1888 to 1890, Mr. Stuart was engaged in reconstruction work, for the Pennsylvania Railroad Company, building shops and yards and rebuilding line and the South Fork and Viaduct Bridges after the Johnstown flood. He also rebuilt the Portage Tunnel at Gallitzin, Pa.

In 1891, he had charge of the change of line at Principio, Md., and also at Washington, D. C., including the elimination of the grade crossing for the Union Station. During this time he also rebuilt the Ebensburg Branch of the Pennsylvania Railroad from Cresson to Kaylor, Pa.

From 1892 to 1895, Mr. Stuart was in charge of the construction of the Broad Street Station at Philadelphia, Pa., and, in 1895 and 1896, of the Delaware Bridge for the Pennsylvania Railroad at Philadelphia, which included the caisson work and superstructure. During 1897 and 1898, the change of line at Bacon Hill and Northeast, Md., of the Philadelphia, Baltimore, and Washington Railroad, was under his direction. In 1899 and 1900, he built the Bond Street Terminal Warehouse and Pier at Baltimore, Md., and in 1900 and 1901, he constructed the Camden Terminal at Camden, N. J.

Mr. Stuart was in charge of the elevation of the railroad through Chester, Pa., from 1901 until 1903. On August 1, 1903, he was appointed Engineer of Construction in charge of all construction work of the Pennsylvania Railroad Company between Philadelphia and Washington, D. C., under the supervision of the Chief Engineer. This included the building of the Wilmington and Washington Elevated Railroads.

On January 31, 1904, he resigned his position with the Pennsylvania Railroad Company and entered the contracting business with Mr. Andy Brann. This partnership afterward became Brann and Stuart Company, Incorporated, of which Company Mr. Stuart was President at the time of his death which took place at Dunedin, Fla., on February 13, 1925.

He was a member of the Engineers Club and the Union League of Philadelphia, the Scotch-Irish Society of Pennsylvania, the Philadelphia Yacht Club, and an Honorary Member of the Philadelphia Lehigh Club.

Mr. Stuart was elected a Member of the American Society of Civil Engineers on May 4, 1904.

* Memoir compiled from information furnished by Joseph J. Vogdes, M. Am. Soc. C. E.

JUDSON GILMAN TABLER, M. Am. Soc. C. E.*

DIED DECEMBER 28, 1924

Judson Gilman Tabler, the son of William D. and Mary (Reader) Tabler, was born on August 4, 1877, in Washington, D. C., where he received his education and grew to manhood.

Mr. Tabler was a Draftsman in the United States Patent Office at Washington when war was declared against Spain in 1898 and he promptly resigned his position to enlist. He served during that war with Company F of the 3d Volunteer Engineers and was in Cuba when mustered out of service. He remained on the Island until July, 1902, being engaged during this time as a Instrumentman on highway and railway construction.

In the summer of 1902, he returned to the United States and for the remainder of that year was located in Jennings, La., on irrigation work, going from there to Mexico in December to accept a position with the National Railways of Mexico. He remained in Mexico for more than eleven years, or until 1914, when the revolutionary state of the country had paralyzed all construction work. During this time Mr. Tabler rose from Instrumentman to the position of Chief Construction Engineer for the Company, having held many responsible and important positions in the interim. When forced out by the Revolution in 1914, he was engaged in building a railroad from Tampico to Vera Cruz, involving very difficult construction problems.

After his return to the United States, Mr. Tabler was employed for a time as Assistant Resident Engineer on maintenance of way by the International and Great Northern Railroad Company. In January, 1916, he became Principal Assistant Chief Engineer of the Berthe Engineering Company of Charleston, Mo., Consulting Engineers for various drainage and flood protection projects and other work. Except for a few months with the United States Engineers in Texas, in 1916, and a year spent in laying out and supervising the construction of a plant at Penniman, Va., including buildings, sewers, railroads, and yards, for the Dupont Powder Company, in 1917 and 1918, during the World War, he remained with the Berthe Engineering Company until June, 1921, when he resigned to accept a position with the Virginia State Highway Department. While with the Berthe Engineering Company, he had charge of construction work valued at more than $3 000 000, including ditches, levees, pavements, flood-gates, sewers, and reinforced concrete and sub-foundation work.

Mr. Tabler remained with the Virginia State Highway Department until January, 1924, when he resigned to accept the position of County Engineer of Bedford County, Virginia, with headquarters at Bedford, where he had made many friends.

In the comparatively short span of life alloted to him Mr. Tabler had a wide and varied experience. The writer knew him intimately for more than twenty-seven years, having first met him in the Army in 1898, and after-

* Memoir prepared by L. T. Berthe, M. Am. Soc. C. E.

ward worked with him for years in Cuba, Mexico, and the United States. He was a man of real ability, at his best when conditions were most difficult, never losing his temper or his judgment in times of emergency and always ready to expend his last ounce of energy to "put the job through". Men who worked with him invariably not only admired and respected him as an Engineer, but valued him as a friend. He inspired true and lasting friendships among his fellow workers. Mr. Tabler was in every way the personification of an engineer and a gentleman and his memory will live long in the hearts of all who knew him. He was married in El Paso, Tex., to Dora M. Wrieth, who survives him.

He was a member of the American Association of Engineers, of the Masonic Fraternity, and of the Christian Church.

Mr. Tabler was elected a Member of the American Society of Civil Engineers on December 6, 1920.

JAMES TOWNSEND TAYLOR, M. Am. Soc. C. E.*

DIED MARCH 17, 1924.

James Townsend Taylor was born in Waiaha, Kona, Hawaii, on March 19, 1859. He was the son of the Rev. Townsend Elijah and Persis Goodale (Thurston) Taylor.

California having become the home of the family, he attended Golden Gate Academy, Washington College, and the University of California.

In 1877, Mr. Taylor began his engineering work with the South Pacific Coast Railroad Company and remained in its service until 1879. He was with the California State Engineering Department in 1880 and 1881; with the Pomona Land and Water Company in 1883; and served as City Engineer of Pomona, Calif., in 1887 and 1888. Mr. Taylor was engaged in public and private practice in Southern California from 1889 to 1896, and was connected with work on an irrigation project in New Mexico from 1896 to 1898. From 1899 until his death he was engaged in public works and carried on a private practice in Hawaii.

He was a member of the Honolulu Chamber of Commerce, the Honolulu Commercial Club, the Independent Order of Odd Fellows at Pomona, Calif., and the American Association of Engineers.

He was married on October 31, 1894, to Ethel May Webster, who, with a son, Thurston W. Taylor, survives him.

Mr. Taylor was elected a Member of the American Society of Civil Engineers on January 3, 1894.

* Memoir prepared by Charles H. Kluegel, M. Am. Soc. C. E.

TOBIAS TONNESEN, M. Am. Soc. C. E.*

DIED FEBRUARY 22, 1925

Tobias Tönnesen, the son of the Captain of the Harbor of Mandal, Norway, was born in Mandal on January 10, 1867.

After finishing school at home, he went at the age of 18 to Gothenburg, Sweden, to study engineering at the Chalmerska Institut of Technology. In his veins, however, ran the blood of the old Vikings and, in 1887, he left the Institute to embark for the United States and eventually landed at New York, N. Y.

At first he found it difficult to secure a position to his liking, but he finally succeeded in obtaining employment in a bridge shop, where he painted bridge girders. Not long afterward Mr. Tönnesen was promoted to a position in the Designing Department as a Draftsman.

In 1889 he went West, where he held several positions, first in the City Engineer's Office in Seattle, Wash., and, later, as a Topographer and Instrumentman on the Great Northern System. Subsequently, he became Assistant Engineer on the Everett and Monte Christo Railway; the California Midland Railroad, at San Francisco, Calif., and the San Francisco and Great Salt Lake Railroad. Mr. Tönnesen was also employed on irrigation and municipal work in the State of Washington; with the Nelson and Fort Sheppard Railroad, at Nelson, B. C., Canada; with the Great Northern Railroad; and also on the Portland, Ore., Water-Works.

Leaving the Northwest, Mr. Tönnesen went, in 1895, to Guatemala where he was engaged as an Assistant Engineer on the Ferro Carril Verapaz, Ferro Carril del Norte, and Ferro Carril Central. While thus employed he decided that it would be to his advantage to complete his theoretical knowledge of engineering and, therefore, he returned to Gothenburg in 1897 to enter again the Chalmerska Institut of Technology, from which he was graduated in 1899.

During his stay in Guatemala, Mr. Tönnesen had made the acquaintance of the owner of large coffee plantations, a Norwegian, Carlo Z. Thomsen, a resident of Hamburg, Germany, who introduced him to members of the large German Company, Otavi Minen und Eisenbahngesellschaft, of Berlin. This firm engaged him as a Consulting Engineer during the construction of its 350-mile narrow-gauge railway (0.60 m.) called the Otavi Railway, in South-West Africa, at the time the longest narrow-gauge railway in the world. The actual work was started in 1903, and was completed as far as the Tsumeb Copper Mine in 1906. During this period the Germans were at war with the Hereros.

On this railway Mr. Tönnesen had an opportunity to show his great ability and experience in railway construction. It was not only the longest, but also the most carefully constructed narrow-gauge railway in the world and

* Memoir prepared by H. S. Hanssen, Esq., Marseilles, France.

gained wide renown. The contractors were Arthur Koppel and Company, of Berlin, which firm was also in charge of the location of the railway.

After the completion of the Otavi Railway, Mr. Tönnesen was engaged in 1907 as General Manager to the South-West Africa Company, Limited, of London, England, for its large estates and mining properties at Grootfontein in the northern part of South-West Africa. With the exception of a few years spent in Norway during the World War, when he was interested in mining in Sweden, he remained in this position until his death.

While in South-West Africa Mr. Tönnesen made numerous expeditions to its northern part to investigate the country, which was little known to white men, and he lectured on these expeditions and on the country before the Royal Geographical Society, London, to a large audience. On one of his trips he penetrated into Portuguese Angola, where he contracted sleeping sickness which ultimately caused his death. He died on shipboard on his way to his home in Oslo, Norway, on February 22, 1925, and was buried at sea. He is survived by his wife and two children, who live in Oslo.

As a memorial to him the South-West Africa Company, Limited, has erected at Grootfontein, a bronze bust, which stands on a 6-ft. base of Norwegian Laborador syenite. The bust was made by a young Norwegian artist.

Mr. Tönnesen was a real man, of strong opinions and principles, who did not hesitate to fight for what he thought to be right. He was unusually energetic and industrious, never sparing himself. He was gifted with common sense and had a wide, practical knowledge for which he was probably indebted to his experience in the United States, a country which he admired and often mentioned.

In addition to being the recipient of the Royal Norwegian Order of St. Olav, Mr. Tönnesen was also decorated with the Prussian Order of the Red Eagle for his services rendered in the construction of the Otavi Railway in South-West Africa.

Mr. Tönnesen was elected a Member of the American Society of Civil Engineers on May 1, 1901.

SAMUEL WHINERY, M. Am. Soc. C. E.*

DIED JANUARY 14, 1925.

By the death of Samuel Whinery, at East Orange, N. J., on January 14, 1925, the Society lost one of its oldest and most distinguished members, and the profession lost one of its notable and patriotic figures, one whose devotion to its highest ideals will ever stand as a shining example for its younger members.

Samuel Whinery, the son of Robert W. and Susan (Enlow) Whinery, was born near Salem, Ohio, on November 20, 1845. In 1853, the family moved to a farm in Jennings County, Indiana, where young Samuel attended the public schools. Later, he attended the Friends' School near Salem, Ind., and continued his education by two terms at Indiana University.

Between the ages of eighteen and twenty-one, he taught in the county schools. During this period he devoted all his leisure time to systematic study, especially of Civil Engineering. It was in this wise that young Whinery obtained that firm and solid foundation upon which his great scientific and engineering career was built. One must pause to compare the very limited opportunity then afforded for professional education in the Middle West with its present-day colleges and universities equipped with large, highly trained and experienced staffs. Can one gainsay that young Whinery, with only a few textbooks and no teachers, but with a studious inclination, a character formed upon the simple and strong faith of the Friends, the mental solitude of a sparsely settled country, reached a professional goal that is seldom equalled by those fortunate enough to have the advantages of a modern technical education?

About 1868, the Indianapolis and Vincennes Railroad was being promoted to develop the part of Indiana in which Mr. Whinery lived. When the locating party took the field, he joined it, and thus gained his first experience, interest, and apprenticeship in railroad engineering. Within a year (1868), he became Resident Engineer in charge of construction on a 13-mile section of this road.

In 1869, he was appointed Resident Engineer of Construction on the Indianapolis and St. Louis Railroad at Terre Haute, Ind. Following the completion of his residency, he built the railroad shops at Mattoon, Ill., and was then appointed First Assistant Engineer on the location and construction of the Cincinnati, Rockport and Southwestern Railroad in Southern Indiana, on which he was engaged for two years.

In 1873, he accepted a position with the Cincinnati Southern Railroad, notable then as now as being an enterprise built and owned by the City of Cincinnati, Ohio. The survey of this railroad was a distinct advance in the location of railroads. The theory of the economics of railway location was used throughout in the far-sighted policy of its Engineering Staff of which Mr. Whinery was an influential member, the Chief Engineer having been the late L. G. F. Bouscaren, M. Am. Soc. C. E. After the completion of the loca-

* Memoir prepared by Frederic Molitor, M. Am. Soc. C. E.

tion, Mr. Whinery had charge of a residency and finally was made Division Engineer in charge of the Chattanooga Division. Thus, at thirty years of age, Samuel Whinery had local charge and the responsibility of the heavy construction of this Division.

Upon the completion of the Cincinnati Southern Railroad, in 1878, Mr. Whinery was induced to accept a position as Civilian Assistant Engineer in charge of the Muscle Shoals Improvement of the Tennessee River. In this position, his experience in charge of railroad construction, his executive ability, and his diplomatic talents were of inestimable value to the officers of the Corps of Engineers, U. S. Army.

In 1881, his services were again sought by railroad companies. He was offered and accepted the charge of the location and construction of the Northern Division of the New Orleans and Northeastern Railroad. During the first year of its operation he acted as Superintendent, and it was at this time that the telephone was first used in train dispatching. Mr. Whinery early had seen the many advantages of this new invention, and, consequently, made use of it during the construction stages of the work. When train service was inaugurated, its use was continued as the means of communication between dispatchers and train crews, and he, therefore, was the first to use the telephone for this purpose.

In 1884, the first period of Mr. Whinery's career ended. Upon the location and construction of railroads he had served his apprenticeship in practical engineering and had risen to responsible charge of work. His services and fidelity had been of the greatest aid to his chiefs, his talents had impressed the profession, and his administrative ability had been established. In short, he had acquired that firm basis which qualified him to "go on his own" as a consultant in private practice. For the following three years his work was in the South and he executed many important commissions of varied character, which called for a broad knowledge of engineering. His most important achievement during this period was the design and construction of the Incline Railroad up Lookout Mountain, at Chattanooga, Tenn., rising 1 200 ft. in less than 1 mile.

In 1887, he received a flattering offer from the Warren-Scharff Asphalt Company to direct its installations. For one year, he served as Assistant Manager in charge of its road pavements and engineering work. Here his professional talents found a large field of usefulness in the growing public demands for better streets, and highways. At the end of a year he was appointed Vice-President and General Manager of the Company, which position he held for twelve years (serving as President for the last six months), or until the Company was merged with the "Asphalt Trust".

Notwithstanding the responsibilities of his office with this Company, Mr. Whinery managed to be of service in other fields of engineering. Among other activities, he served as a member of the Engineering Commission to investigate a new water supply for the City of Cincinnati (1896-97), and as President of the Water Commission of Wyoming, a suburb of Cincinnati. In these undertakings his researches and studies again showed his great power of analysis,

and his sometimes new and always advanced professional ideas. His conclusions have long since been proved correct.

In March, 1901, Mr. Whinery opened an office in New York, N. Y. He had not become known to the general public, but his professional standing among his associates had placed him among the leaders of engineering thought and accomplishment. He practiced in New York, with marked success, for twenty-two years, retiring in 1923, with fifty-five years of active professional work to his credit and to the good of his clients and the public.

Among the many important works with which he was identified or directed during this last epoch of his career were the following: Reports (1903) on the transportation problems of New York, and on the extension of the pierhead lines in the North River; Consulting Engineer to the Finance Commission of Boston, Mass.; Consulting Engineer (1907-08) to the Commission on City Expenditures of Chicago, Ill.; Consulting Engineer (1905) to the President of the Borough of Manhattan, New York; Chairman of the New Jersey Commission to re-appraise railroads and canals; President of the Water Commission of East Orange, N. J.; report on the elimination of railroad grade crossings, at East Orange. He also assisted Gustav Lindenthal, M. Am. Soc. C. E., in research work in connection with some of the details of the famous New York Connecting Railroad Bridge over Hell Gate.

Although beyond the age of military service at the time of the World War, Mr. Whinery offered his services, and was placed by the U. S. Navy Department on the Reserve Officers' Examining Board of the Bureau of Yards and Docks. He spent an arduous term in the civil side of prosecuting the war. His ready and patriotic encouragement was extended to those emergency Engineer Officers who were in active service. The writer cherishes the simple and beautiful words he had from Mr. Whinery, both on leaving for active service in France and on his return. In a word, Mr. Whinery was a patriot and a militant Quaker during the country's experience in the World War.

He was always an advocate of the Engineer taking his part in public affairs, and lending his experience and advice to the proper solution of public questions, where engineering and economics were factors. His was not a passive part; on the contrary he gave liberally of his time and vast experience as evidenced by the fact that for many years he was Chairman of the Committee of Engineering and Sanitation of the Merchants' Association of New York. He also served for several years as President of the Board of Education of East Orange.

His active interest in engineering education in this country, particularly for a broader and better curriculum, led the Universities of Cincinnati, Illinois, and Cornell to invite him to lecture before their engineering students.

Many of the older members of the Society feel that Mr. Whinery's best example to the younger members, and one of his leading contributions to the profession, was expressed in his determined and devoted stand for an established Code of Ethics. The writer believes that it is largely, if not wholly, due to Mr. Whinery that professional conscience was awakened on this sub-

ject. At least, it is believed that he was the first to bring the subject before the profession in an explanatory and constructive way.

On his retirement from the Presidency of the Cincinnati Engineers' Club at the Annual Meeting on December 15, 1892, the subject of his address was "Ethics of Civil Engineers", and this exhaustive and constructive paper has been preserved to the profession.* It is worthy to be read by every engineer, because even now, after all the engineering societies have finally adopted Codes, it will be found that few of them have neglected at least some of his early suggestions. In this able address, Mr. Whinery refers to ethics as "being the science of right conduct". Can it be better expressed? Then, again, he said: "Such a code must be built up along the lines of the system of morals, which is universally recognized as the outgrowth and sequence of the Ten Commandments". Could the construction of a code of ethics be builded on a firmer or safer foundation? And, further, he said: "No class of men has the moral right to set up itself a standard of conduct, which, however, advantageous it may be for their selfish ends, shall disregard the rights and courtesies due to those who are not members of their particular calling". Could there be a better interpretation? He said, also: "It is feared that civil engineers are sometimes remiss in that scrupulous regard for the rights and reputations of their professional brethren, which is so carefully observed in other professions". Did he then speak wrongly? Is this statement not as true to-day as it was in 1893?

The duty of the engineer to the public as then expressed by Mr. Whinery is as follows:

"The engineer owes to the public his earnest services as a good citizen in the highest sense that the word implies. He has no right to neglect his share of those political and social duties which fall to the lot of every patriotic citizen. It is a fact frequently remarked that the civil engineer of the better class is not often found in the ranks of the leaders of civic and social life".

This seems unhappily as true to-day as when Mr. Whinery made the statement thirty-two years ago. It was these sentiments that Mr. Whinery spoke among his associates and professional friends. They bore fruit when in June, 1911, the American Institute of Consulting Engineers adopted a Code of Ethics (the first engineering code in the United States, it is believed), prepared by a committee of which the late John F. Wallace, Past-President, Am. Soc. C. E., was Chairman. As a member of this Committee the writer can now testify that Mr. Whinery's address of December, 1892, was one of the guiding factors in its preparation. His influence was doubtless again felt when, on September 2, 1914, the Society adopted a Code of Ethics.

From 1915 to 1922, Mr. Whinery was Chairman of the Committee on Professional Practice and Ethics of the American Institute of Consulting Engineers. During this time the Committee passed upon many cases of the Institute's Code and upon interpretations of it. His work was accomplished so splendidly and carefully that the Institute in 1923, upon his retirement from this important office, named him Chairman Emeritus. He continued to give

* *Engineering News*, January 26, 1893.

valuable advice to the Committee, notwithstanding his increasing years. Only a short time before his death he stated that he felt his life work would be incomplete until the Engineering Profession had adopted a Code of Ethics, and it was his hope that engineers would abide by it as the medical and legal professions have done.

Mr. Whinery was the author of "Municipal Public Works" (1903), and of "Specifications for Pavements and Roads". He also contributed largely to the publications of various professional societies and to technical magazines.

He was a Charter Member of the American Institute of Consulting Engineers (1910) and served on its Council in 1916, and from 1919 to 1921, and was also Vice-President for two years, 1920 and 1921. He was also a member of the American Society of Mechanical Engineers, American Institute of Mining and Metallurgical Engineers, American Public Health Association, and the American Academy of Political and Social Science.

Mr. Whinery was married on November 10, 1875, to Elizabeth A. Crawford, daughter of John Crawford, of Somerset, Ky. Besides his widow, he is survived by the following children: Samuel Brent Whinery, an engineer, Charles C. Whinery, Maurice R. Whinery, Andrew J. Whinery, a lawyer, John E. Whinery, and a daughter, Elizabeth Whinery. For the last twenty years of his life, he resided in East Orange, N. J.

It is by the wide variety of his professional work, the detailed research and analyses of his conclusions, and the thoughtful expression of his reports that his professional career is best measured, marking him as outstanding on the long roll of membership in the Society.

This memoir may best be concluded by a statement of Mr. Whinery's worth as a man and as an engineer, contributed by one of the leaders of the profession and one whose gift of expression is so well known and appreciated, William J. Wilgus, M. Am. Soc. C. E.:

"I had for him a rare combination of affection for his lovable qualities and respect for his professional attainments and judicial character. In fact, his sweetness of disposition, ability as an engineer, and devotion to the highest ideals of our calling, marked him as a man out of the ordinary, whose passing from our midst leaves a niche that will be most difficult, if not impossible, to fill. At least, he is enshrined in our memory as one whose example we should all aspire to follow".

Mr. Whinery was elected a Junior of the American Society of Civil Engineers on April 1, 1874, and a Member on May 4, 1881. He also served on the Board of Direction in 1891 and from 1899 to 1901, and as Vice-President in 1892 and 1893.

CHARLES SUMNER WILLIAMSON, M. Am. Soc. C. E.*

DIED MARCH 31, 1923.

Charles Sumner Williamson was born at Cleveland, Ohio, on April 12, 1874, the son of Samuel Williamson and Stella E. (Sumner) Williamson. His mother was a direct descendant of Increase Sumner, one of the early Governors of the State of Massachusetts. His father also came from a long line of Colonial families in the United States.

Following his preparatory education in the public schools of Cleveland, Mr. Williamson received his technical and engineering training in the Case School of Applied Science, from which he received the degree of Bachelor of Science in 1895 and that of Civil Engineer in 1898.

From 1894 to 1895, he worked in the office of a local Civil Engineer. From 1896 to 1898, he was in the employ of the King Bridge Company and the Variety Iron Works of Cleveland. Except for this minor work, Mr. Williamson was employed in the hoisting and conveying machinery business throughout all his comparatively brief career. One of his earlier engagements was with the Brown Hoisting Machinery Company of Cleveland, with which he served, successively, as Draftsman, Squad Foreman, and Designing and Erecting Engineer, his work having to do with the design and installation of car dumpers for transferring coal from railroad cars to Lake vessels, ore and coal-handling bridges, and other special types of material-handling equipment.

Following this period with the Brown Hoisting Machinery Company, covering the principal part of the time from 1895 to 1904, he was made Contracting Sales Engineer of Heyl and Patterson, Incorporated, of Pittsburgh, Pa., which position he held for seven years. In this capacity Mr. Williamson played an important part in establishing and building up the ore and coal-handling machinery department, which specialized in the development, production, and installation, at the Lake coal and ore docks and at blast furnaces, of ore and coal-handling equipment of the bridge and hoisting tower type.

In 1911, he became associated with the Mead-Morrison Manufacturing Company, Constructing Engineers, of Boston, Mass., as Western Manager, with headquarters at Chicago, Ill., his duties being those of Managing and Contracting Engineer for iron ore and coal-handling machinery. He was later promoted to be Vice-President, still retaining charge of the Western District, and remained with the company in this capacity until he was compelled to retire from active business on account of ill-health. While with the Mead-Morrison Company, Mr. Williamson's activities were not limited to America, but extended to Europe and Australia.

Mr. Williamson was fortunate during his early practical experience, while with the Brown Hoisting Machinery Company, in being brought in contact

* Memoir prepared by a Committee consisting of G. H. Hutchinson, *Chairman*, W. H. Hoyt, J. N. Hatch, and William S. Monroe, Members Am. Soc. C. E., and Messrs. A. M. Merriweather and C. C. Brooks.

with Mr. Alex E. Brown, the pioneer in the development and introduction of the mechanical handling of materials, a man of remarkable personality, whose clear vision, inventive genius, indomitable will, and persistent effort had much to do in making possible the world supremacy of the Great Lakes, in the handling and transportation of bulk cargo material.

Although the pioneering work had been done, and much accomplished in the line of the mechanical handling of bulk materials before Mr. Williamson entered the field, he had been intimately associated with the progress made in the previous twenty-five years. His activities covered the entire period of development of the more modern type of material-handling equipment. Various improvements in mechanical detail and in methods of material handling stand to his credit, some of which he protected by letters patent.

Mr. Williamson was a great lover of fine horses and possessed several prize winners.

On August 14, 1914, he was married to Grace Elizabeth Meigs, of Madison, Wis., who, with one child, survives him.

Mr. Williamson was elected an Associate Member of the American Society of Civil Engineers on February 7, 1906, and a Member on October 31, 1911.

FREDERIC IRVING WINSLOW, M. Am. Soc. C. E.*

DIED FEBRUARY 21, 1924.

Frederic Irving Winslow was born at New Bedford, Mass., on January 30, 1863, the son of George William and Jane Lucretia (Southwick) Winslow.

He received his early education in private and public schools with one year in High School. In 1877, he removed to Boston and attended the English High School from which he was graduated in 1881, having received the Lawrence Prize and the Franklin Medal. Subsequently, he was graduated from the four-year course in Mechanical Design in the South Boston School of Art.

Mr. Winslow's first position was in the City Surveyor's office at Boston, in 1881, and he continued in the employ of that city for about thirty-eight years. At first, he was engaged in surveys and, later, entered the City Engineer's office as Transitman in the Water Department and from 1885 to 1911 was Senior Assistant Engineer of the Boston Water-Works. From 1911 to 1916, he served as Engineer in charge of all the extension work, and then became Assistant Engineer on street construction for the City. From October, 1917, to August, 1918, he held the position of Supervising Engineer in charge of the office and the construction at the Squantum Destroyer Plant for the United States Navy Department.

From April, 1919, until his death, Mr. Winslow was Division Engineer of the Sudbury Department of the Metropolitan Water-Works, stationed at Framingham, Mass., and also carried on a consulting practice.

His specialties were hydraulics and water-works. Among his other accomplishments are the extension of water service to Long Island, Boston Harbor; the design and construction of Deer Island Reservoir; and the design and construction of two tunnels in compressed air.

Mr. Winslow was the author of numerous papers on engineering topics, which appeared chiefly in *Engineering News,* for which he was for a short time Boston correspondent, in the *Journal* of the New England Water Works Association, and in the *Harvard Engineering Journal;* and of a chronology of the Boston Water-Works (1912).

He was a member of the Boston Society of Civil Engineers from 1885, having served as Librarian from 1907 to 1913, of the New England Water Works Association from 1892 (he had been Treasurer from 1922 until his death), of the American Water Works Association, of the Boston Congregational Club, and of the Royal Arcanum. He was a Republican in his political affiliations.

Mr. Winslow was married on June 15, 1892, to Myrtle S. Smith, of South Newbury, Ohio, who survives him, with their son, Irving H. Winslow.

* Memoir prepared by John C. Chase, M. Am. Soc. C. E., and Charles W. Banks, Assoc. M. Am. Soc. C. E.

His death occurred at his home in Framingham on February 21, 1924, after an illness of only a few days.

He was a great student, making a practice to read about two hundred volumes annually for many years. He was a frequent attendant at engineering meetings in Boston and had a wide acquaintance. He was a genial, companionable man, highly esteemed by all who knew him—one whose passing has left a noticeably vacant place, and whose memory will long be cherished by his many friends.

Mr. Winslow was elected a Member of the American Society of Civil Engineers on May 6, 1914, and was a Charter Member of the Northeastern Section of the Society. During the last year of his life he had rendered the Society valuable service in the preparation of memoirs of a number of New England members for whom none had ever been written.

JOHN ROSS CHAMBERLIN, Assoc. M. Am. Soc. C. E.*

DIED DECEMBER 15, 1925

John Ross Chamberlin was born in Rochester, Ohio, on March 15, 1876. He was the son of Dr. Charles S. Chamberlin, a practicing physician, who died when John was five years of age. His mother, Mrs. Tillie (Kisinger) Chamberlin, is still living.

Mr. Chamberlin received his early education in district schools and worked on the farm during vacations. When he was seventeen years of age the family moved to Tiffin, Ohio, and he entered the Academy of Heidelberg University in the fall of 1894. During the summer months he worked for the County Engineer, Mr. Charles J. Peters, and it was here that he acquired his first knowledge and experience as a civil engineer. In the fall of 1898, he entered the Ohio State University where he remained until April, 1902. He then withdrew from the University and went to Peru where he spent a year with the Engineering Corps in charge of the construction of the Cerro de Pasco Railway.

On his return to the United States in 1903, Mr. Chamberlin accepted a position with the Baltimore and Ohio Railroad, with headquarters at Baltimore, Md. In the fall of 1905, he returned to the Ohio State University as Instructor in Civil Engineering, and was, successively, Instructor and Assistant Professor of Civil Engineering until 1912. He was graduated from the Ohio State University with the degree of Civil Engineer as of the Class of 1902.

In 1912, he was appointed Division Engineer in the Bureau of Bridges of the Ohio State Highway Department, and, in 1913, Chief Engineer of Bridges, in which capacity he served until 1919.

During this time Mr. Chamberlin was quite active in the study of the economics of highway bridge construction, and several *Bulletins* pertaining to bridge and pavement design were published by the Highway Department under his direction. In 1915 to 1918 he made a study of highway bridge specifications and, in 1918, the specification for highway structures of the Ohio State Highway Department was published. Many new and important provisions in this specification, especially with reference to reinforced concrete floors, and the determination of the required waterway for bridges, were the work of Mr. Chamberlin.

In October, 1919, he received an appointment as Senior Highway Bridge Engineer in the United States Bureau of Public Roads and spent a year in Washington, D. C. He was then transferred to District No. 5 at Omaha, Nebr., where he served until his death.

He was married in 1907 to Ada Maurer, of Chillicothe, Ohio, who, with five children, two sons and three daughters, survives him.

* Memoir prepared by Clyde T. Morris, M. Am. Soc. C. E.

Mr. Chamberlin was appointed a member of the Special Committee on Concrete and Reinforced Concrete Arches of the Society in May, 1923. On learning of his death the following minute was signed by all the members of the Committee and sent to the Board of Direction:

"It was with deep regret that we, the members of the Committee on Concrete and Reinforced Concrete Arches of the American Society of Civil Engineers, learned of the death of John R. Chamberlin.

"Mr. Chamberlin was appointed on the Committee in May, 1923, and was a faithful and interested participant in its work until his death. He brought a wealth of good judgment and wise counsel to our work and his quiet courteous manner and lovable disposition endeared him to all.

"We feel keenly the loss of his good counsel in our proceedings and of his genial presence, and wish to express our sorrow at his loss, and our sympathy to his family which has lost a kind and loving father.

"(Signed) W. M. Wilson,
Geo. E. Beggs,
E. H. Harder,
A. C. Janni,
Clyde T. Morris."

Mr. Chamberlin was elected an Associate Member of the American Society of Civil Engineers on May 6, 1914.

JOHN STERLING DEANS, Assoc. M. Am. Soc. C. E.*

DIED AUGUST 18, 1924.

John Sterling Deans, the son of the late John Sterling Deans, M. Am. Soc. C. E., and Clara Barr Deans, was born in Phœnixville, Pa., on July 5, 1891. His father was for many years prominently connected with the Phoenix Bridge Company of Phœnixville, as Vice-President and Consulting Engineer.

Mr. Deans received his degree of Bachelor of Philosophy from the Sheffield Scientific School in 1912, and was in the employ of the Pennsylvania Railroad Company from 1912 to 1916, first, in the Construction Department and, later, in the Maintenance-of-Way Department.

From 1916 to 1917, he was connected with the National Aniline and Chemical Company as Superintendent of Engineering Construction of the Abbott Road Plant at Buffalo, N. Y.

Mr. Deans enlisted in the Ordnance Corps of the United States Army, and was commissioned a First Lieutenant on October 5, 1917, and assigned to the Construction Section of the Supply Division at Washington, D. C., where he was in charge of the design of railroad and civil engineering work. He was promoted to the rank of Captain in June, 1918, and in the following September was sent to France. There he was assigned to the Construction and Maintenance Division of the Ordnance Department.

Mr. Deans was honorably discharged from the Army in January, 1919, and then entered the construction business as General Superintendent for the J. N. Byers and Son, Incorporated, of Buffalo. At the time of his death, he was Secretary of the firm.

He was married in 1916 to Harriet Gertrude Byers, a sister of Mr. J. Newton Byers. Mrs. Deans survives him, with a son and two daughters; he also leaves his mother, brother, and two sisters.

Mr. Deans was elected an Associate Member of the American Society of Civil Engineers on September 9, 1919.

* Memoir prepared by Emile Low, M. Am. Soc. C. E.

RAYMON EDGAR FULCHER, Assoc. M. Am. Soc. C. E.*

DIED JULY 14, 1925.

Raymon Edgar Fulcher was born at Jackson, Calif., on August 4, 1879. His early education was received in the public schools and High School of Oakland, Calif. During vacations and at other times until he was nineteen years of age, he was engaged in and about the gold mines and ore-dressing plants of the Mother Lode District of California, with his uncle, Wilton E. Darrow, and it was after this experience that his leaning toward an engineering career developed and became the most prominent factor in his life's work. Mr. Fulcher was largely self-educated in engineering, having been a keen observer and a persistent reader and student of technical civil engineering literature.

In 1904, he passed an examination at Sacramento, Calif., and was appointed Deputy County Surveyor of Tuolumne County, California. He also served as Deputy United States Mineral Surveyor and was engaged in underground mine surveying on the Mother Lode Mines in the vicinity of Sonora, Calif.

Mr. Fulcher's work as an engineer was varied in character, embracing mining, railroad engineering, tunnel construction, road work, earth-fill dams, rock-fill dams with concrete face, high-tension transmission-line construction, pumping plants, electric car lines, and oil pipe-line construction. As a result of his experience in mining and kindred activities he examined and reported on many mining properties and oil prospects in California, and, later, in Arizona.

In 1905, Mr. Fulcher was engaged by Sanderson and Porter as Field and Construction Engineer on work for the Stanislaus Electric Power Company, in California, which included the location of a construction railroad, flume and dams, and new road work and transmission lines. In 1911, he built an electric car line between the towns of Raymond and Southbend, Wash., on Willapa Harbor. He continued with Sanderson and Porter on hydro-electric development construction in British Columbia and Vancouver and on a pumping plant at Burbank, Wash., until 1914, when he was appointed Field Engineer in charge of the construction of the Valley Oil Pipe Line, extending 170 miles from Coalinga to Martinez, Calif., on the Bay of San Francisco.

From 1916, until the summer of 1918, Mr. Fulcher was engaged in a similar capacity on the construction of an oil pipe line across the States of Oklahoma and Missouri, terminating on the east bank of the Mississippi River in Illinois, a few miles above St. Louis, Mo. The crowning achievement of his career as an Engineer was probably the laying of this pipe line across the Mississippi, which was an important link in supplying fuel oil to the Allied fleets during the latter period of the World War.

During this work, which was continued without interruption through the excessively cold winter of 1917-18, Mr. Fulcher contracted pneumonia, which made it necessary for him later to live in Tucson, Ariz. While there, he acted as Engineer in charge of the installation of a 1 000-h.p. Diesel engine electric

* Memoir prepared by Wynne Meredith, M. Am. Soc. C. E.

unit for the Tucson Gas, Electric Light, and Power Company. He then engaged in building construction and general engineering practice, and, later, specialized in roofing and roof covering, developing a successful business of which he was in charge at the time of his death. He died on July 14, 1925, at Phœnix, Ariz., of bronchial pneumonia, caused by the extreme heat.

Mr. Fulcher was married on March 8, 1901, to Blanche E. Divoll, of Sonora, Calif. His widow and three daughters survive him.

As an engineer of ability, Mr. Fulcher combined with his technical attainments, an open mind, executive qualities, and a winning personality. To his more intimate friends he will be remembered for his modest ways, his fine sense of humor, and those rare qualities of mind and heart that so endeared him to all with whom he came in contact.

Mr. Fulcher was elected an Associate Member of the American Society of Civil Engineers on March 4, 1913.

JOHN STANTON GOODELL, Assoc. M. Am. Soc. C. E.*

DIED NOVEMBER 13, 1925

John Stanton Goodell was born at Amherst, Mass., on January 20, 1875. He was the elder son of the late Henry Hill Goodell, formerly President of the Massachusetts Agricultural College, and Helen Stanton Goodell. He was descended from Puritan ancestors, the first of the family to come to America having been Robert Goodale who settled in Salem, Mass., in 1634. Eighty or more members of the family spelling the name either "Goodale" or "Goodell" served in the Revolutionary War.

Mr. Goodell received his education at the Massachusetts Agricultural College, at Amherst, and, later, at the Rensselaer Polytechnic Institute, Troy, N. Y., where he completed his course in Civil Engineering.

From March 1, 1899, until February, 1908, he was connected with the Gulf, Colorado and Santa Fé Railway Company, in Texas, as Chainman, Rodman, Instrumentman, Levelman, and Transitman on locations at different times. He also served as Assistant Engineer on the Northern Division of the railway, under F. Merritt, Division Engineer, at Clebourne, Tex., and as Office Engineer under C. F. W. Felt, M. Am. Soc. C. E., Chief Engineer, at Galveston, Tex.

In February, 1908, Mr. Goodell resigned, to accept a position with The Kwong Tung Yueh-Han Railway Company, Limited, at Canton, China, serving as Principal Assistant Engineer and, later, until August, 1910, as Engineer of Maintenance of Way, under the late Sir Chentung Liang Cheng, former Ambassador to the United States, who at that time was President of the Company.

From August, 1910, to October, 1911, he was engaged in private practice at Amherst, Mass., principally on land surveys, work on sewer lines, replacing lost highway monuments, etc. From October, 1911, to July, 1916, Mr. Goodell served as Manager of a rubber plantation in Nahiku, Island of Maui, Hawaii, and from July, 1916, to September, 1921, he was employed as Assistant Engineer in the Construction Department of the Atchison, Topeka and Santa Fé Railway Company, under C. F. W. Felt, Chief Engineer, at Chicago, Ill.

While in this position Mr. Goodell was engaged in checking estimates for proposed construction work in Missouri and later was in charge of a field office at Brunswick, Mo., where estimates, location and right-of-way maps, profiles, plans for the elimination of highway grade crossings, etc., were made for a proposed line from Standish to Moberly, Mo.

From July 21, 1917, to June 1, 1921, he was in charge of the construction of the Barton County and Santa Fé Railway from Holyrood to Galatia, Kans. On the completion of this work he returned to Amherst, Mass., where he engaged in private practice, continuing in this work until 1924 when his health became impaired.

* Memoir compiled from information on file at the Headquarters of the Society.

Mr. Goodell was married on May 29, 1906, to Edith Friese, at Galveston, Tex., who survives him. He is also survived by his mother, Mrs. Helen S. Goodell, of Amherst, Mass., and a brother, Dr. William Goodell, of Springfield, Mass.

Mr. Goodell was elected an Associate Member of the American Society of Civil Engineers on March 7, 1906. He was also a member of the American Railway Engineering Association.

ROBERT HUGH McNEILLY, Assoc. M. Am. Soc. C. E.*

DIED MAY 8, 1925.

Robert Hugh McNeilly was born on September 30, 1879, near Hustonville, Lincoln County, Ky. His father was Dr. James H. McNeilly, a Presbyterian minister and a former Captain and Chaplain in the Confederate Army. His mother was Mary Weatherford McNeilly.

Mr. McNeilly received his engineering education at Vanderbilt University, Nashville, Tenn., from which he was graduated with the degree of Bachelor in Engineering, in 1902 (conferred in 1908). He received the degree of Civil Engineer from the University in 1915.

He was employed as a Draftsman in the Ordnance Department, United States Army, until 1904. From 1904 to 1905 he was Constructing Engineer for several water supply and hydro-electric plants in Tennessee and Mississippi, and from 1905 to 1906, he was Assistant Professor of Civil Engineering at the University of Mississippi, after which he was again employed by the U. S. Army in the capacity of Engineer and Superintendent of Construction on the Columbus, Ohio, Barracks from 1906 to 1907. During 1907, he held the position of Assistant Engineer for the Muscle Shoals Hydro-Electric Power Company.

From 1907 until his death, Professor McNeilly was a member of the Engineering Faculty at Vanderbilt University and during that time he also conducted a private engineering practice.

It was in his capacity as a teacher that Professor McNeilly accomplished most for his students and friends. He had a singularly happy and cheerful disposition, was efficient, earnest, and just, and always ready to help in any task or problem where he might be needed. He was the moving spirit in the organization of the Student Chapter of the Society at Vanderbilt University, which has been named the Robert H. McNeilly Chapter in honor of him.

Professor McNeilly was drowned in the *Norman* tragedy in the Mississippi River, near Memphis, Tenn., on May 8, 1925. He was married to Marian Brown Stockell on June 8, 1904, and is survived by Mrs. McNeilly and a son, Stockell McNeilly.

In his address at the memorial services to the Vanderbilt University Alumni who perished in this disaster, Chancellor Kirkland said with respect to Professor McNeilly: "He helped lift the burdens of others. He did not put his burdens on you."

Professor McNeilly was elected an Associate Member of the American Society of Civil Engineers on November 26, 1923. He was also a member of the Engineering Association of Nashville.

* Memoir prepared by Hunter McDonald, Past-President, Am. Soc. C. E., and L. R. Currey, Jr., Assoc. M. Am. Soc. C. E.

RICHARD EDWARD PHILLIPS, Assoc. M. Am. Soc. C. E.*

DIED AUGUST 8, 1925.

Richard Edward Phillips was born in Lockport, N. Y., on November 23, 1880, and while still in his early youth moved to Buffalo, N. Y. At the age of seventeen he terminated his attendance at High School and started his engineering career in the employ of Mr. Henry L. Lyon, a civil engineer, engaged in lot surveying.

In 1899, Mr. Phillips entered the employ of the New York Central Railroad Company at Depew, N. Y. It was in the shops of this Company that he acquired a knowledge of practical mechanics.

In 1902, he accepted an appointment as Chainman in the Engineering Department of the State of New York. At that time the State was extensively engaged in work on the Barge Canal and highways preliminary to the large scale construction which later was undertaken. Mr. Phillips was engaged in highway work for about a year when he was transferred to work on the Barge Canal, with which he was identified for the remainder of his life.

He rose in the Department of the State Engineer and Surveyor from Chainman to Supervising Engineer, and for some years prior to his death held the title of Engineer of Claims. Until the Barge Canal was completed, he was actively engaged in the design and supervision of important features of that project. Later, many large damage claims resulting from extra compensation demanded by contractors and by private property and water-power owners were filed against the State. Mr. Phillips' duties consisted of the investigation and technical defense of these claims.

It was in the latter connection that he displayed his unusual ability. His exceptional knowledge of the relation of law to engineering and his information relative to the cost of construction and water power values made his services highly valuable to both the Engineering and Legal Departments of the State of New York.

Mr. Phillips' health failed about a year prior to his death and he was granted a leave of absence from his duties in the hope of effecting his recovery. All efforts toward this end were unavailing, and he died at Saranac Lake, New York, on August 8, 1925.

He was married in 1904 to Emma Christine Reed, of Albany, N. Y., by whom he is survived, with two daughters, Mrs. Louise Carey and Miss Marion Phillips.

Mr. Phillips was elected an Associate Member of the American Society of Civil Engineers on May 7, 1913.

* Memoir prepared by F. P. Williams, M. Am. Soc. C. E.

FRANK LAWRENCE SHELDON, Assoc. M. Am. Soc. C. E.*

DIED JUNE 22, 1925

Frank Lawrence Sheldon, the son of Frank Perry and Nellie (Noyes) Sheldon, was born in Providence, R. I., on August 1, 1883. He was a direct descendant of Samuel Winsor, who married Mercy Williams, a sister of Roger Williams. His father, the founder of the firm of F. P. Sheldon and Son, was a noted mill engineer, having designed and re-organized many of the most prominent textile establishments in the United States.

Mr. Sheldon's earlier education was received in the public schools of Providence, and at Riverview Military Academy, Poughkeepsie, N. Y. In 1903, he entered Rensselaer Polytechnic Institute, Troy, N. Y., as a student in Civil Engineering, but left that institution in 1905, to enter his father's employ as Resident Engineer on mill construction, his first work having been on the buildings for the Lorraine Manufacturing Company at Pawtucket, R. I.

After serving for several years in this position, he entered the office of the Company and assisted in the design of various industrial plants. In 1912, he went to Knoxville, Tenn., to represent the firm of F. P. Sheldon and Son and to supervise the building of a large mill and weave shed for the Brookside Mills, under its plans. On the completion of this construction, he again took up office work, and, at the time of his death, was second in charge of the office, planning the work for the drafting force, checking plans and computations, and assisting in textile research.

Mr. Sheldon was a member of the Rensselaer Society of Engineers and of the American Society for Testing Materials, having served on its Committee on Textile Materials, as he was familiar with textile manufacturing and had made considerable research in this art.

Having been a proficient athlete in his school days—he had been a member of the football and hockey teams at Riverview Military Academy and at Rensselaer Polytechnic Institute—he always maintained a great interest in sports and was a keen student of modern football tactics. He was also fond of boating, hunting, and fishing, being at the time of his death a member of the Rhode Island Fish and Game Protective Association. Among the fine arts, music was his greatest delight, and while at Riverview Military Academy he was a member of the Glee Club.

Mr. Sheldon died, after a brief illness, at his home in Providence, on June 22, 1925, and is survived by his widow, Mrs. Jetty L. (Wilson) Sheldon, to whom he was married on March 12, 1907, a son, Frank L., Jr., a sister, Mrs. James B. Barrett, and a brother, Arthur N. Sheldon, of the firm of E. P. Sheldon and Son.

Mr. Sheldon was elected an Associate Member of the American Society of Civil Engineers on June 6, 1921.

* Memoir prepared by Frederick H. Paulson, Jun. Am. Soc. C. E.

ALBERT FRANKLIN SICKMAN, Assoc. M. Am. Soc. C. E.*

DIED OCTOBER 17, 1925.

Albert Franklin Sickman, son of John and Martha Pomerene Sickman, was born at Snowden, Pa., on December 10, 1856. He received his technical education at the University of Pittsburgh, Pittsburgh, Pa., from which he was graduated in 1878.

In July, 1878, Mr. Sickman went to Holyoke, Mass., and entered the service of the Holyoke Water Power Company, remaining in the continuous employ of that Company until his death—a period of forty-seven years.

He went to Holyoke at the invitation of his brother, Mr. James M. Sickman, then the chief engineering member of the office force of the Holyoke Water Power Company. This organization, however, at that time, did little engineering work, being mainly engaged in giving lines and grades for new streets and in general surveying. Soon afterward, in 1879, the Company undertook the organization of a systematic control and lawful allotment to each mill owner of the quantity of water he should draw from the Company's canals—the common receptacle from which they all drew the water that was then converted into power by each mill owner.

For lack of such control and allotment, water was being largely overdrawn, wasted, and was even at work in a manner to cause the destruction of some of the canals. This called for the services of an hydraulic engineer, and, as a pupil of the late James B. Francis, Past-President, Am. Soc. C. E., of Lowell, Mass., Clemens Herschel, Past-President, Am. Soc. C. E., was chosen for this work.

Mr. Herschel went to Holyoke in 1879, and "Frank" Sickman, as he was generally called, was designated to be Mr. Herschel's first Assistant. At that time, at twenty-three years of age, Mr. Sickman was the same quiet, conscientious worker that he remained to the day of his death. He had been firmly grounded in the elements of his profession, by faithful study at the University of Pittsburgh, and Mr. Herschel takes pleasure in recalling his ready response, as a most apt pupil, to every demand made on him.

When Mr. Herschel resigned his position as Hydraulic Engineer of the Holyoke Water Power Company, in 1889, Mr. Sickman became his successor. At that time the system of charging for excess drafts of water by the mill owners, and thus keeping control of the draft by each one of them, had become firmly established, but naturally required expert continuance of the work. The far-famed Holyoke Testing Flume had been established in 1881, and called for skilled work in meeting the needs of American wheel builders. No one thing has contributed so much, probably, to the present eminent and useful state of the art of hydraulic turbine building in the United States, as the work done in this flume since its foundation, and, to a large extent, by Mr. Sickman after 1889.

* Memoir prepared by Clemens Herschel, Past-President, Am. Soc. C. E., and Robert E. Barrett, M. Am Soc. C. E.

In October, 1913, he was elected Assistant Treasurer of the Company and, in November, 1919, was also made Clerk, both of which positions he held at the time of his death.

He was a master of hydraulic problems and familiar with every detail of the history and developments of the work at Holyoke, and in his death, the Company that he had served so long and faithfully suffered an irreparable loss.

Mr. Sickman had varied interests outside his profession. He was a keen student of Nature, an authority on the New England trees, and knew every wild flower of the section, and where and when to find it.

He was always courteous and affable and his genial disposition endeared him to his associates; he was ever fair and considerate in his relations with those under him.

Mr. Sickman was twice married. His first wife died many years ago, leaving four children, all of whom survive him. In 1909, he married Margaret Griffin, of Holyoke, who also survives him.

He was a member of the New England Water Works Association and of the Engineering Society of Western Massachusetts.

Mr. Sickman was elected an Associate Member of the American Society of Civil Engineers on March 4, 1903.

NATHANIEL AUGUSTINE THAYER, Assoc. M. Am. Soc. C. E.*

DIED SEPTEMBER 10, 1925.

Nathaniel Augustine Thayer was born in South Boston, Mass., on November 4, 1880. He was the son of the late Edmond G. Thayer, a Civil Engineer and Architect of Boston, and Florence Hamilton Thayer.

Mr. Thayer was graduated from the Quincy, Mass., High School, and from the Lawrence Scientific School of Harvard University, in 1902, with the degree of Bachelor of Science. For several years after his graduation from college he was a Rodman and, later, an Instrumentman with the Cleveland, Chicago, Cincinnati, and St. Louis Railroad Company, after which, he spent a year as Structural Draftsman for J. R. Worcester and Company, Consulting Engineers, Boston, engaged in detailing and designing steel and reinforced concrete structures.

From 1906 to 1909, he served in the Bridge Engineering Department of the New York Central and Hudson River Railroad Company; as Structural Draftsman for Vielé, Blackwell, and Buck, New York, N. Y., on the design of a wooden flume and steel and wooden head-gate for water-power development at Cobalt, Ont., Canada; and as Structural Detailer on buildings for Post and McCord, and, later, for Gunvald Aus, M. Am. Soc. C. E. In 1909 and 1910, he was employed as a Structural Steel Draftsman with the New York Public Service Commission, First District, on designs for subways and elevated railways for New York City.

During the latter part of 1910 and throughout most of 1911, Mr. Thayer was engaged by the Erie Railroad Company to work on plans for the wooden dock and for a grade-crossing elimination at Youngstown, Ohio, following which, he served as Structural Steel Designer for the Board of Education, School Building Department, New York City, and also held the position of Assistant Engineer with the Board of Transportation of the City of New York, Robert Ridgway, Past-President, Am. Soc. C. E., Chief Engineer.

Through intensive study Mr. Thayer became a Certified Public Accountant in the State of New York. He undertook this work in order to be thoroughly grounded for an independent study which he was making of industrial corporation finance.

He died of pneumonia on September 10, 1925, at St. Luke's Hospital, New York City, after an illness of only four days, and is survived by his mother, Mrs. Edmond G. Thayer, of Wellesley Hills, Mass., a sister, Mrs. Raymond E. Huntington, and two brothers, Frederick G. Thayer, of Wellesley Hills, and Lucien H. Thayer, of Dorchester, Mass.

He was a member of The Harvard Engineering Society, and the Unitarian Church.

Mr. Thayer was elected a Junior of the American Society of Civil Engineers on April 5, 1910, and an Associate Member on April 2, 1912.

* Memoir prepared by Theodore Reed Kendall, Assoc. M. Am. Soc. C. E.

EDMUND BOYD ULRICH, Assoc. M. Am. Soc. C. E.*

DIED NOVEMBER 20, 1925.

Edmund Boyd Ulrich was born at Reading, Pa., on September 25, 1871 the son of Dr. Daniel and Mary (Boyd) Ulrich. He received his education in the public schools of his native city, and was graduated from High School in 1885.

Immediately after his graduation, Mr. Ulrich entered the service of William H. Dechant, Civil Engineer, and after serving successively as Rodman and Transitman for several years, accepted a position as Transitman on a railroad construction operation in North Carolina. He then returned to Reading and served as Instrumentman on the construction of the Neversink Mountain Railroad, the Mohnton and Adamstown Electric Railroad, and other local construction operations.

In 1894, Mr. Ulrich entered the employ of the City of Reading, as Transitman, attached to the City Engineer's Staff, and served in this capacity during the construction of the trunk line intercepting storm sewer and further work for the initial district of municipal sanitary sewers, including a pumping station.

In 1903, he established an engineering office, and engaged in surveying and general engineering practice until April 12, 1909, the date of his appointment to the office of City Engineer of Reading, for a term of three years. He was re-appointed to this office, successively in 1912, 1916, and 1920, serving continuously for fifteen years until May 7, 1924. Mr. Ulrich then re-established a surveying and engineering office, and in conjunction therewith served as City Engineer for Mahanoy City, Pa.

He was actively affiliated with and served as Secretary of the American Turbit (pigeon) Club. He owned select pigeons and enjoyed a National reputation as a pigeon fancier and competent judge, thus becoming a factor in promoting pigeon and poultry exhibits.

Mr. Ulrich was in ill-health for seven weeks before his death on November 20, 1925. He is survived by his widow who was Bessie Chamberlain, of Winston-Salem, N. C.

Mr. Ulrich was elected an Associate Member of the American Society of Civil Engineers on April 6, 1909.

* Memoir prepared by E. Clinton Weber, Esq., Reading, Pa.

FRANKLIN JAMES VAN HOOK, Assoc. M. Am. Soc. C. E.*

DIED JULY 26, 1925.

Franklin James Van Hook, the son of Frank and Matilda (Wallace) Van Hook, was born at Lockport, N. Y., on July 31, 1881. Prepared for college in local schools, he entered the Massachusetts Institute of Technology, and was graduated in 1906 with the degree of Bachelor of Science (in Civil Engineering).

Employment by the "Big Four" Railroad Company, at Wabash, Ind., the Charles River Basin Commission, the New York State Water Supply Commission on the Racquette River, and the Commissioners of Sewerage at Louisville, Ky., occupied the first five years of Mr. Van Hook's technical career. Later, he was engaged on grade-crossing elimination at Nashville, Tenn., for the Louisville and Nashville Railroad Company.

In 1912, Mr. Van Hook entered the service of the City of Cincinnati, Ohio, in connection with the preparation of a plan of comprehensive sewerage. In this work he made a particular study of rainfall and run-off, and outlined requirements for relief drainage. Following this engagement, he served as Resident Engineer for the Louisville and Nashville Railroad Company on the construction of the First Avenue Viaduct at Birmingham, Ala. During 1915, 1916, and 1917, he was Superintendent of Construction for the Jefferson Construction Company of New Orleans, La. In this capacity, and in addition to other work, he supervised the installation of the Warrior River steam power plant of the Alabama Power Company.

The call of the World War found Mr. Van Hook debarred from active service. His desire to help took him into cantonment construction at Camp Meigs and elsewhere for the Construction Division of the United States War Department. In 1918 and 1919 he was Field Engineer for Westinghouse, Church, Kerr and Company on the construction of the United States Government Nitrate Plant at Muscle Shoals, Ala.

He spent the period from 1919 to 1924 in Cleveland, Ohio, where he served chiefly as Designer and Estimator of industrial buildings for the Boldt Construction Company and the Sam W. Emerson Company.

In 1924, Mr. Van Hook was made General Manager of the Oil City Wood Working Manufacturing Company, Oil City, Pa., and, later, became a Director of the Company. At the time of his death, he was engaged on plans for enlarging the activities of that firm.

Mr. Van Hook was a member of the Baptist Church. He was a Mason, a Rotarian, a Director of the Western Pennsylvania Builders' Supply Association, and held membership in other organizations, both civic and social.

* Memoir prepared by Frank C. Tolles, M. Am. Soc. C. E.

He was married in 1916 to Madge Nave, of Louisville, Ky. Mrs. Van Hook and two children, Robert Wallace and Annie Laurie, survive him.

His career is typical of many who make up the profession and help to formulate and sustain its best traditions. It is a career which subordinates self in loyal devotion to the interests of employer or client. Mr. Van Hook was such an engineer. His abilities were not inconsiderable. His life was useful.

Mr. Van Hook was elected an Associate Member of the American Society of Civil Engineers on May 7, 1913.

WILLIAM OLIN WALKER, Assoc. M. Am. Soc. C. E.*

DIED MAY 8, 1925.

William Olin Walker was born at Chuckey City, Tenn., on July 18, 1890. His father, Thomas S. Walker, and his mother, Mary (Dooley) Walker, were descendants of the sturdy early settlers of Tennessee and Virginia.

Mr. Walker was educated at the Morristown, Tenn., High School, De Pauw University, Greencastle, Ind., where he took a Liberal Arts Course, and in the Extension Division of the University of Wisconsin. He was not graduated from De Pauw University, although for several years he alternated periods of college work there with periods of engineering employment for which he early showed an inclination.

During the summer of 1907, he was Rodman on the Cincinnati, New Orleans and Texas Pacific Railway Company (Southern Railway System), at Oakdale, Tenn., and during the summer of 1908, was employed in a similar capacity with the County Highway Engineer at Greenville, Tenn. From January to September, 1909, he served as Rodman with the Southern Railway System, and as Rodman and Instrumentman with the County Highway Engineer at Morristown, Tenn. During the summer of 1911, and part of 1912, he was Masonry Inspector with the Louisville and Nashville Railroad Company, resigning to accept a position as Building Inspector with the Illinois Central Railroad Company on construction at Paducah, Ky., and other locations.

After another year at De Pauw University (1913-14), Mr. Walker re-entered the service of the Illinois Central Railroad Company, and attained a varied and broad experience in railroad engineering—maintenance of way work, location, construction, and office practice—as follows: From October, 1915, to February, 1918, he was Instrumentman on maintenance of way, and had charge of laying out work on the construction of a new yard at Baton Rouge, La., and terminal facilities at Mattoon, Ill. From February to August, 1918, he had charge of a field party on a 100-mile preliminary survey for a new trunk line. In August, 1918, he became Acting Resident Engineer at Champaign, Ill., in charge of the construction of a classification yard. From January, 1919, to January, 1920, he was employed as Engineer Accountant at various points on the Illinois Central System, reclassifying accounts to prorate the cost of construction and improvements between the Railroad Administration and the Railroad Corporation.

In January, 1920, Mr. Walker entered the employ of the Sinclair Refining Company, at Coffeyville, Kans., as Cost Engineer. His work consisted of keeping detailed costs on the construction of a $5 000 000 refinery, also of making appraisal of an old refinery plant. His ability and thorough, painstaking work won recognition and he was transferred to the general office of that Company at Chicago, Ill., in April, 1921. In this position he checked cost reports from all the Company's refineries, and also assisted in reclassifying accounts for insurance. In December, 1921, he was given charge of the cost work in

* Memoir prepared from information on file at the Headquarters of the Society.

connection with the construction of new refineries at Coffeyville, Kansas City, Mo., Houston, Tex., and Marcus Hook, Pa., with headquarters at Coffeyville. During October, 1923, he was transferred to the refinery at East Chicago, Ind., as Assistant Engineer of Construction, in addition to his duties of Cost Engineer at the East Chicago Plant. The completion of the construction of the new refinery at East Chicago, in November, 1924, marked the approximate completion of the $40 000 000 construction program of the Sinclair Refining Company, in which Mr. Walker took an active part from its beginning.

On the completion of this work he accepted a position as Engineer for the H. W. Nelson Construction Company of Kentucky, with headquarters at Fulton, Ky., where he had charge of the construction of approximately thirty miles of the new line of railroad being built by the Illinois Central Railroad Company, from Edgewood, Ill., to Fulton.

A Convention of the Association of Engineers of the Mid-South was held at Memphis, Tenn., on May 8, 1925. Many prominent engineers were brought together at this meeting, especially men of the profession from the Central Southern States, the majority of whom were members of the Society. The United States Government Engineers extended the Association an invitation to visit the Government revetment plant about twelve miles south of Memphis, near Coahoma Bend. Soon after leaving the revetment plant on their return to the city, one of the boats, the United States Steamboat *Norman,* sank in the Mississippi River. Mr. Walker and twenty-two others lost their lives in this disaster.

Perhaps two of Mr. Walker's most striking characteristics were his enthusiasm for his work and his keen interest in civic affairs. He was highly esteemed by his employers, respected and admired by his associates and subordinates, and known by his friends to have had fine ideals and deep convictions. He was a man of strong character, who never flinched from his duty, and yet was possessed of a tender devotion to his family and an innate courtesy and kindliness toward all.

Early in life he became a member of the Methodist Episcopal Church, of which he remained a faithful and consistent adherent. As a Knight Templar, Mr. Walker was active in Masonic circles.

In 1922, he was married to Mattie Sue Berry, of Barnesville, Ga., who, with two children, Meriam and Edith, survives him. He is also survived by four sisters, Mrs. E. T. Hall, of Brookfield, Mo., Mrs. R. B. Walker, of Walla Walla, Wash., and the Misses Clara and Eunice Walker, of Morristown, Tenn., and one brother, F. C. Walker, of Chicago, Ill.

Mr. Walker was elected a Junior of the American Society of Civil Engineers on March 7, 1921, and an Associate Member on May 28, 1923.

GEORGE BURNHAM, JR., Affiliate, Am. Soc. C. E.

DIED NOVEMBER 22, 1924.

George Burnham, Jr., the son of George and Anna (Hemple) Burnham, was born in Philadelphia, Pa., on November 30, 1849. His father was associated with Matthias Baldwin in the early days of locomotive building and, later, was Senior Member of the firm of Burnham, Parry, and Williams, predecessor of the Baldwin Locomotive Works.

George Burnham, Jr., was educated in the public and private schools of Philadelphia, preparatory to entering the Rensselaer Polytechnic Institute, at Troy, N. Y., from which he was graduated in 1872 with the degree of Civil Engineer.

During the summer vacation of 1871, he was employed as Rodman with a field party on railroad work for the Bennett's Branch Extension, connecting the Allegheny Valley Railroad with the Philadelphia and Erie Railroad.

After his graduation in 1872, Mr. Burnham was engaged on surveys in Fairmount Park, Philadelphia, and as Leveler on a railroad survey from Paoli to Chester, Pa., for the Pennsylvania Railroad Company, under the late James McCrea, M. Am. Soc. C. E., who afterward became President of the Company. Samuel Rea, Hon. M. Am. Soc. C. E., was also a member of this party.

In 1873 and 1874, Mr. Burnham was Rodman on the location and construction of a branch of the Pennsylvania Railroad from Williamsburg, Pa., to the Springfield, Pa., iron ore mines, and in 1874 and 1875 served as Leveler on the Bridge Division of the Bound Brook Railroad, Philadelphia to New York, N. Y. (now the Reading Central).

With the late D. McN. Stauffer, M. Am. Soc. C. E., he had entire charge of the construction of the bridge over the Delaware River which, with trestle approaches and bridges over canals on the Pennsylvania and New Jersey sides, was more than a mile in length. During this work he was stationed at Yardleyville, Pa.

On the completion of the bridge, Mr. Burnham returned to Philadelphia and, after 1875, when he entered into business with Mr. Nelson Stowe in the manufacture of the Stowe flexible shaft, never again engaged in the practice of his profession. From 1875 to 1880, he was Treasurer of the Barr Pumping Engine Company and Managing Director of the Spiral Weld Tube Company.

On September 1, 1880, he became associated with the firm of Burnham, Parry and Williams and served in the Treasurer's Department until January 1, 1896, when he became a member of the firm. On December 31, 1906, he retired from active business. His other business connections during these periods of active work and after retirement were, as follows: Director of the Central National Bank; Keystone Telephone Company; Keystone Coal and Iron Company; C. S. Wheeler Manufacturing Company; United Utilities and Service Company; Mineral Development Company; and the Integrity Trust Company.

* Memoir prepared by Edward B. Guthrie, M. Am. Soc. C. E.

Mr. Burnham was deeply interested in civic affairs, both municipal and Federal, and for many years was a leader in movements for the betterment of Philadelphia, in the words of one of his associates, "not asking for office, emolument, not even fame, only to be allowed to serve the city he loved." It was in this work and other civic matters that Mr. Burnham was truly notable, rather than in his career as an engineer which covered a period of only four years.

He was connected with various civic organizations, as follows: In 1880, he became a member of the Citizens Municipal Association and was also a Charter Member of the Philadelphia Civil Service Reform Association of which he was President in 1904. In 1890, he became a Charter Member and for ten years was President of the Philadelphia Municipal League. In 1894, this organization with the City Club of New York issued a call for the foundation of the National Municipal League of which Mr. Burnham was Treasurer for twenty-five years. In 1892, he was appointed a member of the Committee of 100 in Philadelphia and took a prominent part in its activities. In 1904, he became a member of the Committee of 70 and was engaged in its work at the time of his death. In 1905, he became a Charter Member of the City Club of Philadelphia and served as its President for ten years. In 1913, he served as a member of the Committee of 100, the purpose of which was to forward the election of Mayor Blankenburg. In 1921, he was appointed by the City Club of Philadelphia as its representative on the Board of the Thomas Harrison Municipal Trust. He was made Chairman of the Board and held this office until his death.

On January 15, 1924, a Memorial Meeting was held at the Social Service Building in Philadelphia, at which addresses were delivered on the character and activities of Mr. Burnham by the following co-workers in reform matters: Messrs. Thomas Raeburn White, whose subject was, "Services in Politics"; Samuel S. Fels, who spoke on "Municipal Research"; W. W. Montgomery, on "Civil Service Reform"; Sherman C. Kingsley, on "Philanthropy"; J. Henry Scattergood, on "The Man"; Richard S. Childs, on "Municipal Reform"; and James G. McDonald, on "The City in Foreign Affairs".

To depict the fine character of Mr. Burnham the following editorial is quoted from the *Philadelphia Public Ledger:*

"George Burnham

"By the death of George Burnham, the city has lost one of its best friends. He stood confidently for everything that was honorable and upright and law-abiding in municipal government. He devoted time and strength and liberally gave of his own means in the furtherance of causes in which he believed, not asking if they were popular or likely to be victorious. There was in the man a fine spirit of chivalry and loyalty that endeared him to all who strove beside him for better things. Modest to the point of diffidence, he never put himself forward, he never asked the credit for anything he did. He disliked to make speeches or even to preside at meetings, but he never shirked his duty in movements for the general welfare. In fact, there was no undertaking for the good of the city with which his name and his effectual effort were not identified.

In these he was the friendly, kindly, devoted counselor and partner. He was an example of the political crusader who is not a fanatic: he was that rare phenomenon, a reformer with a sense of humor and a dispassionate willingness to hear the other side. Important factor that he was in business life, it is as civic patriot that Philadelphia will gratefully remember him; and his city will commend him to posterity as a shining pattern of high-minded citizenship."

To these tributes, the writer wishes to add his own, speaking of Mr. Burnham as a friend and acquaintance of many years, dating from 1871. His gift of friendship equalled, or even surpassed, all others, and those whose privilege it was to know him feel that the world is made poorer by his death.

Mr. Burnham was married to Anna B. Lewis, on April 14, 1881, who, with two sons, Enoch Lewis Burnham and George Burnham 3d, and two daughters, Mrs. Arthur Peck, and Mrs. Albert DeSilver, survives him. He is also survived by two sisters, Miss Mary A. Burnham, and Mrs. Theodore J. Lewis.

Mr. Burnham was elected a Junior of the American Society of Civil Engineers on January 6, 1875, and an Affiliate on July 2, 1890.

COLEMAN MERIWETHER, Affiliate, Am. Soc. C. E.*

DIED OCTOBER 8, 1924.

Coleman Meriwether, the son of Charles and Patti (Barbour) Meriwether, was born in Louisville, Ky., on July 14, 1875. He received his early education in private schools of that city and in the Lawrenceville Preparatory School, at Lawrenceville, N. J.

In September, 1894, Mr. Meriwether entered the Engineering Department of Snead and Company Iron Works, at Louisville, as Draftsman. In March, 1896, he resigned this position to become Manager of the Louisville Branch of the Pope Manufacturing Company of Hartford, Conn. In April, 1899, he entered the office of the Louisville and Nashville Railroad Company, at Louisville, as Assistant Engineer, where he remained until, in June, 1900, he became Draftsman in the office of the Chief Engineer of the Baltimore and Ohio Railroad, at Baltimore, Md.

In April, 1901, he was appointed Chief Draftsman in the office of the Chief Engineer of the Southern Railway Company (St. Louis-Louisville Lines), at Louisville, but in January, 1904, he was made Land and Industrial Agent and transferred to Birmingham, Ala. From January to September, 1904, he served as Chief Draftsman in the Chief Engineer's office of the St. Louis-San Francisco Railway Company, at Cape Girardeau, Mo., resigning to accept a similar position with the Seaboard Air Line Railway Company at Portsmouth, Va.

About this time, Mr. Meriwether became interested in protecting timber piles by using lock-joint pipe, and developed the sewer pipe joint known as the Meriwether system of lock-joint pipe. From April, 1905, until August, 1917, he served as President and Chief Engineer of the Lock Joint Pipe Company of New York, N. Y., and Ampere, N. J., and from August, 1917, to January, 1919, as Manager of the Cement Products Bureau of the Portland Cement Association, of Chicago, Ill. From January, 1919, to April, 1920, he was associated with Mr. H. R. Duckwall, of Indianapolis, Ind., in the development of high-pressure reinforced concrete water pipe to a satisfactory conclusion, and for almost a year thereafter he was interested in the promotion of this type of pipe at Louisville. In January, 1921, he organized the Meriwether Pressure Pipe Company, of which he was Vice-President and Engineer until his death.

In his efforts to popularize reinforced concrete pipe, Mr. Meriwether traveled throughout much of the civilized world and made many friends wherever he went. He was widely known as an inventor of concrete pipe joints, having obtained seven patents on reinforced concrete specialties, and as a manufacturer of reinforced concrete pipe.

On June 21, 1919, he was married to Jessie Burks Scott, of Lynchburg, Va., who survives him.

* Memoir prepared from information on file at the Headquarters of the Society.

He was a member of the American Society for Testing Materials, American Concrete Institute, Concrete Products Association, and the Engineering Institute of Canada. He was also a member of the Engineers Club of New York and of the Country Club at Louisville, Ky.

In an obituary notice published elsewhere,* it was said that:

"A fitting epitaph for Coleman Meriwether may well include these thoughts: 'He achieved success in that he lived well, laughed often, was loved by many. He left the world better in that his work for civilization endures and has been an inspiration to others. His memory is revered by many friends'."

Mr. Meriwether was elected an Affiliate of the American Society of Civil Engineers on February 7, 1906.

---

* *Concrete Products,* November, 1924, p. 72.

WILLARD ADELBERT SMITH, Affiliate, Am. Soc. C. E.*

DIED NOVEMBER 29, 1923.

In the death of Willard Adelbert Smith, the nation has lost one of its best-known authorities on the history and status of railroad transportation in the United States. Although he had passed the traditional age of three score years and ten he had in no sense lost interest in the pressing questions of the day, his activity in portraying the truth of railroad conditions having been maintained to the time of his sudden failure in health, about a year before his death.

His acquaintance and influence in the railroad industry were far-reaching. He had met railway men in all grades of service and authority, from division operating officials to the highest executives, and was constantly being called into their councils. There were but few men, outside of those actually employed in railway service, to whom was given the opportunity to know as much of the railway industry from the inside as was the case with Mr. Smith throughout his long career.

Willard Adelbert Smith was born on a farm, near Kenosha, Wis., on September 20, 1849. He was the son of William Harrison and Mehitabel (Allen) Smith, who emigrated to Wisconsin from New Hampshire in 1841. His paternal ancestors came from England in 1640, and his mother's family came also from England at an early day and settled in the State of New York. His father was an Abolitionist whose home was a station on the "Underground Railway", serving as a hiding place for fugitive slaves.

Mr. Smith was educated in the common schools of Kenosha, the High School of Rockford, Ill., and Shurtleff College, at Upper Alton, Ill., from which he was graduated, in a literary course, in 1869. He next entered the Law Department of Washington University, at St. Louis, Mo., from which he was graduated in 1872. He was admitted to the Bar, in the State of Missouri, in 1870, and to practice in the United States Courts, in 1871. In later years, the degrees of Master of Arts and Doctor of Laws were conferred on him by Shurtleff College.

From his early choice of occupation it was the destiny of Willard Smith to become a publisher; and his ability to master the varied scope of his activities, both private and public, throughout his life, developed from his experience with the publishing business as the nucleus. He first entered publication work in 1871, as Editor and Publisher of the *St. Louis Railway Register.* Three years later he acquired the ownership of the *Railway Review,* of Chicago, Ill., which he retained until he died. Thus, at the time of his death, his ownership and management of the *Railway Review* lacked but a few months of a full half century. In 1897 the name of the publication was changed to the *Railway and Engineering Review,* and in 1914 it was changed back again to the *Railway Review.*

In his charge and direction of the publication of this weekly railway newspaper and magazine Mr. Smith was, except during a few short periods, edito-

* Memoir prepared by the late W. M. Camp, M. Am. Soc. C. E.

rial writer as well as the head of the business management. Liberally educated and versatile, he early acquired a broad knowledge of the railroad transportation development of the country, in the technique of construction, equipment and operation, as well as of the financial and executive management of the properties. In such an experience he saw the railroad mileage of the nation expand from about 55 000 to 260 000; and the progress of Government regulation of the railroads he had followed, studied, and written of, critically and ably, from its birth through the subsequent involved and shifty situation.

Under the guidance of Willard Smith the attitude of the *Railway Review* on railroad questions was independent, espousing the cause of the railroads against the many unjust assaults of legislative authority, in the past, and freely criticizing railroad officials for errors of management or policy whenever that view seemed sufficiently well supported by the facts. In his editorial ideas and expressions the man was entirely frank and fearless. The motto of his editorial attitude on all questions was "to think clearly, to speak plainly, and to say the thing that ought to be said." His command of English was excellent, he had the habit of speaking plainly, and when his thought was written down it was so clearly and so courageously expressed that there was no need for "interpretation." Being an accomplished public speaker his voice, as well as his pen, was often called into service.

It was these abilities and qualifications that brought about Mr. Smith's appointment on July 27, 1891, as Chief of the Department of Transportation at the World's Columbian Exposition, held in Chicago in 1893. A broad and careful canvass of the views of railroad executives, by the Exposition authorities, as to the logical man for this work decided the matter for Willard A. Smith, and he undertook the work enthusiastically. For a whole year he traveled through Europe making arrangements for the foreign exhibits. How well he succeeded has become a matter of history. While his editorial ability had gained for him a national reputation, the organization which he developed to display the material progress of railroads throughout the world made him a man of international renown. Among the outstanding features of the result were the historical exhibit of equipment of the Baltimore and Ohio Railroad; the extensive display of track and equipment by the Pennsylvania Railroad; and the great track exhibit of Mr. A. Haarmann, of Germany.

After the Chicago World's Fair, Mr. Smith temporarily laid aside active management of the *Railway Review* to engage in manufacturing. In 1894, he became President of the Cloud Steel Truck Company of Chicago, and, later, Vice-President of the National Malleable Castings Company.

In 1899, he went to France as Chief of the Department of Transportation and Engineering for the American Commission to the Paris Exposition of 1900. His previous travels in Europe on exposition business, the acquaintanceships formed, and his eminent success as head of a department at the Chicago Exposition seven years earlier, were experiences that served him to much advantage in his connection with this foreign Exposition. An innovation of the American exhibit that had not been anticipated by the French,

but which was one of the purposes of Mr. Smith, was the display of American-built steel cars, placed on the grounds with some difficulty by means of barges on the River Seine, of hoisting machinery, and of special tracks. It has been said that this exhibit led to the introduction of steel cars on European railways. On his return from Paris that year he again became actively engaged with the *Railway Review,* continuing as President, which office he had never relinquished while engaged with outside enterprises; and it should not be overlooked that for many years he was also the publisher of the *Railway Master Mechanic* and of the "Railway Official List."

In the organization for the Louisiana Purchase Exposition, in St. Louis, Mo., in 1904, again he was sought as Chief of the Department of Transportation, and again he accepted the office. The exhibit was housed in a single building covering sixteen acres. It included, as in 1893, the historical railway exhibit of the Baltimore and Ohio Railroad, and examples of the heaviest railway rolling stock of the day, locomotives and cars; but perhaps the most worthy effort and result of the exhibition of rolling equipment was the display of the latest refinements of design and service. Notable exhibits of this kind were the numerous designs of modern draft gear; the practical operation and tests of air-brake equipment for an 80-car freight train, by the Westinghouse Air Brake Company; and the locomotive testing plant of the Pennsylvania Railroad, maintained in continuous operation during several weeks. The thoroughness with which this plant was designed and installed within the short time available, and its very satisfactory operation as a testing device, won great praise for the motive power officials of the railroad and for the staff of experts who conducted the tests.

It was through the suggestion and strong appeal of Mr. Smith that the management of the Pennsylvania Railroad had been led to decide on a locomotive testing plant as the distinguishing feature of its exhibit, and he was made a member of the Advisory Board which co-operated with the Railroad Company in conducting the important series of tests that were there carried out. The other members of this Board were the late Theodore N. Ely, M. Am. Soc. C. E., and J. J. Turner. The data and results of these tests were published in a separate volume by the Railroad Company. The plant was subsequently removed to the Pennsylvania Shops at Altoona, Pa.

Perhaps the most spectacular feature of the Transportation exhibit—at any rate so regarded from the popular standpoint—was a 120-ton, Atlantic type locomotive and tender of the "Big Four" Railway, mounted on a 70-ft. turntable displayed by the Chicago Bridge and Iron Works. The turn-table was carried on a "center" supported on a concrete pier, in the ordinary way, with the lower flanges of the girders 4 ft. clear of the floor. The locomotive was blocked clear of the turn-table rails, so that its wheels could revolve; and by means of an electric drive both the turn-table and the locomotive drivers were kept continually in motion, the table swinging on its center.

A remarkable feature of the Transportation exhibit, not so well appreciated at that time but now of historic interest, was a Department of Aeronautics, conducted under the immediate direction of the late Octave Chanute, Past-

President, Am. Soc. C. E. For this purpose a field of ten acres was fenced off as part of the Exposition Grounds, and gliding experiments were conducted at frequent intervals. The motive power was a stationary street-car motor geared to a drum carrying 1 000 ft. of light steel cable. In these experiments the biplanes would often rise to a height of 60 ft. above ground, when the cable would be detached and the pilot would steer the plane around the grounds and make a landing. The attendance of those interested in aviation was large, including some of the foremost inventors of France, Italy, Brazil, and other parts of the world, as well as those of the United States, the latter including notably the Wright brothers, who not long after this exhibition achieved epoch-making progress.

At the conclusion of the Exposition, the *Railway Review,* under the direction of Mr. Smith, published a volume covering the railroad exhibits of the Exposition, in much detail. The book contains more than 600 illustrations.

In recognition of Mr. Smith's technical and executive abilities as an organizer of railroad exhibitions, he became the recipient of many honors and decorations. He was appointed and served as a Delegate of the State Department of the United States Government to the International Railway Congress which met in Paris, in 1900, and in Washington, in 1905. He was honored with medals by the Governments of France, Germany, and Italy, for services in connection with the World's Columbian Exposition; and was presented with the famous Tiffany "Transportation Vase" by the American exhibitors in the Department of Transportation, World's Columbian Exposition, as a testimonial of his eminent services as Chief of that Department. He was decorated Chevalier of the Legion of Honor, by France, and, in 1907, promoted to Officer of the Legion of Honor. He was decorated with the Royal Order of the Crown by Germany; and with the Imperial Order of the Rising Sun by Japan. Mr. Smith was the last surviving Chief of Department of the Chicago World's Fair.

He had long been an active member of several railroad and engineering associations, including the Master Car Builders' Association; the American Railway Master Mechanics Association; the Western Society of Engineers; the Western Railway Club; and the American Society of Railroad Superintendents. Locally, he was a member of the Union League Club, the Chicago Engineers' Club, and had been a Trustee of the University of Chicago from 1894 until he felt obliged, by failing health, to tender his resignation, a few months before his death. For a long time he served as the Chairman of the Press and Extension Committee of that institution. He was a Patron and Honorary Curator of the Field Museum of Natural History and, for many years, a Trustee of the Memorial Baptist Church. He also served as President of the Chicago Baptist Social Union for two years.

Mr. Smith was married on May 1, 1872, to Maria C. Dickinson, of St. Louis, Mo., who passed away suddenly about five years before his death. He is survived by three children: Mrs. B. V. Crandall, of Kenilworth, Ill.; and Miss Edith and Harold A. Smith, of Highland Park, Ill., the last named becoming President of the *Railway Review* on the death of his father.

In his private and social life, as well as in his business career, Mr. Smith was widely recognized as a fine type of gentleman. He was a man of extraordinary intellectual force and culture, with broad and charitable views; and to know him was to admire him. His impulses were humanitarian, and the serious bent of his nature was educational. He had been a student all his life, and a constant reader of the best literary talent of his time.

Schooled by contact with some of the best engineering minds and methods of the country, and having intimate knowledge of the progress of the design of railway rolling stock, shop, and other equipment, he was not infrequently called into consultation for opinions or advice on engineering enterprises.

Mr. Smith was elected an Affiliate of the American Society of Civil Engineers on September 2, 1914.

GEORGE LEE ANDERSON, Jun. Am. Soc. C. E.*

DIED MAY 8, 1925.

George Lee Anderson was born in Poland, Ind., on October 7, 1894. As his mother died when he was about two years of age, he was sent to live with his grandparents near Sunman, Ind.

He was graduated from the district school near Sunman in 1908 and entered the High School at Greensburg, Ind., from which he was graduated in 1913. In September, 1913, he entered Purdue University, West Lafayette, Ind., taking the course in Civil Engineering. After two years at Purdue, he entered the employ of the Surveyor of Benton County, Indiana, as Draftsman and Computer.

In September, 1916, Mr. Anderson entered the United States Government service as a Surveyman, attached to the U. S. Engineer's Office at Memphis, Tenn. He remained in this position until 1918, when he entered the military service as a Private in the 472d Engineers, serving in the capacity of Levelman and Plane-Table Operator until his discharge in February, 1919.

In March, 1919, he returned to the U. S. Engineer's Office at Memphis as a Surveyman, remaining there until September of that year, when he returned to Purdue University to continue his course in engineering. During the summer of 1920, Mr. Anderson was employed as a Draftsman and Computer by Ayres and Miller, Engineers, of Memphis. He returned to Purdue University in September, 1920, where he completed his course and received the degree of Bachelor of Science in Civil Engineering, in June, 1921.

From July, 1921, until August, 1922, Mr. Anderson was employed in the U. S. Engineer's Office, at Memphis, as a Structural and Mechanical Draftsman. He then entered the employ of the firm of Ayres and Miller, as Office Engineer, retaining that position until his death.

Mr. Anderson was of a modest and retiring disposition and spent his spare time in reading both engineering and classical literature, possessing a remarkable memory of both. He was thorough and painstaking in every detail of his work, and, although only a young man, was an engineer of ability and possessed a high standard of integrity and professional conduct.

He was a member of the Engineers Club of Memphis, and was among those who lost their lives when the Steamer *Norman* sank in the Mississippi River on May 8, 1925. On board this steamer was a party of engineers who had been on an inspection trip down the river as part of the program of the Convention of the Association of Engineers of the Mid-South held in Memphis on May 7 and 8, 1925. He is survived by his father, Mr. Oliver C. Anderson, of Sunman, Ind.

Mr. Anderson was elected a Junior of the American Society of Civil Engineers on June 19, 1922.

* Memoir prepared by Garner W. Miller, Assoc. M. Am. Soc. C. E.

Williamson, Charles Sumner. 1706.
Winslow, Frederic Irving. 1708.

METERS.

"The Improved Venturi Flume." Ralph L. Parshall. (With Discussion.) 841.

MORTAR.

Review of literature on expansion and contraction of cements, mortars, and concrete. 297.

NAVIGATION.

"The St. Lawrence Waterway to the Sea." Francis C. Shenehon. (With Discussion.) 444.

ODORS.

"Detection and Elimination of —": A Symposium. Irving I. Goldsmith, Stephen DeM. Gage, Samuel A. Greeley, John F. Skinner, and Robert Spurr Weston. 339. Discussion: Joseph A. Warren, Charles A. Holmquist, George H. Shaw, L. L. Tribus, John V. Lewis, I. S. Osborn, Morris M. Cohn, C. E. Keefer, C. G. Gillespie, T. Chalkley Hatton, N. E. Loomis, and Edward Wright. 413.

— and health. 328.

OIL REFINERIES.

Detection and elimination of odors from —. 383.

OIL STORAGE.

"Fire-Banks for —." H. H. Hall. 225. Discussion: H. L. Shoemaker, Frank A. Epps, and Ralph J. Reed. 252.

PAVEMENT.

"The Effect of Moisture on Concrete." W. K. Hatt. (With Discussion.) 270.

"The Hexagonal Slab Design of Concrete —." Lewis A. Perry. 1296. Discussion: E. G. Hooper, S. Herbert Hare, Jacob Feld, H. O. Root, and Wesley Vandercook. 1312.

PORTS.

See HARBORS.

POWER PLANTS.

"Co-Ordination of Irrigation and Power." William Kelly. (With Discussion.) 1429.

"High Specific Speed Hydraulic Turbines in Their Bearing on the Proportioning of the Number of Units in Low-Head Hydro-Electric Plants": A Symposium. George A. Orrok, Lewis F. Moody, Forrest Nagler, George A. Jessop, Charles C. Egbert, and John P. Hogan. (With Discussion.) 615.

PUMPS.

"Municipal Water Supply Problems of Atlanta, Georgia." Paul H. Norcross. (With Discussion.) 579.

RAILROAD TERMINALS.

River-rail terminal. 1138.

RAILROADS.

"Relation of the Ohio River and Its Tributaries to Transportation in the United States": A Symposium. C. W. Kutz, H. B. Luther, Frank H. Alfred, and Julian Pollak. (With Discussion.) 1105.

"The Engineer as a Railroad Executive." Julius Kruttschnitt. 696.

RAINFALL.

"Flood Flow Characteristics." C. S. Jarvis. (With Discussion.) 985.

REFUSE DISPOSAL.

Elimination of odors from garbage disposal works. 361.

REPORTS OF COMMITTEES.

"Progress Report of the Special Committee on Steel Column Research." F. E. Turneaure, C. G. E. Larsson, B. R. Leffler, G. L. Taylor, and S. H. Widdicombe. 1485.

RESERVOIRS.

"The Oradell Dam of the Hackensack Water Company." Nicholas S. Hill, Jr. (With Discussion.) 1181.

RIVERS.

"Co-Ordination of Irrigation and Power." William Kelly. (With Discussion.) 1429.

"Relation of the Ohio River and Its Tributaries to Transportation in the United States": A Symposium. C. W. Kutz, H. B. Luther, Frank H. Alfred, and Julian Pollak. (With Discussion.) 1105.

"Stream Pollution": A Symposium. W. H. Frost, Emery J. Theriault, H. W. Streeter, and J. K. Hoskins. (With Discussion.) 1331.

"The St. Lawrence Waterway to the Sea." Francis C. Shenehon. (With Discussion.) 444.

ROADS.

"The Effect of Moisture on Concrete." W. K. Hatt. (With Discussion.) 270.

"The Hexagonal Slab Design of Concrete Pavement." Lewis A. Perry. (With Discussion.) 1296.

RUN-OFF.

"Flood Flow Characteristics." C. S. Jarvis. (With Discussion.) 985.

Maximum observed flood discharge rates and expected — from various drainage basins arranged according to area. 1003.

SANITATION.

"Detection and Elimination of Odors": A Symposium. Irving I. Goldsmith, Stephen DeM. Gage, Samuel A. Greeley, John F. Skinner, and Robert Spurr Weston. (With Discussion.) 339.

"Stream Pollution": A Symposium. W. H. Frost, Emery J. Theriault, H. W. Streeter, and J. K. Hoskins. (With Discussion.) 1331.

"The Atmosphere and Its Relations to Human Health and Comfort." C.-E. A. Winslow. (With Discussion.) 316.

SEDIMENTATION.

"Municipal Water Supply Problems of Atlanta, Georgia." Paul Norcross. (With Discussion.) 579.

"Permissible Canal Velocities." Samuel Fortier and Fred C. Scobey. (With Discussion.) 940.

SEWAGE DISPOSAL.

Bibliography relating to studies of stream pollution, sewage, and water supplies. 1339.

Control of odors from sewage treatment plants. 376.

"Stream Pollution": A Symposium. W. H. Frost, Emery J. Theriault, H. W. Streeter, and J. K. Hoskins. (With Discussion.) 1331.

SLABS.

"The Effect of Moisture on Concrete." W. K. Hatt. (With Discussion.) 270.

"The Hexagonal Slab Design of Concrete Pavement." Lewis A. Perry. (With Discussion.) 1296.

SLUICES.

"The Oradell Dam of the Hackensack Water Company." Nicholas S. Hill, Jr. (With Discussion.) 1181.

SPILLWAY.

"Side Channel Spillways: Hydraulic Theory, Economic Factors, and Experimental Determination of Losses." Julian Hinds. 881. Discussion: C. H. Howell, H. B. Muckleston, I. Gutmann, A. J. Wiley, Ivan E. Houk, and J. C. Stevens. 928.

"The Oradell Dam of the Hackensack Water Company." Nicholas S. Hill, Jr. (With Discussion.) 1181.

STADIUM.

AUTHOR INDEX

ALFRED, FRANK H.

"Comparison of Rail and River Transportation Costs in Relation to the Ohio River and Its Tributaries." 1127.

Relation of the Ohio River to transportation. 1170.

ALLEN, KENNETH.

Stream pollution. 1388.

AMMANN, O. H.

Secondary stresses in bridges. 150.

ANDERSON, GEORGE LEE.

Memoir of. 1738.

AREND, ALBERT C.

Oradell Dam, Hackensack Water Company. 1208.

BAHJEJIAN, K. P.

Secondary stresses in bridges. 154.

BAKER, CHARLES HINCKLEY.

Memoir of. 1552.

BALDWIN, WILLIAM JAMES.

Memoir of. 1553.

BARDOL, FRANK VALENTINE ERHARD.

Memoir of. 1555.

BARNES, M. G.

Relation of the Ohio River to transportation. 1160.

BARRIL, GUION VICTOR.

Memoir of. 1557.

BARROWS, H. K.

High specific speed hydraulic turbines. 688.

BEANFIELD, R. McC.

Secondary stresses in bridges. 206.

BECK, EDWARD ADAM.
Memoir of. 1559.

BEGGS, GEORGE E.
Secondary stresses in bridges. 170.

BEGIEN, R. N.
Relation of the Ohio River to transportation. 1141.

BENZENBERG, GEORGE HENRY.
Memoir of. 1550.

BERNARD, MERRILL M.
Flood flow characteristics. 1086.

BLACK, W. M.
Relation of the Ohio River to transportation. 1157.
St. Lawrence Waterway to the sea. 555.

BOWSER, EDMUND HAMILTON.
Memoir of. 1562.

BRANCH, THOMAS PETTUS.
Memoir of. 1564.

BRYAN, FRED AZDELL.
Memoir of. 1566.

BUDGE, ENRIQUE.
Memoir of. 1569.

BULL, ANDERS.
Notes on shear in compression members. 1424.

BURNHAM, GEORGE, JR.
Memoir of. 1728.

CAIN, WILLIAM.
Secondary stresses in bridges. 151.

CAMP, WALTER MASON.
Memoir of. 1573.

CARTER, C. E.
The improved Venturi flume. 856.

CHAMBERLIN, JOHN ROSS.
Memoir of. 1710.

CHANDLER, ELBERT M.
Permissible canal velocities. 958.

CHEEVER, MARKHAM.
Co-ordination of irrigation and power. 1478.

CHESTER, J. N.
Water supply problems of Atlanta, Ga. 610.

CHURCHILL, CHARLES S.
Relation of the Ohio River to transportation. 1146.

COHN, MORRIS M.
Detection and elimination of odors. 426.

COLLIER, B. C.
Multiple-arch dam at Gem Lake, California. 767.

COMSTOCK, CHARLES W.
Flood flow characteristics. 1069.
Multiple-arch dam at Gem Lake, California. 782.

CORNISH, L. D.
Relation of the Ohio River to transportation. 1145.

CRAWFORD, ANDREW WRIGHT.
Excess condemnation in city planning. 838.

St. Lawrence Waterway to the sea. 558.

POLLAK, JULIAN A.
"River-Rail Terminal." 1138.

POOLE, CHARLES OSCAR.
Memoir of. 1675.

POWELL, AMBROSE VINCENT.
Memoir of. 1678.

PRATLEY, P. L.
Secondary stresses in bridges. 158.

PRICHARD, HENRY S.
Notes on shear in compression members. 1412.
"Utilizable Capacity of Steel Members of Structures." 1213.

PURDON, C. D.
Flood flow characteristics. 1090.

REED, OREN.
Multiple-arch dam at Gem Lake, California. 760.

REED, RALPH J.
Fire-banks for oil storage. 255.

REYNOLDS, WILLIAM LeROY.
Memoir of. 1680.

RICE, LINDLEY MARSHALL.
Memoir of. 1682.

RICHE, C. S.
St. Lawrence Waterway to the sea. 564.

RICKETTS, A. T.
Oradell Dam, Hackensack Water Company. 1206.

ROBERTS, GEORGE THOMAS.
Memoir of. 1684.

ROHWER, CARL.
Permissible canal velocities. 968.
The improved Venturi flume. 875.

ROOT, H. O.
Hexagonal slab design of concrete pavement. 1315.

ROTCH, WILLIAM.
Memoir of. 1685.

RUSHMORE, DAVID B.
St. Lawrence Waterway to the sea. 550.

RUTTAN, HENRY NORLANDE.
Memoir of. 1687.

SABIN, L. C.
St. Lawrence Waterway to the sea. 535.

SADLER, H. C.
St. Lawrence Waterway to the sea. 523.

SCHAEFFER, AMOS.
Memoir of. 1689.

SCHEIDENHELM, F. W.
Multiple-arch dam at Gem Lake, California. 772.

SCHMITT, F. E.
Capacity of structural steel members. 1284.

SCOBEY, FRED C.
"Permissible Canal Velocities." 940.

SEARS, HORACE H.
Excess condemnation in city planning. 829.

SHAW, GEORGE H.
Detection and elimination of odors. 421.

SHAW, GRANVILLE WHEATON.
Memoir of. 1692.

SHEARWOOD, F. P.
Secondary stresses in bridges. 202.

SHEDD, THOMAS C.
Secondary stresses in bridges. 174.

SHELDON, FRANK LAWRENCE.
Memoir of. 1719.

SHENEHON, FRANCIS C.
"The St. Lawrence Waterway to the Sea." 444.

SHERMAN, L. K.
Flood flow characteristics. 1038.

SHOEMAKER, H. L.
Fire-banks for oil storage. 252.

SICKMAN, ALBERT FRANKLIN.
Memoir of. 1720.

SKINNER, JOHN F.
"Control of Odors from Sewage Treatment Plants." 376.

SMITH, G. E. P.
Effect of moisture on concrete. 310.

SMITH, WALTER M.
St. Lawrence Waterway to the sea. 554.

SMITH, WILLARD ADELBERT
Memoir of. 1733.

SOPER, GEORGE A.
The atmosphere and human health. 333.

STEINMAN, D. B.
Secondary stresses in bridges. 172.

STEVENS, J. C.
Permissible canal velocities. 967.
Side channel spillways. 933.
The improved Venturi flume. 872.

STOCKTON, ROBERT S.
Permissible canal velocities. 959.

STREETER, H. W.
"The Rate of Atmospheric Reaeration of Sewage Polluted Streams." 1351.

STUART, JOSEPH THOMPSON.
Memoir of. 1695.

TABLER, JUDSON GILMAN.
Memoir of. 1696.

TAYLOR, G. L.
"Progress Report of the Special Committee on Steel Column Research." 1485.

TAYLOR, HARRY.
Relation of the Ohio River to transportation. 1153.

TAYLOR, JAMES TOWNSEND.
Memoir of. 1698.

THAYER, NATHANIEL AUGUSTINE.
Memoir of. 1722.

THERIAULT, EMERY J.
"The Rate of Deoxygenation of Polluted Waters." 1341.

TIBBETTS, FRED. H.
Co-ordination of irrigation and power. 1472.

TONNESEN, TOBIAS.
Memoir of. 1699.

TRIBUS, L. L.
Detection and elimination of odors. 422.

TURNEAURE, F. E.
"Progress Report of the Special Committee on Steel Column Research." 1485.

TURNER, C. A. P.
Capacity of structural steel members. 1271.
Multiple-arch dam at Gem Lake, California. 743.
Notes on shear in compression members. 1409.
Secondary stresses in bridges. 155.

ULRICH, EDMUND BOYD.
Memoir of. 1723.

VANDERCOOK, WESLEY.
Hexagonal slab design of concrete pavement. 1318.

VAN HOOK, FRANKLIN JAMES,
Memoir of. 1724.

VEDDER, A. L.
"The Use of Excess Condemnation in the Opening, Widening, and Extension of Streets." 796.

von ABO, CECIL VIVIAN.
"Secondary Stresses in Bridges." 1.

von FABRICE, R.
Capacity of structural steel members. 1280.

WALKER, E. G.
Notes on shear in compression members. 1411.
St. Lawrence Waterway to the sea. 566.

WALKER, WILLIAM OLIN.
Memoir of. 1726.

WALLER, LAURENCE J.
Secondary stresses in bridges. 203.

WARREN, JOSEPH A.
Detection and elimination of odors. 413.

WAUGH, E. J.
Multiple-arch dam at Gem Lake, California. 746.

WEIR, M. W.
Excess condemnation in city planning. 839.

WEISS, ANDREW.
Permissible canal velocities. 965.

WELLS, WILLIAM FIRTH.
Stream pollution. 1399.

WESTON, ROBERT SPURR.
"The Detection and Elimination of Odors from Oil Refineries." 383.

WHEELER, WALTER H.
Multiple-arch dam at Gem Lake, California. 742.

WHINERY, SAMUEL.
Memoir of. 1701.

WHITE, LAZARUS.
Oradell Dam, Hackensack Water Company. 1207.

WHITE, W. M.
High specific speed hydraulic turbines. 690.

WHITNEY, FRANK O.
Excess condemnation in city planning. 837.

WHITTAKER, H. A.
Stream pollution. 1386.

WIDDICOMBE, S. H.
"Progress Report of the Special Committee on Steel Column Research." 1485.

WIGGIN, THOMAS H.
Multiple-arch dam at Gem Lake, California. 743.

WILEY, A. J.
Side channel spillways. 930.

WILLIAMS, F. P.
St. Lawrence Waterway to the sea. 528.

WILLIAMS, FRANK B.
"The Present Status of Excess Condemnation in the United States." 792.

WILLIAMS, GARDNER S.
St. Lawrence Waterway to the sea. 546.

WILLIAMS, MAURICE W.
St. Lawrence Waterway to the sea. 551.

WILLIAMSON, CHARLES SUMNER.
Memoir of. 1706.

WILSON, CHARLES A.
Relation of the Ohio River to transportations. 1150.

WILSON, W. M.
Secondary stresses in bridges. 182.

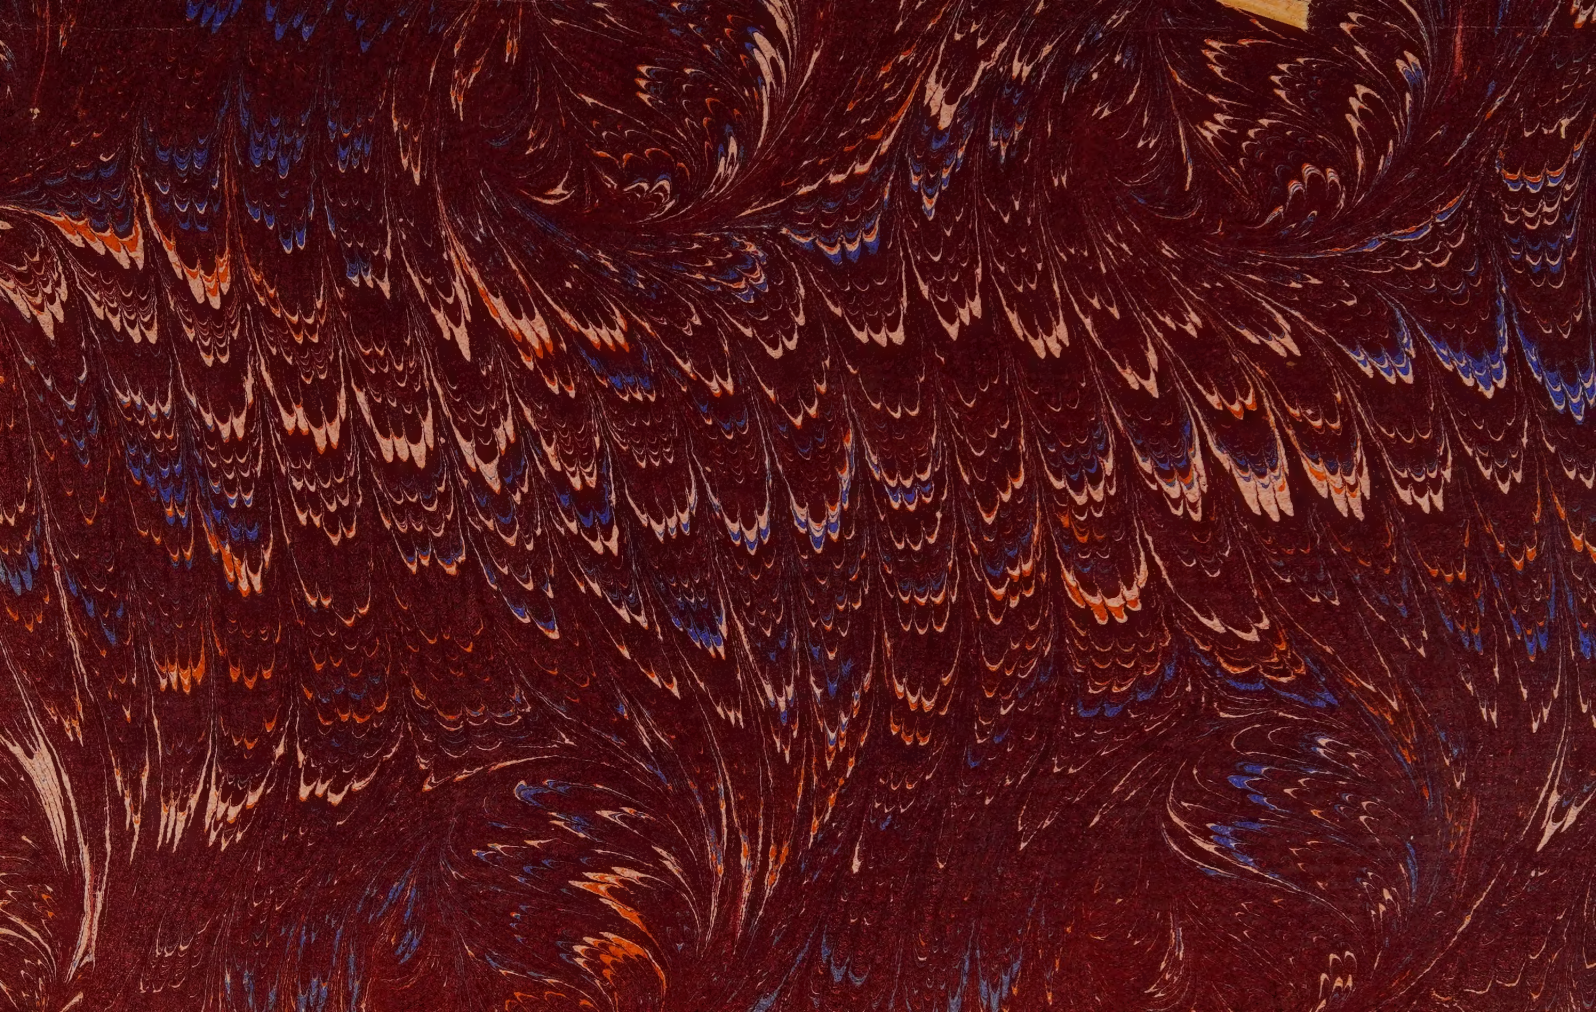
WINGFIELD, NISBET.
Water supply problems of Atlanta, Ga. 611.

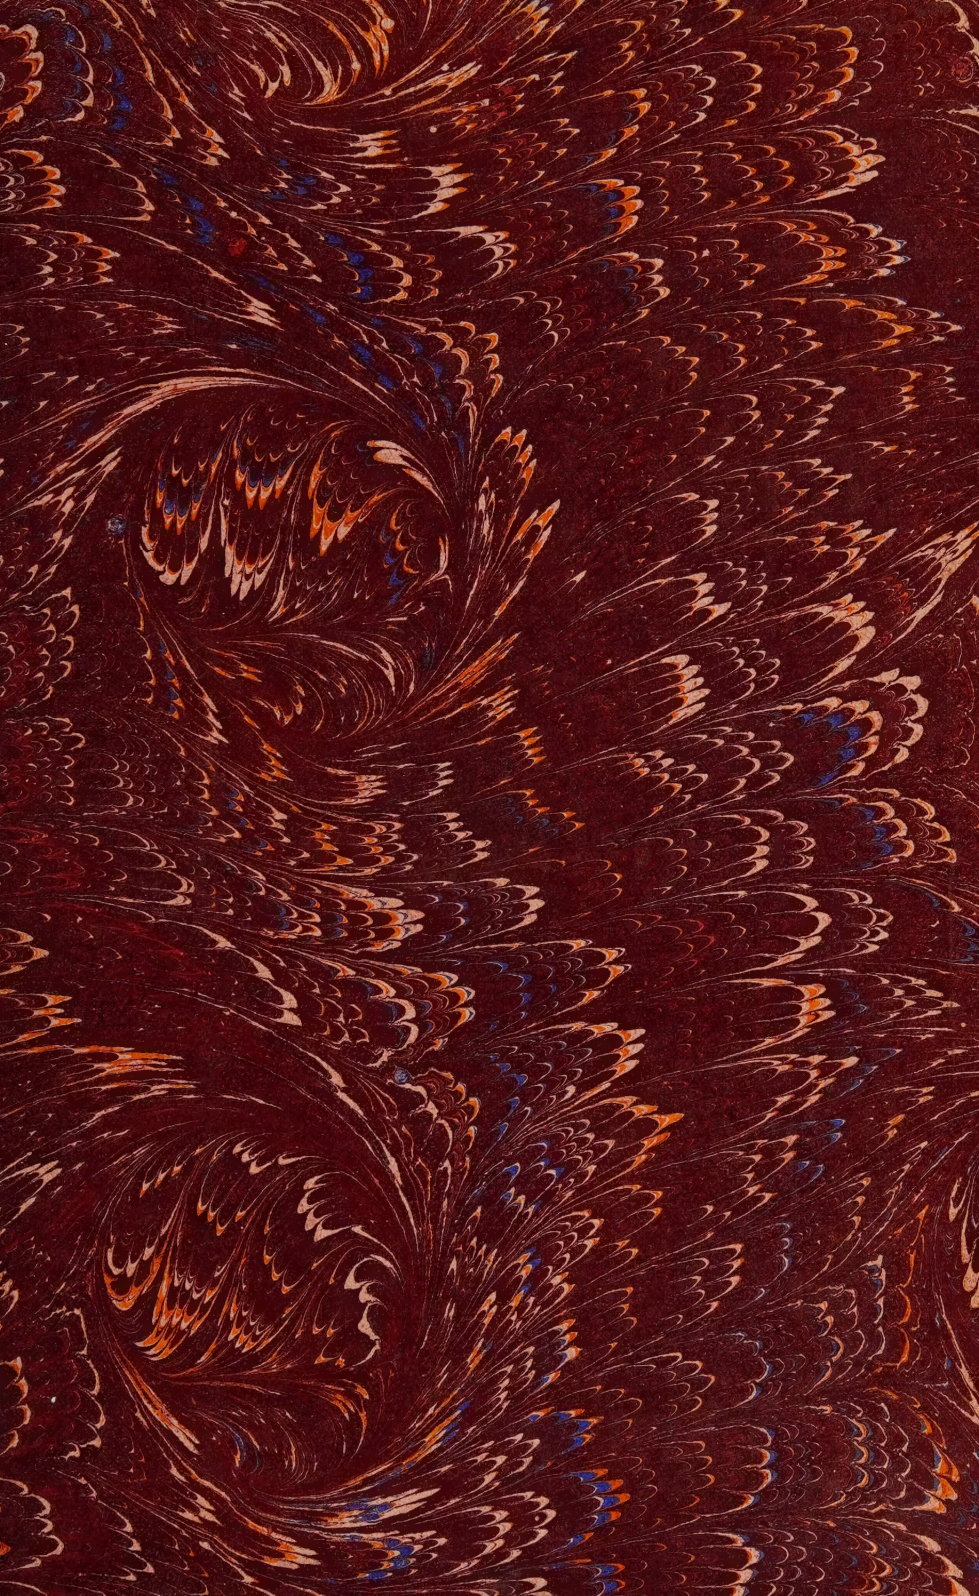
WINSLOW, C.-E. A.
"The Atmosphere and Its Relations to Human Health and Comfort." 316.

WINSLOW, FREDERIC IRVING.
Memoir of. 1708.

WINSOR, L. M.
Flood flow characteristics. 1043.

WOODRUFF, G. B.
Capacity of structural steel members. 1279.

WRIGHT, EDWARD.
Detection and elimination of odors. 438.




WUEST, CHARLES, JR.
Relation of the Ohio River to transportation. 1148.
